Adult Attention Deficit–Hyperactivity Disorder

Nora D. Volkow, M.D., and James M. Swanson, Ph.D.

A 31-year-old middle-school teacher sought medical help because she was having trouble keeping up with her job assignments and responsibilities. Her primary symptoms were an inability to stay focused and being easily distracted. She reported daydreaming with multiple thoughts at the same time, an inability to complete tasks on time, frequently forgetting to do things at work, and being unable to remain still during solitary activities (e.g., watching a movie and reading a book). Her friends described her as excessively talkative, disorganized, impatient, and careless. From childhood, her teachers noted that she was inattentive and messy and often did not turn in homework. She was able to do reasonably well in school despite her symptoms, but more recently, her job demands have overwhelmed her, and she is considering quitting. What would you advise?
men and 3.2% of women met the criteria for ADHD. In some clinical series, the ratio of men to women with ADHD is close to 1:1, whereas the ratio of boys to girls with ADHD is at least 4:1.

**GENETIC AND NONGENETIC FACTORS**

ADHD has a strong genetic component, with heritability of approximately 0.8, suggesting that genetic factors would account for about 65% of phenotypic variance. However, only a few genes associated with ADHD have been identified, mostly in studies of candidate genes, and these genes account for only about 3% of phenotypic variation; genomewide association studies have not identified any additional common variants. This suggests that many unidentified common variants with small effects, gene–environment or gene–gene interactions, rare variants, or a combination of these factors play a prominent role in the genetic cause of ADHD.

Nongenetic factors are also associated with ADHD. Observational studies have shown that the risk of ADHD is doubled or tripled among offspring of mothers who smoked during pregnancy and among persons with evidence of lead exposure in childhood. Persons with obesity or diabetes and those whose mothers had these conditions during pregnancy have also been reported to have an increased risk of ADHD. It is not known whether these associations are causal.

**NEUROBIOLOGIC FACTORS**

Brain imaging studies in persons with ADHD have identified dysfunction of dopamine pathways involved in attention, executive function, and motivation and reward, as well as dysfunction in noradrenergic pathways, particularly those that innervate the prefrontal cortex, which is a central region for executive function. Moreover, stimulant medications, which are the most effective treatments for ADHD, enhance dopaminergic and noradrenergic signaling; this provides support for the involvement of these neurotransmitters in the pathologic process of ADHD.

**STRATEGIES AND EVIDENCE**

**DIAGNOSIS**

The *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association provides guidelines for the diagnosis of ADHD. The current edition (DSM-5), which was approved in December 2012, replaces the fourth edition. New to the DSM-5 is the inclusion of specific examples of how ADHD is manifested in adults (Table 1). This change is based on a recognition of the chronic nature of ADHD and its varying manifestations across the lifespan.

The DSM-5 diagnosis in adults is based on the presence of at least five of nine symptoms in each of two domains — inattention, and hyperactivity.
Table 1. Criteria for the Diagnosis of Attention Deficit–Hyperactivity Disorder (ADHD).*  

### ADHD consists of a pattern of behavior that is present in multiple settings and gives rise to difficulties with social and academic or work performance. The diagnosis requires evidence of inattention, hyperactivity, and impulsivity, or both.

#### Inattention

Six or more of the following symptoms (five or more in adolescents and adults 17 years of age or older) have persisted for at least 6 months to a degree that is inconsistent with the person’s developmental level and that directly affects social and academic or occupational activities:†

- Often fails to give close attention to details and makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate).
- Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures or conversations or when reading lengthy writings).
- Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction).
- Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked; does not finish schoolwork, household chores, or tasks in the workplace).
- Often has difficulty organizing tasks and activities (e.g., has difficulty managing sequential tasks and keeping materials and belongings in order; has messy, disorganized work; has poor time management; tends to fail to meet deadlines).
- Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., doing schoolwork or homework; preparing reports, completing forms, or reviewing lengthy papers).
- Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, or mobile phones).
- Is often easily distracted by extraneous stimuli (in older adolescents and adults, may include unrelated thoughts).
- Is often forgetful in daily activities (e.g., performing chores and running errands, returning telephone calls, paying bills, and keeping appointments).

#### Hyperactivity and impulsivity

Six or more of the following symptoms (five or more in adolescents and adults 17 years of age or older) have persisted for at least 6 months to a degree that is inconsistent with the person’s developmental level and that directly affects social and academic or occupational activities:‡

- Often fidgets with or taps hands or feet or squirms in seat.
- Often leaves seat in situations in which one is expected to remain seated (e.g., leaves his or her place in the classroom or office).
- Often runs about or climbs in situations in which it is inappropriate. (In adolescents or adults, this symptom may be limited to feeling restless.)
- Often is “on the go,” acting as if “driven by a motor” (e.g., is unable to be still or feels uncomfortable being still for an extended period of time in restaurants or meetings; other people may perceive him or her as being restless and difficult to keep up with).
- Often talks excessively.
- Often blurs out an answer before a question has been completed (e.g., completes people’s sentences and “jumps the gun” in conversations, cannot wait for next turn in conversation).
- Often has difficulty waiting his or her turn (e.g., while waiting in line).
- Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities or uses other people’s things without asking or receiving permission; adolescents or adults may intrude in or take over what others are doing).

#### Symptoms that cause impairment

Several symptoms of inattention or hyperactivity and impulsivity were present before 12 years of age.

Criteria for the disorder are met in two or more settings (e.g., at home, school, work, or with friends or relatives).

There is clear evidence that the symptoms interfere with or reduce the quality of social, academic, or occupational functioning.

The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better accounted for by another mental disorder (e.g., a mood disorder, an anxiety disorder, a dissociative disorder, or a personality disorder).

#### Current presentation‡

Combined presentation: criteria for both inattention and hyperactivity and impulsivity have been present for the past 6 months.

Predominantly inattentive presentation: criteria for inattention are met but criteria for hyperactivity and impulsivity are not met.

Predominantly hyperactive and impulsive presentation: criteria for hyperactivity and impulsivity are met and criteria for inattention are not met.

---

* The criteria are based on the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5). ADHD denotes attention deficit–hyperactivity disorder. The table is adapted from the American Psychiatric Association.†

† The DSM-5 committee considered reducing the cutoff to four symptoms for the diagnosis in adults (as suggested by some follow-up studies), but this was not accepted or included in the final version.

‡ An earlier revision of the DSM-5 added four additional symptoms of impulsivity to give this domain more prominence, but this addition was not included in the final version.

§ In persons (especially adolescents and adults) who currently have symptoms with impairment that no longer meet the full criteria, “in partial remission” should be specified.

not be accurate.24 Self-report of current symptoms in adults can also be problematic, since it is less predictive than reports from others regarding problems with employment (e.g., job dismissal and failure to be promoted), domestic life (e.g., strained relationships with one’s spouse and children or divorce), and social activities (e.g., friendship breakups).7 Thus, the DSM-5 recommends obtaining information from a friend or family member with long-term knowledge of the person.

The diagnosis of adult ADHD is complicated by the common co-occurrence of psychiatric conditions,11,25 most frequently substance-use disorders, generalized anxiety disorders, and mood disorders. Some psychiatric conditions, such as depression and bipolar disorder, and some medical conditions, such as thyroid diseases and sleep disorders, may underlie ADHD symptoms,26 but these diagnoses can be ruled out by confirming that symptoms were present during childhood, except in instances in which these disorders might have been unrecognized. Assessment in adults is further complicated because some persons feign ADHD “symptomlike behaviors” to obtain stimulant medications for diversion to nonmedical use27 and because the symptomlike behaviors can be present in adults without a pathologic condition.

MANAGEMENT

Pharmacotherapy

Randomized, controlled trials of pharmacotherapeutic agents in adults with ADHD (Table 3) have consistently shown positive short-term effects, including symptom reduction and improvement in daily functioning.29 However, evidence of positive effects on long-term outcomes is limited and mostly derived from observational studies that show some benefits in functioning, self-esteem, and work performance29,30; a Swedish registry-based study (which included hospitalized persons) showed reduced risks of criminal behavior among persons with ADHD who were receiving treatment for the disorder than among those who were untreated.31 Although the consensus is that sustained treatment is necessary for ADHD, few randomized trials have assessed the efficacy and safety of approved ADHD medications in the long term (26 months) for adults.32 The determination of benefit is complicated by poor adherence to medication and discontinuation of treat-
mentation and by coexisting psychiatric conditions.\textsuperscript{29} One recommended strategy is to temporarily discontinue the medication after 1 or 2 years of treatment to determine whether benefits are lost; a loss of benefits would suggest that the medication is still useful.

Stimulant Medications

Stimulants (amphetamine and methylphenidate) are the most effective medications for the treatment of adult ADHD. Initially, immediate-release formulations were used, with multiple doses administered during the day (up to four doses) to maintain efficacy. ADHD symptoms diminish shortly after the administration of these agents, but symptoms reappear 3 to 4 hours later, as the medication starts to clear from the body. (The elimination half-life of methylphenidate is approximately 2 to 3 hours, and the elimination half-life of amphetamine is approximately 4 to 6 hours.) Subsequently, controlled-release formulations, which release medication gradually throughout the day and are intended for once-daily dosing, were developed, and they are currently used more commonly than immediate-release formulations.\textsuperscript{33} In controlled studies,\textsuperscript{34} most adults with ADHD have had a favorable clinical response to either methylphenidate or amphetamine, so there is no recommendation to start with one as opposed to the other. Approximately 70% of adults with ADHD have immediate improvement in attentiveness and reduced distractibility, with moderate-to-large effect sizes; effects are seen within 1 hour after administration (with both immediate-release and controlled-release formulations). Controlled-release formulations with a duration of efficacy of 6 to 10 hours might result in higher compliance than immediate-release formulations, since they may require only once-daily dosing (with a maximum of two doses), but data comparing rates of adherence to these medications are lacking. Clinical studies reveal considerable variation among persons with respect to the most effective dose of stimulant medication, and adjustments in the dose are necessary to maximize control of symptoms while minimizing adverse effects.

Methylphenidate and amphetamine have similar adverse effects. These include insomnia, dry mouth, decreased appetite, weight loss, headaches, depression, and anxiety. Some patients have fewer side effects with one of the agents than with the other; thus, it is reasonable to try the alternative if these effects limit the use of the initial agent. Stimulants are contraindicated in patients with hypertension, psychosis, or tics, since these conditions might be exacerbated by these medications.\textsuperscript{28} In a large retrospective cohort study, current use of stimulants drugs was not associated with an increased risk of serious adverse cardiovascular events among young or middle-aged adults.\textsuperscript{35} A meta-analysis of treatment trials, however, showed significant increases in the resting heart rate (5.7 beats per minute) and systolic and diastolic blood pressure (1.2 mm Hg) with stimulant medications, as compared with placebo.\textsuperscript{36} The Food and Drug Administration (FDA) recognizes that data on long-term risks among adults with ADHD are limited and recommends that stimulants (or atomoxetine [discussed below]) should not be used in “patients with serious heart problems or for whom increased blood pressure or heart rate would be problematic.”\textsuperscript{37} For patients who are being treated with stimulants, the FDA advises that the heart rate and blood pressure be monitored periodically (every 3 months).

Stimulant medications have a potential for abuse and thus are classified by the Drug Enforcement Agency as Schedule II substances. They increase levels of dopamine in the human brain, which is the mechanism by which drugs of abuse exert their rewarding effects. The risk of abuse is increased among persons with a history of a substance-use disorder.\textsuperscript{26,38} The controlled-release formulations are harder to inject or snort than the immediate-release formulations and thus are less likely to be abused. Stimulants are also abused for their purported cognitive-enhancing effects.\textsuperscript{39} In adolescents and college students, this nonmedical use may be as prevalent as medical use for the treatment of ADHD.\textsuperscript{27} About 5% of persons without ADHD who use stimulants for nonmedical purposes are expected to increase their use, leading to abuse and dependence.

Nonstimulant Medications

The only nonstimulant medication approved for adult ADHD is atomoxetine. Atomoxetine is a blocker of norepinephrine transporters that enhances noradrenergic signaling in the brain and dopaminergic signaling in the frontal cortex, since in this brain region, norepinephrine trans-

porters also remove dopamine. Two randomized phase 3 clinical trials involving a total of 536 patients followed for 10 weeks showed the efficacy of atomoxetine in adults with ADHD. Atomoxetine has a lower potential for abuse than stimulants and may be preferred in patients with ADHD and substance-use disorders and those who have tics, anxiety, or psychosis.

However, atomoxetine appears to be less effective than stimulant drugs in reducing ADHD symptoms (on the basis of comparisons of effect sizes separately reported for each medication), and 1 to 2 weeks of treatment are required for full benefits to emerge. There is no evidence that atomoxetine has a better safety profile than stimulant medications, and it should be used cautiously in patients with cardiovascular disease (including hypertension or cerebrovascular disease). Other nonstimulant medications are used on an off-label basis in adults with ADHD; examples include modafinil, guanfacine, venlafaxine, bupropion, and desipramine. However, the evidence base for these medications is limited to a few randomized trials of short duration and small overall samples.

Modafinil (approved by the FDA for the management of excessive sleepiness associated with narcolepsy, obstructive sleep apnea, and shift-work sleep disorder in adults) has been suggested as an option for patients with ADHD who do not benefit from stimulants or atomoxetine or in whom these agents have unacceptable side effects. This suggestion is based on short-term randomized trials showing a benefit of modafinil in reducing ADHD symptoms in patients, mostly in children and adolescents. However, patients should be informed of the small risk of the Stevens-Johnson syndrome. The most empirical evidence of efficacy involves cognitive behavioral interventions. Randomized trials have shown that training in behavioral and cognitive strategies to manage ADHD (i.e., training in time management, prioritization, organization, problem solving, motivation, and emotional regulation) results in reduced symptoms and improved functioning, regardless of whether patients are receiving medications for ADHD. These nonpharmacologic treatments are recommended for adults with ADHD. The most empirically supported interventions are recommended for adults with ADHD.

interventions are usually used as adjuncts to pharmacologic therapy.45

AREAS OF UNCERTAINTY

The long-term benefits versus harms of stimulant treatments and nonstimulant treatments in adults with ADHD have not been investigated adequately. Overall results of six open-label trials of 6 to 24 months’ duration suggest that the clinical response is sustained, but data from controlled follow-up studies of medication benefits and adverse effects with longer, consistent use have not been reported.34,46

Clinical trials of medications for ADHD have been largely short-term and have predominantly involved young and middle-aged adults. Data are lacking on long-term benefits and risks and on risks among elderly patients. Nonmedical use of prescription stimulants is increasing, including use that is intended to enhance performance in persons without ADHD.39 The consequences of these patterns of misuse are poorly understood.

The genetic and pathophysiological features of ADHD in adults remain incompletely understood. This incomplete knowledge contributes in part to the persistent controversy over the assignment of a pathologic label to behaviors that some view as variants on a spectrum of normal functioning.

The DSM-5 definition of ADHD highlights the attention deficit, but the clinical manifestations include deficits in reward and motivation.21,22,47,48 Adults with ADHD have reduced responses to rewards and are less motivated to engage in and follow through on everyday activities.49 Thus, a motivation deficit might contribute to ADHD symptoms and should be considered in treatment.

GUIDELINES

The DSM-5 provides guidelines for the diagnosis of ADHD in adults.3 Recommendations for the diagnosis and management of ADHD have been published by the Centers for Disease Control and Prevention (www.cdc.gov/ncbddd/adhd/treatment.html).

The National Institute for Health and Care Excellence50 and the European Network Adult ADHD51 have provided guidelines for nonpharmacologic and pharmacologic treatments for ADHD in adults. The recommendations in this article are consistent with these guidelines.

CONCLUSIONS AND RECOMMENDATIONS

The woman described in the vignette has symptoms of inattention and distractibility that suggest ADHD. Medical assessment and psychiatric evaluation are required to make the diagnosis and to rule out coexisting conditions that could account for her presentation or that might complicate or contraindicate treatment. Given the limitations associated with self-reported symptoms, corroboration of the nature of the symptoms by a friend or family member and an onset of symptoms dating back at least to 12 years of age are helpful in establishing the diagnosis.

Once the diagnosis is confirmed, we would discuss treatment options: pharmacotherapy to ameliorate her symptoms and cognitive behavioral therapy to help her develop skills to compensate for the deficits. She should be informed about the paucity of long-term data regarding the use of stimulant medications in adults and about the risks, including increases in the pulse rate and blood pressure, as well as the possibility, though unlikely, of abuse. If the patient had no contraindication to stimulant medication (e.g., cardiovascular disease, seizures, or psychosis), we would prescribe a stimulant (either controlled-release methylphenidate or amphetamine), and we would adjust the dose in the ensuing weeks as needed for efficacy and on the basis of any adverse effects. The patient should be followed regularly for any adverse events that would warrant discontinuation of the drug.

Dr. Swanson reports receiving consulting fees to his institution from Noven Pharmaceuticals, lecture fees from Johnson & Johnson and Janssen, travel support from Shire, and payment for providing testimony as an expert witness for Janssen–Ortho on the pharmacokinetic and pharmacodynamic properties of methylphenidate, and filing a lawsuit to be named as an inventor on filed patents 6,930,129; 8,163,798; and 6,919,373 regarding a method for treating attention deficit–hyperactivity disorder. No other potential conflict of interest relevant to this article was reported.

Disclosure forms provided by the authors are available with the full text of this article at NEJM.org.

We thank Dr. Laura Thomas for her help in drafting the initial version of the manuscript and Dr. Tim Wigal for referring the patient described in the vignette.
