ABSTRACT: This work reported on a bilayer photoelectrode constructed by ZnO nanoparticle (NP) film and ZnO microsphere (MS) scattering layer for CdS/CdSe quantum dot cosensitized solar cells (QDSCs) with a power conversion efficiency (PCE) of greater than 5%. We controlled the growth orientations of ZnO crystals to form nanosheets, which attached together and assembled into MS due to the high surface energy of the nanosheets. MSs were used as a top layer to effectively increase the light diffusion and harvesting to enhance photogenerated current. In comparison with ZnO NPs photoelectrode, the short circuit current density ($J_{sc}$) of ZnO NPs/MSs photovoltaic cell increased from 10.3 mA/cm$^2$ to 16.0 mA/cm$^2$, which was an enhancement of 55%. To further increase the fill factor and PCE of QDSCs, ZnO NPs/MSs was treated in the solution of H$_3$BO$_3$ and (NH$_4$)$_2$TiF$_6$ to form an enhancement of 55%. To further increase the fill factor and PCE of QDSCs, ZnO NPs/MSs was treated in the solution of H$_3$BO$_3$ and (NH$_4$)$_2$TiF$_6$ to form a barrier surface layer, which suppressed the charge recombination and prolonged electron lifetime. As a result, the solar cell displayed $J_{sc}$ of 17.13 mA/cm$^2$, $V_{oc}$ of 0.56 V, FF of 0.53, and PCE of 5.08%, one of the highest values for ZnO-based QDSCs at this time.

1. INTRODUCTION

The establishment of low cost and high performance solar cells for sustainable energy sources to replace fossil fuels has become an urgent subject imposed on scientists around the world. As a cost-effective alternative to silicon-based photovoltaics, quantum dot sensitized solar cells (QDSCs) have attracted considerable attention recently and showed promising development for next generation solar cells. QDSCs can be regarded as a derivative of dye-sensitized solar cells (DSCs), which were first reported by O’Regan and Grätzel in 1991. However, QDSCs use semiconductor quantum dots (QDs) as the photosensitizer instead of organic dyes because of their versatile optical and electrical properties, such as (1) tunable band gap depending on QD size, (2) larger extinction coefficient, (3) high stability toward water and oxygen, and (4) generation of multiple excitons with single-photon absorption. The theoretical photovoltaic conversion efficiency of a QDSC can reach up to 44% in view of the multiple exciton generation (MEG) of QDs. Among the various QDs that are used for QDSCs, CdS, and CdSe are attractive owing to their high potential for light harvesting in the visible light region. CdSe has a band gap of 1.7 eV and may therefore absorb photons with wavelengths shorter than 700 nm, and shows better performance compared to CdS. CdS has usually been used to induce CdS/CdSe cosensitization, which broadens the optical absorption of QDs. So far, CdS/CdSe cosensitized QDSCs with TiO$_2$ electrodes have reached power conversion efficiencies (PCE) higher than 5%. Porous nanoparticle films, such as TiO$_2$ and ZnO, are commonly used for the photoelectrode of QDSCs. However, the small size of the nanoparticles makes the porous films transparent to visible light, which weakens the light harvesting. Recently, the light scattering layer on the surface of the film has been adopted as an effective means to improve the light harvesting of photoelectrodes. In fact, the light scattering layer can cause optical reflection or diffusion to extend the traveling distance of incident light within a photoelectrode film. The enhancement of light scattering on QDSCs can be realized through the use of either a bilayer structure consisting of a light scattering layer over a nanocrystalline film, or a binary combination composed of a nanocrystalline film mixed with submicrometer-sized particles. Various types of light scattering layer, such as photonic crystals and dielectric multilayers, have been introduced to increase the absorption path-length of photons, create confinement properties to enhance light harvesting and decrease the probability of charge recombination.

In comparison with TiO$_2$, ZnO has higher electron mobility, making it an ideal photoelectrode material for QDSCs. However, the PCE of ZnO-based QDSCs is still lower than that of TiO$_2$-based devices due to the high surface charge recombination in ZnO. The high surface charge recombination can be attributed to many defects on ZnO surface, which ultimately boosts the surface charge recombination. In addition, the chemical stability of ZnO is less than that of TiO$_2$, which makes it easy for ZnO to react with the electrolyte. The instability also decreases the performance of QDSC.

Tian and Cao et al. developed a facile modification method for ZnO mesoporous photoelectrode. This method not only opened the apertures to improve the distribution of QDs in the photoelectrode, increased the specific surface area and reduced the surface defects of ZnO photoelectrodes to accommodate more QDs, but also suppressed the charge recombination and prolonged electron lifetime by introducing a barrier layer.

In this work, we designed a light-scattering layer of ZnO microsphere (MS) with assembled nanosheets for the first time. MSs have larger surface area and high diffuse reflection effect to enhance the light capture of the photoelectrode based on ZnO nanoparticles. After that, the ZnO photoelectrodes were immersed in an aqueous solution of 0.01 M zinc nitrate, 0.01 M hexamethylenetetramine (HMT) and 0.001 M trisodium citrate at 70 °C for 10 h. The films were drained from the reaction solution and then calcined at 350 °C for 30 min. As for the surface modification process, the films were treated in the aqueous solution of 0.1 M H$_3$BO$_3$ and 0.04 M (NH$_4$)$_2$TiF$_6$ at room temperature for 30 min. After that, the films were drained from the reaction solution and washed several times by deionized water. Then the modified films were calcined at 400 °C for 30 min.

2. EXPERIMENTAL PROCEDURES

2.1. Preparation of ZnO Nanoparticles Film and Microspheres Layer. ZnO nanoparticles with the size of 20–30 nm were prepared by a facile precipitation method. A 0.06 M KOH aqueous solution was gradually added into 0.03 M zinc acetate methanol solution at 60 °C for 60 min, and then were centrifuged and dried at 70 °C. ZnO nanoparticles, ethyl cellulose, and α-terpineol were mixed to paste with weight proportion of 20, 10, and 70%, respectively. The paste was then coated on a fluorine-doped tin oxide (FTO) glass substrate via doctor blading method to get mesoporous films. The as-received ZnO films underwent a sintering process at 480 °C for 30 min. The ZnO nanoparticle films were immersed in an aqueous solution of 0.01 M zinc nitrate, 0.01 M hexamethylenetetramine (HMT) and 0.001 M trisodium citrate at 70 °C for 10 h. The films were drained from the reaction solution and then calcined at 350 °C for 30 min. As for the surface modification process, the films were treated in the aqueous solution of 0.1 M H$_3$BO$_3$ and 0.04 M (NH$_4$)$_2$TiF$_6$ at room temperature for 30 min. After that, the films were drained from the reaction solution and washed several times by deionized water. Then the modified films were calcined at 400 °C for 30 min.

2.2. Fabrication of CdS/CdSe Sensitized Solar Cells. For the growth of CdS quantum dots, the films were first immersed in a 0.1 M cadmium nitrate (Cd(NO$_3$)$_2$) methanol solution for 1 min. Successively, the films were dipped into a 0.1 M sodium sulfide (Na$_2$S) methanol solution for another 1 min to allow S$^2-$ to react with the preadsorbed Cd$^{2+}$, leading to the formation of CdS. This procedure was denoted as one SILAR cycle. In total, five SILAR cycles were employed to obtain a suitable amount of CdS on the TiO$_2$ film. In a subsequent step, CdSe was deposited on the CdS-coated substrates through a chemical bath deposition (CBD) method. In brief, 0.1 M sodium selenosulfate (Na$_2$SeSO$_3$), 0.1 M cadmium acetate Cd(CH$_2$COO)$_2$, and 0.2 M trisodium salt of nitrilotriacetic acid (N(CH$_2$COONa)$_3$) were mixed together with a 1:1:1 volume ratio. The CdS/CdSe quantum dot sensitized solar cells based on such photoelectrodes displayed a high PCE of 5.08%.
employed in this study was composed of 1 M S and 1 M Na2S in deionized water. The counter electrode was a Cu2S film fabricated on brass foil. The preparation of the Cu2S electrode can be described as follows: brass foil was immersed in 37% HCl at 70 °C for 5 min, then rinsed with water and dried in air. Following this step, the etched brass foil was dipped into 1 M S and 1 M Na2S aqueous solution, resulting in a black Cu2S layer forming on the foil.

2.3. Characterization. The morphology of the samples was characterized by scanning electron (SEM, JSM-7000) and transmission electron (TEM, Tecnai G2 F20) microscopy. The photovoltaic properties were measured using a CHI electrochemical workstation under AM 1.5 simulated sunlight with a power density of 100 mW/cm². Optical absorption (Shimadzu 3600 UV/vis/IR spectrometer) was used to study the light absorption properties of the samples. Electrochemical impedance spectroscopy (EIS) was carried out using a CHI electrochemical workstation to investigate the electronic and ionic processes in the QDSCs.

3. RESULTS AND DISCUSSION

Figure 1a shows the SEM image of the bilayer structured photoelectrode constructed by a bottom film with the thickness of ~12 μm and the top layer with the thickness of ~10 μm. The bottom film is a layer of ZnO nanoparticles (NPs) with the diameter size of 20–30 nm as shown in Figure 1b. The mesoporous ZnO NPs film serves as QDs scaffold to collect and transfer the excited electrons from QDs. ZnO NPs are synthesized through hydrolyzing the ZnO colloid in methanol solution. The methanol not only provided the medium for the reactions, but also acted as ligands to help to grow equiaxial crystals and control the particle size.27 The top of the photoelectrode is a ZnO microspheres (MSs)-based scattering layer, which enhances the light reflectance to harvest more light absorption. Figure 1c,d display that the ZnO MSs are assembled by nanosheets with the size of ~5 nm in thickness and ~50 nm in length. As displayed in Figure 3b and the corresponding inset, the lattice constant and FFT diffraction pattern demonstrate that the nanosheet exhibits a single crystalline structure with (100) facet predominant, indicating that the fastest growth direction for ZnO nanosheet crystal is ⟨100⟩ orientations during the synthesis process. Although the synthesis mechanism of the MSs is not entirely clear, a schematic of the proposed formation mechanism of MSs and nanosheet is illustrated in Figure 4. It has been proposed that HMT reacts with water to produce ammonia, which in turn reacts with water to generate OH−.28,29 HMT can keep a low supersaturation reaction environment of reacting Zn2+ with OH− for ZnO crystals. The chemistry of the process is summarized as follows:

\[ \text{C}_6\text{H}_{12}\text{N}_6 + 6\text{H}_2\text{O} \rightarrow 6\text{CH}_2\text{O} + 4\text{NH}_3 \]  
\[ \text{NH}_3 + \text{H}_2\text{O} \rightarrow \text{NH}_4^+ + \text{OH}^- \]  
\[ \text{Zn}^{2+} + 4\text{OH}^- \rightarrow \text{Zn(OH)}_4^{2-} \]  
\[ \text{Zn(OH)}_4^{2-} \rightarrow \text{Zn(OH)}_2 + 2\text{OH}^- \]  
\[ \text{Zn(OH)}_2 \rightarrow \text{ZnO} + 2\text{H}_2\text{O} \]
Previous research\textsuperscript{30,31} showed that ZnO crystals grow fast along the c-axis (001) orientation in the low concentration of OH\textsuperscript{−} ions solution. The growth along c-axis was suppressed with the increase of the concentration of OH\textsuperscript{−} ions. In the reaction solution of Zn(NO\textsubscript{3})\textsubscript{2} and HMT, HMT slowly generates OH\textsuperscript{−} ions. The concentration of OH\textsuperscript{−} ions always stays at low level. Thus, ZnO crystals grow along ⟨001⟩ orientation to form nanorod. Tian et al.\textsuperscript{32} had studied that citrate ions slowed down crystal growth along the ⟨001⟩ orientation, indicating that more citrate ions absorbed on the (001) facet. As displayed in Figure 4, we deduce that citrate ions (C\textsubscript{6}H\textsubscript{5}O\textsubscript{7}\textsuperscript{3−}) preferably concentrate on the (001) facet due to its high surface energy, which inhibits the growth of ZnO crystal along (001) orientateon. The crystals are still able to grow sideways (such as ⟨100⟩ orientations) in the form of thin sheets, which is consistent with the results of XRD and TEM. A large numbers of nanosheets would form quickly in the solution and then attach together to form hierarchical structured microspheres due to the high surface energy of the nanosheets.

Figure 5 shows the J−V curves for the solar cells measured under the illumination of one sun (AM 1.5, 100 mW/cm\textsuperscript{2}).

The performance parameters, open voltage (V\textsubscript{oc}), short current density (J\textsubscript{sc}), fill factor (FF), and PCE of the solar cells are listed in Table 1. In comparison with ZnO NPs photoelectrode,

J\textsubscript{sc} of the ZnO NPs/MSs increases from 10.3 to 16.0 mA/cm\textsuperscript{2}, which is an enhancement of 55%. So the light scattering is an important cause for the increase of the absorbance of incident photons for the enhancement of photocreated current. Diffuse reflectance and transmittance data can reveal the extent to which incident light is scattered by particles in the photoelectrodes and how much the incident light passes through the photoelectrodes without being scattered.\textsuperscript{33} The ideal light scattering properties of a photoanode should be a high diffuse reflectance and low diffuse transmission. Figure 6a,b shows the diffuse reflection and transmittance spectra curves of ZnO photoelectrodes films. It can be seen that the diffuse reflectance of ZnO NPs/MSs is much stronger than that of ZnO NPs in the 400−800 nm range, which is the main wavelength range for QDs to capture photons. In addition, the diffuse transmittance of the ZnO NPs/MSs is much weaker than that of NPs film, which indicates there are more photons trapped in the NPs/MSs film. Figure 6c shows the effect of light scattering layer on the ZnO photoelectrodes. The results can be attributed to the strong scattering of the MSs, which makes the incident light directly reflect back toward the nanoparticles. As a result, the photocurrent and PCE of the QDSC assembled with ZnO NPs/MSs are increased due to the enhanced light scattering.

Although the J\textsubscript{sc} of QDSCs can be increased by scattering layer, the FF and PCE are still low. The main cause is attribute to the high surface charge recombination due to many defects on the surface of ZnO.\textsuperscript{24} In order to decrease the defects and enhance efficiency of QDSCs, the ZnO photoelectrodes were treated by a facile passivation process. The ZnO NPs/MSs films were immersed in an aqueous solution containing 0.1 M H\textsubscript{3}BO\textsubscript{3} and 0.04 M (NH\textsubscript{4})\textsubscript{2}TiF\textsubscript{6} at room temperature for 30 min. The films were then washed several times with deionized water and annealed at 400 °C (detailed information shown in our previous research\textsuperscript{26}). Such treatment leads to the formation of a thin passivation layer on the surface of the ZnO NPs/MSs. The modification process can be expressed via the following equations:\textsuperscript{26,34}

\begin{equation}
\text{TiF}_6^{2−} + 2\text{H}_2\text{O} \leftrightarrow \text{TiO}_2 + 6\text{F}^- + 4\text{H}^+ \tag{6}
\end{equation}

\begin{equation}
\text{H}_3\text{BO}_3 + 4\text{H}^+ + 4\text{F}^- \leftrightarrow \text{B}_3\text{O}_3^- + \text{H}_2\text{O} + 2\text{H}_2\text{O} \tag{7}
\end{equation}

\begin{equation}
\text{ZnO} + 2\text{H}_2\text{O} \rightarrow \text{Zn}^{2+} + 3\text{H}_2\text{O} \tag{8}
\end{equation}

The reactions 6 and 7 can be shifted to the right by reaction 8, which indicates the dissolution of ZnO can boost the hydrolization of TiF\textsubscript{6}\textsuperscript{2−}. With the dissolution of ZnO, TiO\textsubscript{2} nanoparticles are directly deposited on the fresh surface of ZnO. Figure 7a,b show SEM images of the modified ZnO MSs. It can be seen that MSs appear tarnished, and the edge of nanosheets loses keenness and become mellow. As shown in Figure 7c,d, energy-dispersive X-ray spectroscopy (EDS) mapping images of Zn and Ti elements show the presence of Ti elements on the surface of modified ZnO MSs, which indicates ZnO MSs are coated with TiO\textsubscript{2}.

To evaluate the effect of surface modification on the overall device performance, electrochemical impedance spectroscopy (EIS) measurements were carried out. Figure 8a shows the impedance spectra of the QDSCs measured under the dark condition with forward bias of −0.6 V. In Figure 8a, the semicircle represents the electron transfer at the photoelectrode/QDs/electrolyte interface and the transport in the photoelectrode (R\textsubscript{ct}).\textsuperscript{35} The R\textsubscript{ct} of the modified ZnO NPs/MSs based QDSC is 57.2 Ω, which is more than twice of the ZnO NPs/MSs device (22.7 Ω). The charge transfer resistance at the photoelectrode/electrolyte interface (R\textsubscript{ct}) is determined by both the ZnO and TiO\textsubscript{2} passivation layer, and the total charge transfer resistance can be written by the following eq 9:\textsuperscript{36}

\begin{equation}
R_{\text{total}} = R_{\text{ZnO}} + R_{\text{TiO}_2} \tag{9}
\end{equation}

where R\textsubscript{ZnO} and R\textsubscript{TiO\textsubscript{2}} are the electron transfer resistances induced by the ZnO and TiO\textsubscript{2} passivation layer, respectively. EIS results indicate that electrons in the ZnO photoelectrode with passivation layer are more difficult to recombine with holes in the electrolyte in view of its high R\textsubscript{ct}. R\textsubscript{ct} can be
considered as part of a shunt resistance \( (R_{sh}) \) because it behaves like a diode on the applied bias voltage.\(^{36}\) The \( R_{sh} \) relates to the FF according to the following eq 10:\(^{36}\)

\[
\text{FF} = \text{FF}_0(1 - 1/R_{sh})
\]

where \( \text{FF}_0 \) is the theoretical maximum FF. It can be inferred that the increase in FF of the QDSC assembled with the modified photoelectrode is a result of an increase in \( R_{sh} \). Figure 8b shows the bode plots of the QDSCs with the different photoelectrodes. The curve peak of the spectrum can be used to determine the electron lifetime in the ZnO (according to the equation \( \tau_n = 1/(2\pi f_{\text{min}}) \)).\(^{37}\) It is clear that the electron lifetime for the device with the modified ZnO NPs/MSs photoelectrode is 11.6 ms, which is much longer than the 4.2 ms of electron lifetime for the ZnO NPs/MSs. The electron lifetime \( (\tau_n) \) is directly proportional to \( R_{ct} \) and is calculated by eq 11:\(^{38}\)

\[
\tau_n = R_{ct} \cdot C_{\mu}
\]

where \( C_{\mu} \) is the corresponding chemical capacitance. Consequently, the employment of modified TiO\(_2\) layer can enhance the charge recombination resistance and thus prolong the electron lifetime.\(^{36,39}\) Figure 8c shows the schematic illustration surface charge recombination pathways of QDSC: (A) recombination of electrons in the QD conduction band and holes in the QD valence band; (B) recombination of electrons with the electron acceptors in the electrolyte; (C) back electron injection from ZnO to electrolyte; (D) back electron injection from ZnO to QDs. Among these pathways, processes (A) and (B) can be ignored due to the highly efficient charge separation.\(^{24}\) Recombination pathways (C) and (D) can be considered as the main factors that affect the performance of a QDSC. The recombination depends on photodecote/ODs/electrolyte interfacial resistance. As a barrier layer, the TiO\(_2\) modification layer can increase the interfacial resistance to reduce recombination.\(^{26}\) So, the FF and PCE of QDSCs will be increased evidently by the modification treatment.

Figure 9 shows the \( J-V \) curves for the solar cells measured under the illumination of one sun (AM 1.5, 100 mW cm\(^{-2}\)). Detailed results of the samples are shown in Table 2. Compared with ZnO NPs based QDSC, the FF and PCE of the modified ZnO NPs/MSs based QDSCs increased from 0.36 to 0.53 and 2.89 to 5.08%, respectively. To our knowledge, the PCE of 5.08% is one of the highest respective values for ZnO-based QDSCs at this time.

4. CONCLUSIONS

A bilayer structured photoelectrode of ZnO nanoparticle (NP) film and ZnO microsphere (MS) scattering layer for CdS/CdSe...
quantum dot cosensitized solar cells (QDSCs) was examined in this investigation. The MS layer could effectively increase the light diffuse reflection and harvesting to enhance photogenerated current. However, the FF and PCE of QDSC were still low due to the high surface charge recombination. ZnO NPs/MSs was treated in the solution of H3BO3 and (NH4)2TiF6 to form a thin barrier layer on its surface, which suppressed the charge recombination and prolonged electron lifetime. As a result, the solar cell displayed a high performance, Jsc of 17.13 mA/cm², Voc of 0.56 V, FF of 0.53, and PCE of 5.08%, which was one of the highest respective values for ZnO-based QDSCs at this time.
