Clinical Research Publications on Fetal Alcohol Spectrum Disorders 1985-2025

Susan Jean (Astley) Hemingway, Ph.D.

Professor of Epidemiology and Pediatrics
Schools of Public Health and Medicine
Director: FAS Diagnostic & Prevention Network
FASDPN

University of Washington
Seattle Washington, USA

Table of Contents in Chronological Order of Publication (1985 – 2025)

10. **Critical gestational periods and threshold doses for ethanol teratogenesis**. (1992)

Clarren SK, Astley SJ.
In: Similarities & Differences between Children & Adults. Implications for Risk Assessment.
Guzelian PS, Henry CJ, Olin SS eds. ILSI Press, Washington DC, pp.113-128, 1992.

11. **Cognitive and behavioral deficits in non-human primates associated with very early embryonic binge exposures to ethanol**. (1992)

Clarren SK, Astley SJ, Gunderson VM, Spellman D.
J Pediatrics, 121:789-796, 1992.

12. **Immune function in offspring of nonhuman primates (*Macaca nemestrina*) exposed weekly to 1.8 g/kg ethanol during pregnancy**. (1993)

Grossmann A, Astley SJ, Liggitt HD, Clarren SK, Shiota F, Kennedy B, Thouless M, MaggioPrice L.
Alcoholism: Clinical and Experimental Research 17:822-827, 1993.

13. **Magnetic resonance imaging and spectroscopy in fetal ethanol exposed *Macaca nemestrina*.** (1995)

Astley SJ, Weinberger E, Shaw D, Richards T, Clarren SK.
Neurobehav Tox Teratol 1995;17(5):523-530.

14. **A fetal alcohol syndrome screening tool.** (1995)

Astley SJ, Clarren, SK.
Alcoholism: Clinical and Experimental Research, 1995;19(6):1565-1571.

15. **A case definition and photographic screening tool for the facial phenotype of fetal alcohol syndrome**. (1996)

Astley SJ, Clarren SK.
J Peds. 1996;129:33-41.

16. **FAS Facial Photographic Analysis Software.** **Video Demonstration**
V.1.0, 2004; V.2.0, 2012; V.2.1, 2016.

Astley SJ.
University of Washington, Seattle WA

17. **Purkinje cell deficits in nonhuman primates following weekly exposure to ethanol during gestation**. (1996)

Bonthius DJ, Bonthius NE, Napper R, Astley SJ, Clarren SK, West JR.
Teratology 1996;53:230-236.

18. **The development of the fetal alcohol syndrome diagnostic and prevention network in Washington State.** (1997)

Clarren SK, Astley SJ.
In: The Challenge of Fetal Alcohol Syndrome: Overcoming Secondary Disabilities. Streissguth A & Kanter J (Eds). University of Washington Press, Seattle, pp 40-51, 1997.

19. **Identification of children with fetal alcohol syndrome and an opportunity for referral of their mothers for primary prevention-Washington**. (1998)

Clarren SK, Astley SJ.
MMWR, October 16, 1998;47(40):861-864.

20. **Fetal alcohol syndrome: Changes in craniofacial form with age, cognition and timing of ethanol exposure in the *Macaque***. (1999)

Astley SJ, Magnuson S, Omnell LM, Clarren, SK.
Teratology, 1999;59:163-172.

21. **Number of axons in the corpus callosum of the mature *Macaca nemestrina*: Increases caused by prenatal exposure to ethanol**. (1999)

Miller MW, Astley SJ, Clarren SK.
J Comparative Neurology 1999;412:123-131.

22. **Diagnostic Guide for Fetal Alcohol Syndrome and Related Conditions: The 4-Digit Diagnostic Code. 1st Edition** (1997).

Astley SJ and Clarren SK.
University of Washington Publication Services, Seattle WA, pp. 93, 1997.

23. **Diagnostic Guide for Fetal Alcohol Syndrome and Related Conditions: The 4-Digit Diagnostic Code. 2nd Edition** (1999).

Astley SJ and Clarren SK.,
University of Washington Publication Services, pp. 111, 1999.
https://depts.washington.edu/fasdpn/pdfs/guide99.pdf

24. **Diagnosing the full spectrum of fetal alcohol exposed individuals: Introducing the 4-Digit Diagnostic Code.** (2000)

Astley SJ, Clarren SK.
Alcohol & Alcoholism, 2000;35(4):400-410.

25. **Diagnostic Guide for Fetal Alcohol Spectrum Disorders: The 4-Digit Diagnostic Code. 3rd Edition** (2004).

Astley SJ.
University of Washington Publication Services, Seattle WA, pp. 132, 2004.
https://depts.washington.edu/fasdpn/pdfs/guide04.pdf

26. **Diagnostic Guide for Fetal Alcohol Spectrum Disorders: The 4-Digit Diagnostic Code. 4th Edition,** (2024).

(Astley) Hemingway SJ.
University of Washington, Seattle WA, pp. 115, 2024.
https://depts.washington.edu/fasdpn/pdfs/Guide2024.pdf

27. **A Child with Fetal Alcohol Syndrome**. (2000)

Clarren SK, Carmichael-Olson H, Clarren SGB, Astley SJ.
In: MJ Guralnick (Ed.) Handbook of Clinical Assessment for Young Children with Developmental Disabilities. Baltimore, MD: Paul H. Brookes pp. 307-326, 2000.

28. **FAS primary prevention through FAS diagnosis: Part I. Identification of high-risk birth mother's through diagnosis of their children.** (2000)

Astley SJ, Bailey D, Talbot C, Clarren SK.
Alcohol & Alcoholism 2000;35(5):499-508.

29. **FAS primary prevention through FAS diagnosis: Part II. A comprehensive profile of 80 birth mothers of children with FAS.** (2000)

Astley SJ, Bailey D, Talbot C, Clarren SK.
Alcohol & Alcoholism 2000;35(5):509-519.

30. **Measuring the facial phenotype of individuals with prenatal alcohol exposure: correlations with brain dysfunction.** (2001)

Astley, SJ, Clarren SK.
Alcohol & Alcoholism, 2001;36(2):147-159.

31. **Application of the fetal alcohol syndrome facial photographic screening tool in a foster care population**. (2002)

Astley SJ, Stachowiak J. Clarren SK and Clausen C.
J. Pediatrics, 2002;141(5):712-717.

32. **Fetal alcohol syndrome prevention in Washington State: Evidence of success**. (2004)

Astley SJ.
Paediatric and Perinatal Epidemiology 2004;18:341-355.

33. **Fetal alcohol syndrome: Guidelines for referral and diagnosis**. (2004)

Bertrand J, Floyd RL, Weber MK, O'Connor M, Riley P, Johnson KA, Cohen DE, and National Taskforce on FAS/FAE. Atlanta, GA: Centers for Disease Control and Prevention; 2004.
Astley SJ served on the National CDC Diagnostic Guide Study Work Group.

34. **Diagnosing FAS: Comparison of the 4-Digit Diagnostic Code and Hoyme FASD diagnostic guidelines**. (2006)

Astley, SJ.
Pediatrics 2006;118(4):1532-1545.

35. **Exploring the utility of narrative analysis in diagnostic decision-making: Picture-bound reference, elaboration, and Fetal Alcohol Spectrum Disorders**. (2007)

Thorne JC, Coggins TE, Olson HC, Astley SJ.
Journal of Speech, Language, and Hearing Research, 2007;50(2):459-74.

36. **Responding to the challenge of early intervention for fetal alcohol spectrum disorders (FASD).** (2007)

Olson HC., Jirikowic T, Kartin D, Astley S.
Infants and Young Children. 2007;20:172-189.

37. **Children with fetal alcohol spectrum disorders: problem behaviors and sensory processing.** (2008)

Franklin L, Deitz J, Jirikowic T, Astley, S.
Am J Occupational Therapy 2008;62:265-273.

38. **Neuropsychological and behavioral outcomes from a comprehensive magnetic resonance study of children with fetal alcohol spectrum disorders.** (2009)

Astley SJ; H.C. Olson; K. Kerns; A. Brooks; E. Aylward; TE. Coggins; J. Davies; S. Dorn; B. Gendler; T. Jirikowic; P. Kraegel; K. Maravilla; T. Richards.

The Brain in the Fetal Alcohol Syndrome

Observations in Human and Nonhuman Primates

Sterling K. Clarren, M.D.
Douglas M. Bowden, M.D.
Susan Astley, B.A.

It has been difficult to try to establish a dose-response curve for fetal alcohol syndrome (FAS); but it is likely that, generally, FAS occurs in the offspring of women who are chronic alcoholics. Still, fetal alcohol effects may occur in babies born to women who binge drink or who consume more modest amounts of alcohol. In fact, human and nonhuman primate studies on brain structure and function now strongly suggest that gestational alcohol consumption can effect fetal brain structure and function even in the absence of any external morphologic change such as facial abnormalities or disruption in growth (characteristic of full-blown fetal alcohol syndrome).

A project now under way in our laboratories should help to strengthen the clinical impression that fetal alcohol effects occur in the absence of fully developed fetal alcohol syndrome and to clarify the dose-response curve to some extent. The study will also offer behavioral, neuropathologic, and neurochemical correlations that should provide new knowledge of brain function and may even suggest some more appropriate behavioral therapy or drug intervention for children whose behavior is affected by gestational alcohol exposure.

Characteristics of FAS in Humans and Primates

Youngsters with FAS are microcephalic at birth, (Microcephaly is a condition chracterized by abnormal smallness of the head, usually associated with mental retardation.) Newborns with FAS are usually irritable and tremulous. They often suck poorly and frequently show discomfort with sensory stimulation of any kind. Infants who are intoxicated at birth (due to maternal alcohol consumption prior to delivery) will metabolize ethanol extremely slowly because they are deficient in hepatic ethanol dehydrogenase (the principal enzyme for metabolism of ethanol).

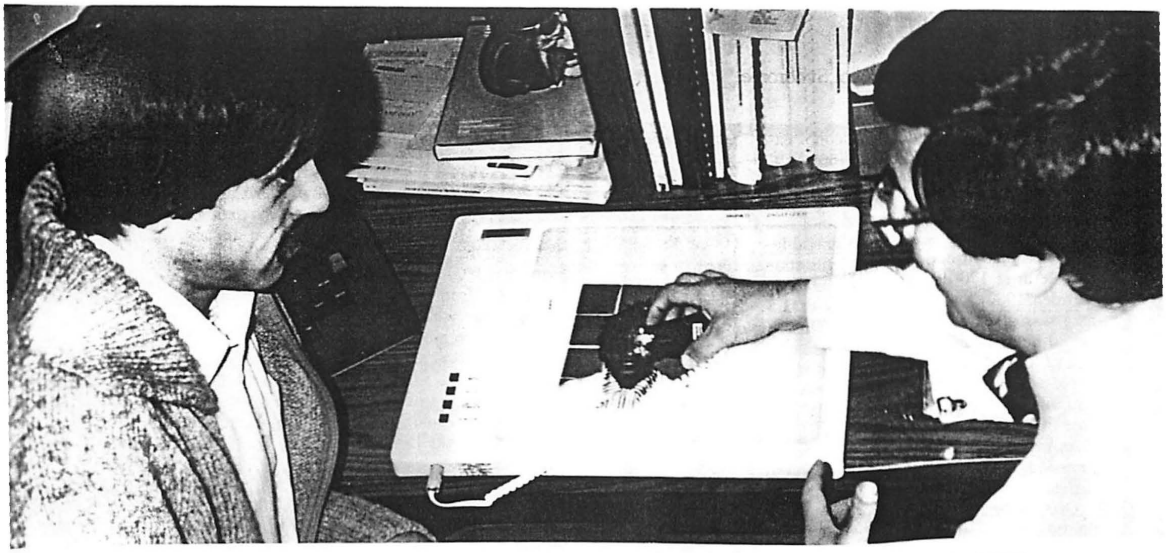
Older children are generally hypotonic (have diminished tone of the skeletal muscles) and are poorly coordinated in motor control. Hypertonicity (a condition in which skeletal muscles exhibit abnormally high resistance to passive stretching) is occasionally noted and may lead to a diagnosis of cerebral palsy, a persisting motor disorder caused by nonprogressive brain damage. Seizures have been rare, although neurological abnormalities may be noted through brain wave recordings using electroencephalography. Increased minor motor movements are nearly always found. These movements seem most typical of FAS children and interfere with their ability to concentrate on any specific learning task. Behavioral therapy and drugs like methylphenidate (a central nervous system stimulant often used in the treatment of hyperkinetic children) have not been successful in controlling this form of hyperactivity.

Only 16 brains of children known to have been exposed to high gestational volumes of ethanol have been reported in the medical literature. The first autopsied study was included in the initial work on FAS by Jones and Smith (1973, 1975). The brain was then included with three others studied by Clarren and colleagues (1978). Clarren found that all four brains displayed similar malformations stemming from errors in migration of brain cells, both neural and nonneural. Hydrocephalus (a condition characterized by an abnormal increase in the amount of fluid in the cranium, causing enlargement of the head and destruction of the nerve cells in the brain) was one consequence of the malformations in two of the infants.

Clarren (1981) later published an additional case. This brain was small in size and was marked by reduction in cerebral white matter (composed of nerve cell fibers), and disorganized migration of nerve cell bodies along the surface of the lateral ventricles (the fluid-filled cavities in each cerebral hemisphere of the brain).

While Majewski and colleagues (1978) reported a normal autopsy in a stillborn exposed to alcohol, Peiffer and colleagues (1979) reported six autopsied cases of FAS with neuropathologic findings. Finally Wisniewski and colleagues (1985) reported five neuropathologic assessments in patients exposed to gestational alcohol. Their examination of the five FAS infants revealed microencephalic brains in all cases, without structural evidence of delay in the brain's maturation. One of the examined brains showed agenesis (absence) of the corpus callosum (the bridge of nerve fibers that facilitates communication between the left and right cerebral hemispheres) and hypoplasia (underdevelopment) of the cerebellar vermis (the middle portion of the twin-lobed cerebellum). Five of the brains studied had only small dysgenetic (defective developmental) changes.

The brains examined in these studies, then, showed similar patterns of brain deformities and lesions. Early errors in migration of embryonic brain cells to their proper positions led to diffuse patterns of malformation in all cases. Later



Drs. Sterling Clarren (right) and Paul Sampson analyze facial features of children known to have been exposed to alcohol during gestation (See sidebar on next page).

gestational exposure presumably produced destructive lesions of the cerebral white matter in a third of the patients (see Table 1). These findings are extensively discussed elsewhere (Clarren and Bowden 1982).

What is of interest to this discussion is the relationship of those brain malformations to the patients' overall appearance. Table 2 shows the clinical features of FAS and neurologic abnormalities. Of the 16 children, 7 would have received the FAS label because they exhibited growth deficiency, the "FAS face," associated malformations, and brain dysfunction. Two of these children had extreme patterns of brain disruption, while five had more mild structural neuropathologic problems. The other nine children would have been labeled clinically as possibly or probably afflicted by fetal alcohol effects because none had a clearly alcohol-related appearance. Indeed, one child was apparently normal. In spite of this, three of these nine children had a severe form of brain disruption. Clearly, then, it is not clinically possible to declare a child free of alcohol-related problems just because growth or appearance is normal.

Attempts to Measure Fetal Risks

Several problems have made it difficult to establish risks to teratogenesis (the production of physical defects in offspring prior to birth) from maternal ethanol consumption. Usually, alcohol consumption has been measured through self-reporting, which is always of uncertain validity. In addition, patterns of drinking vary daily in most people; and it is unlikely that any two human fetuses have ever been subjected to exactly the same exposure pattern. Besides, alcohol absorption and metabolism vary considerably in adults, so fetuses may be exposed to differing conditions despite similar maternal consumption. Finally, accurate assessment of alcohol teratogenesis from study of the individual's appearance (assessing genetic *and* environmental factors) is clearly inadequate.

In order to assess more fully the relationship of altered body structure to brain

Table 1. Neuropathologic Change in 16 Patients with Fetal Alcohol Effects

	Severe	Mild
Cerebral Malformation 14/16		
Neuroglial heterotopias	2	10
Cortical dysgenesis	3	7
Nuclear dysgenesis	3	2
Agenesis of corpus callosum	3	1
Agenesis of anterior commissure	1	1
Cerebral White Destruction 5/16		
Hydrocephalus ex vacuo		6
Periventricular leukomalacia		1
Cysts		1
Cerebellar dysgenesis 10/16	4	6
Brainstem dysgenesis 4/16	3	1

Table 2. A Comparison of Clinical Features of Fetal Alcohol Syndrome to Neuropathologic Alterations in 16 Case Reports

Dysmorphic Pattern	Severe Brain Alteration	Mild Brain Alteration
Face/Growth/Malformations (FAS)	2	5
Face/Growth	2	1
Face/Malformations	—	2
Face	1	1
Growth		1
None		1

structure, brain function, and alcohol exposure, we developed a model for investigating alcohol-related birth defects in the pigtail macaque *(Macaca nemestrina)*. In a pilot study, ethanol was given just once per week to four gravid female macaques from 40 days of gestation until term at 170 days (Clarren and Bowden 1982). A dose of ethanol of 2.5 g/kg was given to three animals. This would be equivalent to human consumption of about 6 drinks at a time and yielding a peak serum ethanol level of about 250 mg/dl. Another animal received a dose of 4.1 mg/kg, which would be equivalent in humans to about 10 drinks at a time with a peak serum level of about 350 mg/dl.

One moderate-dose animal miscarried; the others all carried to term. The high-dose infant macaque was found to be dysmorphic (suffered congenital malformation) and mentally retarded. The brain in this infant at 6 months of age was extremely malformed in many ways similar to those seen in humans afflicted with FAS. The moderate-dose animals appeared to be normal, although one was mildly retarded and the other had borderline normal intelligence on standardized measures of primate performance. At autopsy, however, small neuronal heterotopias (displaced or misplaced tissue) were found in the brain of the mildly retarded animal. In moderately exposed and control animals, the caudate and the putamen (two regions involved in control of body movements) were studied. Dopamine, the principal neurotransmitter in these regions was found to be abnormally active in both of the experimental animals.

The FAS Face

There is no question that the facial characteristics indicative of fetal alchol syndrome change over time from infancy to adolescence and into adulthood. Therefore, if health care professionals are to make the diagnosis of FAS in children at different ages, they need to know what the face looks like at various stages in a child's development, says Sterling K. Clarren, M.D., of the University of Washington School of Medicine.

To help identify precisely what facial features indicate a diagnosis of FAS past infancy, Dr. Clarren and his colleagues have collected photographs of 42 7-year-olds known to have been exposed to alcohol during gestation and are now analyzing their facial similarities with a computer-aided technique called digitization.

Digitization is a process that analyzes geometrical relationships among specific facial features. Specifically, Dr. Clarren and colleagues are studying triangular relationships among the inner and outer angles of the eyelid, the eyebrow, the outer points of the nose and the lips, and a series of points along the lateral aspect and center of the face.

Preliminary results suggest a new description of the "FAS face."

"Prior descriptions of facial characteristics of FAS based on clinical examination have always indicated that the midface of FAS children was the right size, but that their nose was short," Dr. Clarren says. "That's probably wrong. Our studies now indicate that the nose of such a child is probably the right length but that the midface is long. We now have evidence that the chin appears to recede in these children as well."

Clearly a long midface and a short chin are two important features which could be helpful in diagnosing the syndrome, Dr. Clarren says.

The Current Investigation

We have now undertaken a study involving 36 gravid pigtail macaques exposed to a wider range of alcohol dosage. This study will not be completed until 1986 and only one-half of the animals have been fully assessed to date. Still, some trends in the results can be disclosed at this time.

In the current project, the weekly oral exposure to alcohol begins in the week following timed mating—a month before pregnancy is confirmed. In general, it is estimated by the University of Washington Primate Center that 50 percent of females are confirmed pregnant after timed breeding when there is no human interference. The rates of implantation of the fertilized egg in the uterus was found in Table 3. Statistical assessment will not be

done until the study has been completed. Nevertheless, it appears that alcohol affects either conception or implantation at even the lowest levels of weekly exposure to ethanol. The confirmed pregnancy outcomes are shown in Table 4. In the control group and in the lower weekly-ethanol-exposed groups, the fetuses have nearly all been carried to term without difficulty. However, in the high-exposure groups, most of the fetuses have miscarried. In order to bring sufficient fetuses to term, we have adjusted the study as noted in Table 5.

Gravid macaques assigned to dosage groups achieving peak serum ethanol levels below 200 mg/dl receive their first dose with the first week of conception; animals who will achieve a peak serum ethanol level above 200 mg/dl do not receive their first dose until pregnancy is confirmed at 40 days' gestation. The study will be completed when six animals in each serum level category have been fully studied.

With the exception of the weekly dosing, the animals' pregnancies are normally maintained and the animals are observed for weight gain and health. Food intake is monitored daily and is withheld on the morning of dosage. The alcohol (20 percent solution in water) is delivered through a tube inserted through a nostril and extending to the stomach. The animals that serve as controls are given the same amount of sucrose solution that contains the same number of calories as the ethanol dose. The infants are delivered vaginally at term unless medical indications warrant ceasarian section.

After the birth of an infant macaque in the project, a standard set of measures are obtained. These include standard facial photographs, cephalometric radiographs (an x-ray image of the anatomic structures of the head), and such anthropometric measurements as size, weight, and proportion of the head; body size; and foot size. Sensory assessments include examination of the interior of the eye, tests for detailed vision, and studies of brain waves evoked by sensory stimulation. Over the first 6 months of life, the infant animals are tested on numerous standardized scales of primate intelligence and development, including neonatal reflex assessments, infant motor milestone scale, social milestone scale, object-permanence (cognitive) scale, and visual pattern recognition.

At the age of 6 months, various biochemical and neuroanatomical stuides are performed. The studies and the investigators involved in this part of the project are listed in Table 6.

Conclusion

It is as yet premature to make any firm statements about the results of the current investigation, although we do expect to find behavioral changes and pathological system changes at doses lower than those needed for observable body structure changes. We also anticipate finding biochemical changes in the brain that may be correlated with behavioral changes. □

TERATOLOGY 35:345–354 (1987)

Pregnancy Outcomes After Weekly Oral Administration of Ethanol During Gestation in the Pig-Tailed Macaque (*Macaca nemestrina*)

STERLING K. CLARREN, DOUGLAS M. BOWDEN, AND SUSAN J. ASTLEY
Departments of Pediatrics (S.K.C., S.J.A.), Psychiatry and Behavioral Sciences (D.M.B.), and Pharmacology, School of Medicine, Regional Primate Research Center, and Child Development and Mental Retardation Center, University of Washington, Seattle, Washington 98195

ABSTRACT Ethanol was orally administered once per week to gravid pig-tailed macaques (*Macaca nemestrina*) in doses of 0.3, 0.6, 1.2, 1.8, 2.5, 3.3, or 4.1 g/kg. A control group received a sucrose solution, isocaloric and isovolemic to the highest ethanol dose. Pregnancy was followed after 116 possible conceptions in 54 females. Peak plasma ethanol concentrations (PPECs) ranged from 24 ± 6 mg/dl at the 0.3 g/kg dose to 549 ± 71 mg/dl at the 4.1 g/kg dose. An increased rate of spontaneous abortion was related to ethanol exposure at and above 1.8 g/kg (mean PPEC = 205 mg/dl). Pregnancy failure in the first 30 days of gestation increased at doses above 2.5 g/kg. The effect on pregnancy outcome of weekly exposure to ethanol in this nonhuman primate is comparable to available data on humans. The methodology of this study represents an effective model for studying ethanol teratogenesis in a nonhuman primate.

The morphologic and behavioral teratogenicity of alcohol has been well documented in humans (Clarren and Smith, '78). Deficits associated with intrauterine ethanol exposure include diminished growth, increased rates of major anomalies, structural brain anomalies, developmental delay, and behavioral problems. The fetal alcohol syndrome (FAS) represents the full manifestation of intrauterine ethanol exposure. Partial FAS phenotypes and other patterns of dysmorphogenesis are not clinically diagnostic of alcohol teratogenesis but may in fact be causally related. These alternate patterns have been referred to as "possible fetal alcohol effects" or, more recently, "alcohol-related birth defects."

In spite of intensive review of human ethanol consumption during pregnancy, no dose-response curve for ethanol teratogenicity has been established. The reports of alcohol consumption from mothers of infants with FAS are not sufficiently accurate to determine the "dose." Individual variations in consumption patterns of ethanol as well as variations in individual metabolism—both of the mother and of the fetus—further complicate experimental design. It is probable that there is no *single* dose-response relationship for ethanol teratogenesis, but rather that each abnormal outcome in brain structure or function, morphology, and growth has its own dose-response and gestational timing parameters.

There are a number of reasons for studying alcohol teratogenesis in a nonhuman primate model. A generally recognized principle of toxicologic research in animals is that no one species can perfectly model the human situation (Abel, '80). Several rodent models for studying ethanol teratogens have been developed. These models are useful in identifying the range of teratogenic effects, in elucidating the basic biochemical effects of ethanol on mammalian tissue, and in identifying potentially critical periods during gestation when the mammalian fetus is most vulnerable to specific toxic effects of ethanol. Such models are less useful in elucidating dose-response aspects of human FAS. Further, much of the rapid phase of brain growth that occurs in late gestation in humans occurs postnatally in rodents, which renders the small animal model inadequate for deter-

mining the relationship between ethanol exposure and phenotypic changes in brain structure and function.

We have previously reported data from a pilot project in which ethanol was orally administered to four pregnant pig-tailed macaques (*Macaca nemestrina*) (Bowden et al., '83, Clarren and Bowden, '82). The ethanol was given just once per week in order to mimic human binge drinking (intermittent consumption). One animal received a dose of 4.1 g of ethanol per kilogram body weight, while three others received a dose of 2.5 g of ethanol per kilogram of body weight. These doses produced average peak plasma ethanol concentrations (PPECs) of approximately 400 mg/dl in the higher-dose animal and 250 mg/dl in the lower-dose animals. The treatment was initiated in each animal after the confirmation of pregnancy at about 30 days' gestation, and dosing continued thereafter once per week until delivery at about 170 days' gestation.

One of the animals given the 2.5 g/kg dose aborted on the 77th day of gestation, whereas the other animals carried to term. The pregnancies were largely uncomplicated. The infants underwent a variety of psychometric and developmental tests and were assessed anthropometrically and dysmorphologically. At 6 months of age they were killed. Each animal had a complete autopsy with neuropathologic study and several special neurochemical assessments.

The animal exposed to 4.1 g/kg of ethanol was facially dysmorphic and had severe developmental delay. Its brain was dysplastic, with anomalies similar to those previously reported in humans (Clarren et al., '78). The animals exposed to 2.5 g/kg of ethanol appeared morphologically normal, but one had evidence of developmental delay and had more subtle neuropathological anomalies.

The pilot project was conducted with only a few animals and rather large exposure doses, and the animals were not exposed to ethanol in the first 4 weeks of gestation, a period of rapid organogenesis. Nevertheless, the results supported the concept that different alcohol-related teratogenic outcomes could occur at differing ethanol exposures, with behavioral teratogenesis occurring at lower exposures than structural teratogenesis.

The pilot data encouraged us to pursue a more thorough study, and this project was initiated in October 1982. The present study retained the once per week ethanol exposure format of the pilot project, but dosing took place within the first 10 days of conception so that more of the embryonic period was teratogenically vulnerable. In addition, the size of the experimental population was increased, allowing for a wider range of dosing cohorts.

Each infant was assessed in sequential evaluations for growth by using specific protocols for anthropometric measures. Dysmorphology examinations were conducted directly and through standardized radiographs and photographs. A battery of developmental and psychometric tests was completed. At 6 months of age each animal was examined by necropsy, at which time the brain was removed and subdivisions were distributed to scientists who studied specific regions for gross and microscopic anatomy at light and electron microscopic levels. Finally, neurochemical analyses were made of comparable brain regions. The active research phase of this project reached completion with the necropsy of the last macaque offspring in June 1986.

This paper outlines the experimental design, the methods of dosing and assessing the dams, as well as the results that relate ethanol dose levels to gestational outcome. The results in terms of infant development and postmortem findings are being analyzed and will be reported in forthcoming articles.

MATERIALS AND METHODS

Fifty-four adult female pig-tailed macaques (*Macaca nemestrina*) were selected for this project from the breeding colony of the Regional Primate Research Center at the University of Washington. The criteria for selection included good health (normal physical exam, stable weight, normal complete blood count, normal urinalysis, normal serum chemical screen), age between 5 and 15 years, a history of producing at least one viable infant in the previous 2 years, and no unusual history of negative pregnancy outcomes (spontaneous abortions, stillbirths, or early neonatal deaths). These females were classified as low-risk breeders within the colony. The sires came from a group of 26 equally healthy males whose weights were within 1 standard deviation of the mean weight for age of male pig-tailed macaques and who had no evidence of high-risk breeding histories.

Females were mated at the inception of detumescence of the vulvar tissues, the time in their menstrual cycle associated with peak fertility. A laparoscopy procedure was performed within 36 hours of breeding to observe a corpus luteum and confirm ovulation. The laparoscope was inserted through a small incision in the abdominal wall after the animal was anesthetized with intramuscular ketamine, 10 mg/kg. The procedure was generally accomplished in 10 to 20 minutes, and the animal was usually fully alert after 1 hour.

When ovulation was positive, a random assignment to an ethanol dose cohort was given, and the animal began its weekly receipt of ethanol or control solution. Dosing was performed on all animals on the same day of the week. Upon confirmation of ovulation, the pregnant animal was dosed on the next day of the week set aside for dosing. As a result, all animals received their first dose within the first 10 days of gestation.

In our colony, pregnancy is confirmed by uterine palpation at 30 days' gestation. If palpation for pregnancy was negative 30 days after possible conception the mating was declared a failure—the female had either not become pregnant or there had been a direct or indirect embryotoxic event. Animals that were pregnant by palpation at 30 days were maintained in their dose cohort until a birth or spontaneous abortion occurred. Whenever a female was rebred for the project she was randomly assigned to a different dosing cohort. Female animals were removed from the breeding pool after a maximum of four negative palpations at 30 days' presumed gestation or after two positive pregnancies.

The ethanol doses were selected to produce PPECs in a range equivalent to the human range of light social drinking (20–50 mg/dl ethanol) to very heavy binge consumption (up to 600 mg/dl ethanol). Doses included 0.0, 0.3, 0.6, 1.2, 1.8, 2.5, 3.3, and 4.1 g/kg ethanol. The alcohol was diluted by volume in four parts water. A sucrose solution which was isocaloric and isovolemic to the highest ethanol dosage was given to animals assigned to the 0.0 dose group.

The initial study design proposed that breeding, cohort assignment, and dosing would continue until at least seven confirmed pregnancies were followed in each cohort. It was apparent from the outset that ethanol exposure initiated within the 1st week of gestation might interfere with conception or implantation or might be so highly embryotoxic as to significantly decrease the number of confirmed pregnancies in a cohort. We were therefore prepared to shift the dosage schedule and initiate dosing *after* the confirmation of pregnancy at 30 days gestation in any cohort found to be depleted by the early dosing. This procedure was necessary at and above the 2.5 g/kg dose. Animals treated only after confirmation of pregnancy are referred to as "delayed-dose animals," and a "d" is placed after their doses in the text and tables.

The day before each dosing session the animals were weighed, and the volume of ethanol or sucrose solution was calculated. The animals were denied access to food after 5 p.m., and a 24-hour fast commenced in preparation for dosing the following morning. On the morning of the dosing day each animal was brought unsedated from its cage and examined. The resting pulse was recorded, and the uterine height was measured. The dose of ethanol or sucrose was then slowly and carefully delivered over a 5-minute period through a soft nasogastric catheter (size 8, French). After dosing, the animal was returned to its cage and observed periodically. Food was reintroduced at 5 p.m. on that day.

Once every 8 weeks the dosing procedure was followed by a series of blood samples drawn by femoral venipuncture to determine the course of change in ethanol concentration. This was done by recapturing the unsedated animal periodically over a period of time sufficient to allow detection of the ascending and initial descending phases of the ethanol disposition curve. In the animals given 0.3 or 0.6 g/kg of ethanol, blood samples were obtained at intervals of 2, 10, 30, 60, and 150 minutes after dosing. In the animals given 1.2, 1.8, or 2.5 g/kg of ethanol, the blood samples were obtained at intervals of 30, 90, 120, 150, and 210 minutes after dosing. In the animals receiving the 3.3 or 4.1 g/kg ethanol doses, the blood samples were obtained at intervals of 30, 90, 120, 150, and 300 minutes after dosing. The timing of the samples was calculated so that the PPEC could be reasonably well gauged without undue stress from handling the animals. Samples were obtained over sufficient time after the period of peak ethanol concentration such that the remainder of the curve could be simulated by the MKMODEL program (Holford, '81) on the Prophet computer system (Bio-

technology Resources Program, '82). The computer simulation generated plasma ethanol concentrations at 9-minute intervals by using the following Michaelis-Menten equation (Kalhorn et al. '86a):

$$dC/dt = C_0 - [(Vmax\ C)/(Km + C)]$$

where C is the ethanol concentration at time t, Vmax is the maximum velocity of elimination, and Km is the apparent in vivo Michaelis-Menten constant. C_0 is the concentration at time zero, which in our analysis was the last measured plasma ethanol concentration in the elimination phase of each trimester ethanol curve. It is from this point in time that the subsequent course of ethanol elimination was projected by the Michaelis-Menton model. Km and Vmax values were set at 6.5 mg% and 24.8 mg%/hr, respectively. These parameter values were obtained in a pharmacokinetic study of ethanol elimination after intravenous administration to 11 *Macaca nemestrina* (Kalhorn et al., '86a). It was additionally known that the ethanol disposition curve following administration of 0.6 g/kg ethanol in the oral/fasting condition was very similar to that following the same dose in the intravenous/fasting condition (Kalhorn et al., '86b).

The blood samples (1.0 ml) were mixed with ethylenediamine tetraacetic acid (EDTA) and chilled on ice. Within 1 hour, the plasma from each sample was transferred to a 0.5-ml microcentrifuge tube and stored at − 70°C. Ethanol levels were determined from those samples by gas chromatography (Kalhorn et al., '86a) within 6 weeks of acquisition.

The animals were housed in individual cages adjacent to compatible animals in rooms with a general low level of activity. These placements served to minimize stress. The animals were fed 40 biscuits of Purina Monkey Chow daily, supplemented occasionally with a wedge of apple. Leftover biscuits were counted each morning to monitor food intake. As noted above, the biscuits were removed from the animals' cages at 5 p.m. the day prior to dosing, and food was not reintroduced until 5 p.m. on the dosing day. Even minimal food consumption can greatly influence PPEC (Kalhorn et al., '86b), and our procedure permitted the alcohol to be fully absorbed on an empty stomach. Only two animals ever became finicky eaters and decreased their normal food intake significantly over a day or two which was unrelated to dosing and was not accompanied by other signs of illness. These animals' diets were supplemented with a high-calorie supplement (Nutri-cal, Evsco Pharmaceuticals) until usual intake was restored.

When the animals were within 15 days of their estimated date of delivery, they were transferred to a labor and delivery suite where they were monitored for signs of labor every 30 minutes around the clock by closed-circuit television. When signs of active labor were observed, a member of the delivery team was called to attend the birth.

In animals exposed to alcohol from the 1st week of gestation, a decision to perform a caesarian section was made if the fetus maintained a consistent breech position after 160 days' gestation or if the pregnancy went beyond 180 days' gestation without any signs of labor. Caesarian sections were performed on all animals exposed to the very high doses (3.3d or 4.1d g/kg) to minimize perinatal loss in this very high risk group.

Pregnancy outcomes were classified as follows:

1) *Thirty-day pregnancy failure.* A corpus luteum was seen by laparoscopy within 36 hours of mating, but a negative palpation was recorded at 30 days' gestation. This could represent a failure in conception, an early embryotoxic event, or an implantation failure.

2) *Spontaneous abortion.* Any spontaneous termination of pregnancy from 30 days' confirmed gestation to 160 days' gestation.

3) *Stillbirth.* Delivery of a nonviable fetus after 160 days' gestation (In this study stillbirth was always associated with breech position).

4) *Viable infant.* Delivery of an infant with sustained cardiorespiratory function.

RESULTS

One hundred sixteen matings in 54 females were followed by a positive laparoscopy result. Thirty-day pregnancy failure did increase with increasing alcohol dose (Table 1). These rates for pregnancy failure in control and delayed-dose animals 30 days after possible conception are comparable to overall colony figures for pregnancy failure (50%) based on more than 1,000 timed matings. The pregnancy failure rates among animals

[1]Delayed dose, i.e., no exposure to alcohol in the first 30 days of gestation.
*P = .002 (binomial test).

receiving between 0.3 g/kg of alcohol and 1.8 g/kg of alcohol varied from 36% to 67%. These rates were not statistically different from the study control cases by binomial analysis. At the 2.5 g/kg dose, however, five of six animals (83%) had pregnancy failure. Although this rate was not statistically significant, it was higher than the rate at any lower dose and may be clinically relevant. At the 4.1 g/kg dose, 100% of the pregnancies failed, and this was significantly different from the study control group rate (P = .008, binomial test).

The abortion rate among low-risk, breeding, colony-born, single-caged *M. nemestrina* in the colony as a whole is 12–13% (Sackett, '86). The rate of spontaneous abortion increased to 33% at the 1.8 g/kg dose (Table 2). The only animal to become pregnant at the 2.5 g/kg dose also aborted. Among the animals in which ethanol exposure was initiated after 30 days' gestation, a significant increase in miscarriage rate to 43% occurred at the 4.1 d g/kg dose compared to controls, notwithstanding the small sample size (P = .002, binomial test).

Thirty-six animals carried infants to term: 25 delivered vaginally and 11 delivered by caesarian section. Three vaginal deliveries were complicated by unexpected breech positioning and stillbirth. One infant in breech position died in spite of an attempt to salvage it by caesarian section. One of the stillborns had been exposed to the control solution, while another was exposed to the 1.2 g/kg dosage, and two were exposed to the 1.8 g/kg dosage (Table 2). This rate of fetal loss from breech positioning (4/46 = 9%) is comparable to the overall colony rate of 6% in low-risk macaques (Goodlin and Sackett, '83). Thus, there was no evidence that the alcohol exposure changed the rate of breech positioning or stillbirth owing to breech positioning. Indications for caesarian section were randomly distributed as one or two pregnancies in all cohorts except the 0.6 g/kg and 1.8 g/

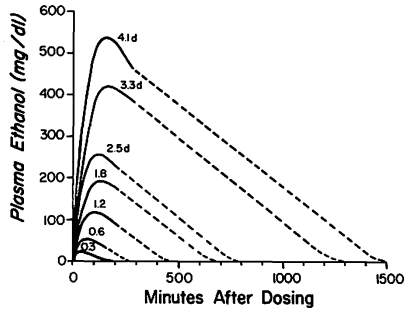

Fig. 1. An ethanol metabolism curve is displayed for each cohort. The numbers next to each curve signify the oral dose in g/kg. The solid portion of each curve represents the fit of observed plasma ethanol concentration within each cohort to the following exponential equation: $f(t) = A(e^{-tT_1} - e^{-tT_2})$, where A = plasma ethanol constant, T_1 = time constant −0.0083, and T_2 = time constant −0.02 (U.S. DHHS, '80). The dotted continuation of each curve is the computer-stimulated elimination phase based on the Michaelis-Menten equation: $dC/dt = C_0 - [(Vmax\ C)/(Km + C)]$.

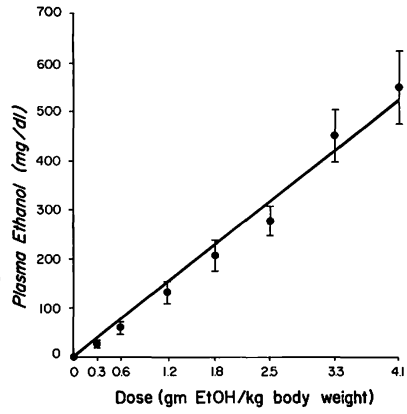

Fig. 2. The mean peak plasma ethanol concentrations with ± 1 standard deivation relate linearly to the ethanol doses. The number of animals studied in each cohort ranged from 4 to 8 with 6 to 16 individual ethanol curves used to calculate each mean and standard deviation.

kg cohorts, in which all births were vaginal, and the 3.3d g/kg and 4.1d g/kg cohorts, in which all four animals were purposefully delivered by section.

The average gestational length was 174 ± 9.3 days in controls and 172 ± 6.8 days in the experimentals pregnancies. The lack of significant differences at any dose (the norm for the colony as a whole was 171 ± 12 days) (Sackett et al., '75) indicated that ethanol exposure had no adverse impact on gestational duration. Neither did alcohol affect the usual nocturnal timing of labor.

The genetic background and physical condition of the animals did not appear to affect the distribution of pregnancy failures or abortions when examined independently of ethanol exposure. Twenty-three animals were bred once, 12 animals were bred twice, 13 were bred three times, and six were bred four times. Each multiply-bred animal was randomly assigned to a different dose cohort with each pregnancy. The distribution of possible pregnancy outcomes among animals with like-study parity was within an anticipated random distribution.

There were no consistent variations in the ethanol disposition curves of animals across the three trimesters. Moderate fluctuations in PPEC occurred in both directions over time. Such fluctuations were expected (Kalhorn et al., '86b).

Because stress may lower PPEC (Kalhorn et al., '86b), it was thought possible that our animals' PPECs could have been decreased through the handling involved in drawing the blood samples. Kalhorn has reported that animals receiving 0.6 g/kg ethanol orally had PPECs of 63 ± 12 mg/dl when nonstressed and 45 ± 6 mg/dl when stressed. The PPECs in our 0.6 g/kg cohort were 59 ± 13 mg/dl—essentially the same as in Kalhorn's fasted nonstressed animals.

The plasma ethanol concentrations for all animals within each cohort were plotted to produce an ethanol disposition curve that represented each dose cohort (Fig. 1). The area under each curve represents the "relative exposure" to ethanol. The mean PPEC at each dose level is displayed in Figure 2. The mean PPEC increased linearly with dose; the range of PPECs of most adjacent cohorts overlapped at the extremes. Unlike PPEC, the "relative exposure" to ethanol increased exponentially with increasing dose (Fig. 3).

The variation of PPEC within each cohort was examined in order to determine if ani-

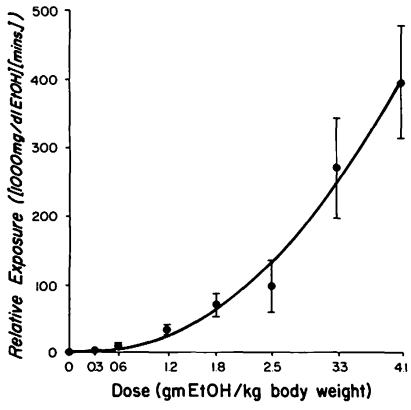

Fig. 3. The mean "relative exposure" to ethanol with ± 1 standard deviation relate exponentially to the ethanol doses.

mals that aborted had the highest PPECs within their dose-cohort. This analysis demonstrated that the abortions were randomly distributed within each group.

The medical records and feeding charts of the dams with pregnancy failures or abortions were examined for evidence of possible etiologic factors other than alcohol exposure. The general health of the dams was excellent, and illness was rare.

All of the animals that received the 4.1d g/kg dose markedly decreased their biscuit consumption on dosing days. Because of the caloric value of the ethanol, however, their overall caloric intake decreased by only 14% on those days, and the animals showed normal pregnancy weight gains.

It was not apparent that exposure to ethanol in any specific pattern of gestational days correlated with pregnancy failure. Animals dosed on gestational days 2, 9, 16, etc., 4, 11, 18, etc., or 7, 14, 21, etc., were all equally likely to have pregnancy failure or success.

The stress of the dosing procedure per se was examined by comparing the 30-day pregnancy-failure rate of the sucrose control animals with that of the delayed-dose animals who experienced no experimental handling until the confirmation of pregnancy. As reported above, pregnancy failures were the same in the two groups (50% vs. 52%), suggesting that the procedure did not induce conceptional difficulty.

At the lower doses of ethanol (0.3–1.2 g/kg), no behavioral change was apparent in the dams after administration. In the intermediate doses (1.8 and 2.5 g/kg), the animals became somewhat quieted, while the animals in the highest dose cohorts (3.3d and 4.1d g/kg) became ataxic, somnolent, and disoriented. One animal in the 3.3d g/kg cohort showed signs of nausea on one occasion. No animal ever became comatose.

DISCUSSION

Two groups of investigators have previously published reports of their efforts in developing primate models for studying ethanol teratogenicity. Altshuler and Shippenberg ('81) maintained constant (24 hour) plasma ethanol concentrations in pregnant rhesus monkeys (*Macaca mulatta*) by using permanent intragastric cannulae. They found that control animals and two animals with blood ethanol concentrations in the 75–100 mg/dl range carried fetuses to term, while two animals with blood ethanol concentrations in the 150 mg/dl range aborted. Jacobsen and coworkers ('80) used the long-tailed macaque (*Macaca fascicularis*) in a project designed to assess teratogenesis by maintaining constant blood ethanol levels with administration through permanent intravenous catheters. Unfortunately, high abortion rates and technical difficulties terminated the study. Jacobsen then trained 15 nonpregnant female animals to consume a diet including ethanol. Four of these females became pregnant and continued to drink. One of the fetuses aborted, one infant was growth retarded and possibly dysmorphic, and two infants were phenotypically normal. The blood ethanol levels were in the 20–50 mg/dl range when measured, but given the methodology, PPEC could not be reliabily or consistently obtained.

In our study we wished to use a dosing sequence that more closely modeled the typical human experience. Humans do not maintain constant plasma ethanol levels. Even the most chronic alcoholics drink intermittently within and across days. Thus we selected an oral rather than venous route of dose administration and a weekly exposure pattern similar to human "Saturday night

TABLE 3. Ethanol dose or alcohol beverage consumption[1]

PPEC	Oral dose ethanol (g/kg)		Equivalent liquor doses (fl oz) in 55-kg women		
(mg/dl)	Macaque	Human[2]	Whiskey[3]	Wine[4]	Beer[5]
24	0.3	0.2	1	3	8
59	0.6	0.4	2	6	16
130	1.2	1.0	5	15	39
205	1.8	1.5	7	23	59

549	4.1	4.1	19	63	161

[1]Required to attain peak plasma ethanol concentrations (PPECs) in human females equivalent to those obtained in pigtailed macaques.
[2]Calculated from formula: predicted PPEC(mg/dl) = 133.8 × Etoh dose (g/kg) (Dubowski, '76).
[3]Ethanol 50% by volume, 12 g/30 ml ethanol.
[4]Ethanol 15% by volume, 3.6 g/30 ml ethanol.
[5]Ethanol 6% by volume, 1.4 g/30 ml ethanol.

drinking." The dosing paradigm produced viable infants through the range of PPECs likely to be achieved in humans.

This report focuses on the study's experimental design, methodology of the prenatal phase, and the pregnancy outcomes. Ethanol was found to increase fetal loss independent of potentially confounding factors such as nutrition, stress, illness, or genetic background. When ethanol exposure began in the first 10 days of gestation there was an increased abortion rate at the 1.8 g/kg dose (PPEC = 205 mg/dl), and above the 1.8 g/kg dose, the pregnancy failure rate became nearly 100%. When ethanol exposure began in the 5th week of gestation there was a statistically significant abortifacient effect at 4.1 g/kg (PPEC = 550 mg/dl).

A follow-up study will be needed with larger animal numbers and more dose cohorts to fully establish if there is a threshold dose or a graded dose response for the fetotoxic effects of oral ethanol. Still, it is reasonable to assume that this effect from weekly alcohol exposure occurs only well above a PPEC of 100 mg/dl, the legal limit of intoxication in humans. In further relating these findings to women, several questions arise. Does the primate fetus experience the same ethanol exposure as its mother? Is macaque ethanol absorption and elimination comparable to human ethanol disposition? Is there evidence to corroborate that ethanol is fetotoxic in humans?

The maternal nonhuman primate PPEC has been found to be comparable to the fetal PPEC through gestation (Hill et al., 1983; Bowden, unpublished observations). Comparable ethanol levels are found in the mother and fetal units, although ethanol elimination is primarily done by the maternal liver.

Formulas have been developed that predict PPEC from the volume of ethanol ingested in humans. By using such a formula (Dubowski, '76), one can estimate the ethanol doses that a typical 55-kg woman would need to ingest to achieve PPECs comparable to those attained by the cohorts in this study (Table 3). The predicted dose estimates for human females are about one-third less than for macaque females at the lower PPEC levels and become equivalent with increasing PPEC. The calculated human doses of ethanol can be converted to fluid ounces of whiskey, wine, and beer (Table 3). Thus, to achieve a PPEC of 205 mg/dl, the PPEC level at which nonhuman primates in this study experienced an increased rate of spontaneous abortion, the average human female would need to consume seven standard drinks (7 fl oz hard liquor, 23 fl oz wine, or 69 fl oz beer) on a weekly basis. Such heavy intermittent alcohol consumption is not uncommon. A recent national survey measuring the drinking patterns of American women found that 2.7% of interviewees regularly drank six or more drinks once or twice per week (Wilsnack et al., '84).

Obviously, while the equivalences presented in Table 3 may be applicable to average macaque and human females, they cannot be applied directly to specific individuals. For example, the range of individual differences in the coefficient for estimating the dose required to produce a given PPEC in human females is more than ± 16% of the mean (Dubowski, '76). Thus, if an alcohol-tolerant human female achieves a PPEC of 205 mg/dl from 7 oz of whiskey, a few women may achieve that blood level at a dose of about 5 oz and a few may require 9 ounces. Other factors such as body weight, gastric contents, and stress, exert considerable influence on the PPEC achieved by a given oral dose (Kalhorn et al., '86b). Nevertheless, our data in nonhuman primates supports other data that suggest that women who drink to levels of marked intoxication on a weekly basis increase their risk of abortion.

The conversions presented in Table 3 can be quite useful in comparing findings from this animal model with the results of epidemiological studies that have aimed at determining levels of alcohol consumption that

may affect spontaneous abortion rates in the human. In a prospective study of 1,200 pregnancies, Sokol et al. ('86) reported an increase in abortions among "heavy drinking" women but did not clarify the specific consumption levels. Kline et al. ('80) reported a case-control study comparing the drinking histories of 616 women who aborted spontaneously with 632 women who carried their pregnancies to at least 28 weeks' gestation. The data suggested that a mean of two standard drinks twice weekly was the minimum threshold for producing an abortion. Harlap and Shiono ('80) prospectively assessed 32,000 pregnancies and reported a doubling of spontaneous abortions in the second trimester for women drinking one to two standard drinks per day on average.

In both of the latter quantitative studies, average alcohol scores were derived by estimating weekly consumption in terms of fluid ounces of absolute alcohol and then dividing by seven to obtain an average daily ethanol consumption in ounces/day (Jessor et al., '68).

The majority of macaques that aborted had mean PPECs above 200 mg/dl. An average human female would achieve a comparable PPEC by consuming five to nine standard drinks containing a total of 2.5 to 4.5 oz of absolute ethanol (Table 3). Such a weekly drinking pattern can be converted to an average alcohol score of 0.4 oz/day to 0.6 oz/day. This is similar to average alcohol scores that can be derived from Harlap and Shiono ('80) and from Kline et al. ('80), which placed the threshold for increased spontaneous abortions in humans at 0.5 oz/day and 0.3 oz/day, respectively.

The magnitude of fetal exposure to an environmental agent and the sequence or number of exposures are both potentially important factors in teratogenesis. The average alcohol score is one attempt at expressing the interaction of amplitude and frequency in ethanol exposure. While the conversion of a weekly consumption amount to an average daily consumption score produces reasonable agreement in the consumption threshold for spontaneous abortion and ethanol exposure between human and nonhuman primates, it raises a new question. Are all dosing patterns that produce an average daily exposure of the same magnitude equally abortifacient, or are some exposure patterns more likely fetotoxic than others?

One reason to suspect that a single large intermittent dose is more detrimental than the same dose distributed over time is seen in Figure 3, where relative exposure is observed to increase exponentially with dose. This reflects the fact that larger doses not only produce higher peak blood concentrations but require longer time periods to clear and thus extend the duration of exposure to ethanol following ingestion of a given amount. Although 1 oz of absolute alcohol consumed daily yields the same average alcohol score as 7 oz of absolute alcohol consumed once weekly, the relative exposure is considerably larger from the single seven-ounce dose than the total of seven one-ounce doses.

Further study needs to be done with the macaque model to determine whether PPEC or relative exposure is a better predictor of prenatal effects. In the meantime, the results of this study suggest that human epidemiological studies may benefit from focusing attention on models that measure total fetal exposure rather than average daily exposures.

We anticipate teratogenic outcomes from in utero ethanol exposure in the liveborn macaques. These problems may not be found to occur at the same exposures as those related to fetal loss. We shall report the outcome of the liveborn infants' development, phenotype, and anatomy as the data analyses are completed.

ACKNOWLEDGMENTS

We wish to thank Jeff Rockey and the entire staff of the Regional Primate Research Center's Field Station at Medical Lake, Washington for their help in selecting and mating the adult animals, William Morton, D.V.M., for monitoring the animals' health and performing the caesarian sections, and the staff at the Infant Primate Research Laboratory for monitoring the animals' labors and assisting with deliveries. We also thank Sarah Phillips for her help in preparing the manuscript.

Physical Anomalies and Developmental Delays in Nonhuman Primate Infants Exposed to Weekly Doses of Ethanol During Gestation

STERLING K. CLARREN, SUSAN J. ASTLEY, AND DOUGLAS M. BOWDEN

ABSTRACT Ethanol was orally administered once per week to 54 gravid pigtailed macaques (*Macaca nemestrina*) in doses of 0.0, 0.3, 0.6, 1.2, 1.8, 2.5 or 4.1 gm/kg from the 1st week in gestation or in doses of 2.5, 3.3, or 4.1 gm/kg from the 5th week. Mean maternal mean peak plasma ethanol concentrations (MPPEC) ranged from 24 ± 6 mg/dl at the 0.3 gm/kg dose to 549 ± 71 mg/dl at the 4.1 gm/kg dose. Thirty-three viable infants were followed from birth to 6 months of age and assessed for growth, health, congenital anomalies and developmental rate. Facial anomalies, growth deficiency, or central nervous system dysfunction were found in 57% of the alcohol-exposed animals. No animal showed all the features of the human fetal alcohol syndrome. Ten of the twelve animals (83%) with mean MPPEC above 140 mg/dl had evidence of a teratogenic impact. The animals with full gestational exposure to ethanol and mean MPPEC between 140 and 249 mg/dl had much more severe and consistent cognitive abnormalities than the animals with delayed gestational exposures, even though the latter were exposed to mean MPPEC between 260 and 540 mg/dl. Conclusions from this study included: 1) ethanol-related behavioral teratogenesis occurred without accompanying physical anomalies, 2) measurable teratogenic effects from *weekly* exposures occurred only at intoxicating doses of ethanol, and 3) early gestational exposure to ethanol appeared to be more damaging to cognitive function than later and considerably greater alcohol exposure.

Central nervous system dysfunction is the most frequent and most severe teratogenic result of intrauterine ethanol exposure (Clarren and Smith, '78). Decreased cognitive ability, distractibility, and hyperactivity have all been frequently observed in children with fetal alcohol syndrome. Intellectual deficits without structural birth defects in other organ systems are observed more frequently in children exposed to ethanol during gestation than in those not exposed (Streissguth et al., '84). Extensive studies in animals, especially rats, confirm the behavioral teratogenicity of ethanol (Bond, '86; Riley et al., '86). There is little useful information available yet, however, concerning the fetal margins of safety in ethanol dosage or exposure pattern. In humans, this lack of information stems from problems in inaccurate reporting of exposure, marked variability in individual drinking patterns leading to artificial averaging of exposures, and difficulty in confident detection of behavioral fetal alcohol effects. Dose-response extrapolation from rodents to humans becomes problematic because small laboratory animals metabolize ethanol differently than primates, have less prenatal brain development, and have a

lower cognitive potential. This study was undertaken as a first step in correlating developmental dysfunction and gestational ethanol exposure in a nonhuman primate (*M. nemestrina*) using a once per week exposure model.

METHODS

A total of 33 liveborn infant macaques were assessed in this project. The methods of managing their pregnancies have been fully reported previously (Clarren et al., '87). Initially it had been planned that each infant would be exposed to ethanol once weekly from the 1st week after its conception until birth about 24 wk later. Dosing was performed on all animals on the same day of the week at 9 A.M. following a 16 hr fast. Maternal dose cohorts were established with ethanol exposures of 0.0, 0.3, 0.6, 1.2, 1.8, 2.5, 3.3, and 4.1 gm/kg. Ethanol was diluted by volume in four parts water and administered via a soft nasogastric catheter. (The 0.0 animals received a sucrose solution that was isocaloric and isovolemic to the highest dose of ethanol and delivered in the same manner.) The dams' plasma ethanol disposition curves were determined in each trimester as previously described (Clarren et al., '87). The mean maternal peak plasma ethanol concentration (MPPEC) of each mother was derived from the three determinations in each animal.

As the study progressed, it became clear that ethanol exposures administered from the 1st week in gestation in doses of 2.5 gm/kg or more (MPPEC 250 mg/dl) were sufficiently toxic so as to preclude an adequate number of viable infant subjects. Consequently, a two-group study was developed: animals dosed at the 1.8 gm/kg level and below received weekly doses from the beginning of pregnancy (subsequently referred to as the full gestation exposure group, or FGE), and animals receiving the 2.5 gm/kg dose or more received their 1st weekly ethanol dose 33 to 46 days postconception (delayed gestation exposure group, or DGE).

Three weeks prior to an expected delivery date, the pregnant dam was transferred to the maternity suite of the Infant Primate Research Laboratory. The maternity suite was a 24 hr care facility where pregnancy and labor were monitored each one-half hour, around the clock, via closed circuit television using an infrared camera to avoid disrupting the animals' normal light/dark cycle. When labor was observed, the obstetrical team was summoned. After the infant was delivered, the mother was sedated with an intramuscular injection of ketamine (10 mg/kg), and the infant and placenta were removed, weighed and examined.

When an infant was to be delivered by caesarian section, the dam was removed to the operating room prior to onset of labor and the procedure was performed under halothane anesthesia by a staff veterinarian. The procedure took approximately 30 min.

Among the FGE animals, 22 had normal, spontaneous vaginal deliveries while five required caesarian section because of persistent fetal breech position or prolonged pregnancy. For five of the six DGE infants, caesarian sections were conducted as a matter of protocol at about 160 days gestation, slightly earlier than a mean term gestation, in order to minimize the risk of perinatal loss in this high exposure and potentially higher risk group. Since the DGE animals were born slightly earlier than the other infants, all test outcomes that were measured as age to criterion were analyzed both in terms of postconceptional age and postnatal age.

The newborn infant exam included ascertaining the simian Apgar score 5 and 10 min following delivery. Assessments included in the Apgar score were the respiratory rate, heart rate, muscle tone, behavioral state, skin coloration, and rectal temperature. These scores were solely used for neonatal monitoring since they were influenced by the maternal sedation. Additionally, the infants were assessed for rooting, sucking, grasping, eyeblink, and righting reflexes. Birthweight was recorded and the infant was placed in an isolette under 24 hr care in the newborn suite. All subsequent testing was done by examiners blind to the gestational ethanol exposures.

The morning after delivery, a more thorough physical examination of the infant was performed. Specific observations included body proportions, pigmentation, head molding, fontanelle size, overriding sutures, facial symmetry, and tooth eruption. Thereafter the animals were weighed and measured at regular intervals. Health was assessed daily. Food intake, sudden changes in weight, diarrhea, or other signs of ill

health were noted. In addition, the infants were carefully scrutinized for major and minor anomalies by a dysmorphologist (SKC).

Computerized medical records were maintained on each infant by the full-time veterinary staff and included information on gestation, body weight, housing, hematology, blood chemistry, and virology.

The feeding schedule for each infant proceeded from a 50% human formula (SMA, Wyeth Laboratories, Philadelphia, PA) and water in a hand-held bottle through a series of self-feeding challenges to total weaning at about 17 postnatal wk. The housing schedule proceeded from isolette through temperature regulation challenges to housing in an individual cage in a large general infant housing suite. The animals were housed with parental surrogates (diapers) until 140 postnatal days of age, and had a daily social experience with groups of like-aged peers in the playroom.

Postnatal growth was followed by obtaining specific anthropometric measures at birth 173, 187, 215, 243, 271, 299 and 355 days after conception (typical gestation being 160 ± 12 days) (Sackett et al., '75). The measures included left foot and crown-rump length, head length and width and head circumference, which was measured above the ears and below the supraorbital ridge. Two independent measures were recorded to the nearest millimeter for each parameter and the mean value used for analysis. At 1 and 6 months of age, standard frontal and lateral cephalometric radiographs and photographs were obtained.

Six infant developmental/behavioral measures were employed. Assessments requiring subjective ranking of behavior and/or performance were conducted by testers for whom inter- and intra-observer reliability was high. All testers were blind to the infants' cohort status.

Neonatal reflex assessments included noting resistance to passive movement of limbs, the strength of grasping, and rooting, sucking, and snouting reflexes; observing the infant's auditory startle response, visual orientation and tracking, the onset of species-specific facial expressions; testing the leg and arm placing reflex, and the clasping and righting reflexes. Each measure was recorded on a six-point ordinal scale. Each exam took approximately 10 min and was performed every other day from birth to 2 wk of age (Infant Primate Research Laboratory, '86; Mowbray and Cadell, '62).

Nutritive sucking capability was measured using a procedure developed by Kron et al. ('63) which has been successfully applied to macaque neonates by Burbacher ('83). Each infant was tested daily from birth through 9 days of age using an apparatus that consisted of a graduated cylinder filled with nutritive liquid. The cylinder was attached through capillary tubing to a nipple that could deliver a consistent flow of the liquid at a constant pressure. Pressure changes were measured by a pressure transducer which was attached to the tubing and connected to a four-channel polygraph. Measures included the age when the infant was first able to suck, the total number of sucks per session, and mean length, amplitude and velocity of each suck.

The *object permanence assessment* documented the development of object permanence conceptualization in the infant macaque from 2 to 16 wk (Redshaw, '78; Williams, '79). The assessment, based on the procedure developed by Piaget for human infants (Flavell, '77), was as follows:

At 2 wk of age, the infant was held by one tester as a second tester presented the infant with one of four tasks. The first task required the infant to reach and grasp an object within plain view. The second and third tasks required the infant to locate and retrieve an object partially and fully hidden from view behind a screen and within a small well. The fourth task required the infant to locate the object placed in one of two covered wells. In all cases, the infant watched the tester hide the object. The infant was allowed 15 sec to respond to each trial. The infant had to reach criterion in task one prior to advancing to the second and third tasks, which were run simultaneously. Criterion had to be reached on both tasks two and three prior to advancement to task four. Testing was performed twice weekly and was scored in three ways: postconceptional age, postnatal age and the number of test sessions to criterion.

The *Wisconsin General Testing Apparatus* (WGTA) was used to measure early infant learning strategies (Harlow, '59). The WGTA was administered 5 days per wk between 4 and 6 months of age postnatally. It provided a measure of an infant's ability to form a systematic pattern of responses

while searching for a reward hidden under colored blocks or within boxes. The infant was placed in a special cage which allowed him access to the testing apparatus without viewing the tester. An opaque barrier prevented the infant from observing stimulus changes between trials. The tester could view the infant through a one-way mirror. The WGTA assessment was comprised of nine individually scored tasks. The infant was adapted to the task of retrieving an apple bit from a food well covered by a small yellow block. Adaptation progressed in three stages as the infant learned to retrieve the apple bit from an uncovered well, a half-covered well and finally, a well completely covered by the yellow block. Upon adaptation, the infant progressed to black/white discrimination. The infant was presented with two blocks, one black and one white, each covering a food well. The infant first had to learn that the reward was always under the black block and then reverse his pattern and learn to retrieve it from under the white block.

Upon mastering this task, the infant proceeded to Hamilton Search activities. Prior to testing, the infant was adapted to the task of retrieving an apple bit from a small box with a hinged lid in three stages: retrieving the bit from an open box, a half-closed box and a fully closed box. Each day the infant was presented with a task and given 25 opportunities to respond to the task. Each response had to be made within 3 min and the infant needed to reach specific criterion on each task before advancing to the next. First, the infant was presented with four closed green boxes arranged in a single row and he or she had to develop an efficient search pattern to locate and retrieve an apple bit that was randomly allocated to one of the four boxes. Next, the apple bit was placed in the box which had been selected least often by the infant and the process of 125 trials was repeated, only this time the infant was allowed to open as many boxes as was necessary to locate the reward. Finally, the infant located the reward which was again placed in the same least-favored box, but this time he or she was only allowed to open one box to locate the reward. Scores were recorded as postnatal age and number of test sessions to criterion. Response latency for each trial was also recorded.

Visual recognition memory was developed as an early measure of intelligence (Fagen, '77). Visual recognition is measured by differential fixation to novel over familiar two-dimensional abstract patterns. Preferential fixation on a novel pattern demonstrates that an infant can distinguish between two patterns and can remember a pattern previously seen. It has been hypothesized that human and nonhuman primates at risk for cognitive deficits direct less visual attention to novel stimuli than control subjects (Gunderson et al., '86). An adaptation of Fagan's novelty paradigm (Fagan, '70) was administered to the infants in this study at 190, 200 and 210 days postconception. Prior to administration of this assessment, visual acuity was examined on all infants and found to be within normal bounds. The visual stimuli used in the novelty paradigm were high-contrast, black and white, abstract patterns. Different patterns were presented to the infant at each test session. The test patterns were back-projected onto a display board through two 9 cm square screens. The tester, holding the infant 36 cm from the stimuli, viewed the animal's face via a video monitor and recorded fixations to the right and left using timers operated by foot pedals. The tester was blind to the animal's exposure and to the stimuli presented on the screen. The infant was first presented with two identical patterns and was required to fixate on them for an accumulation of 60 sec. The animal was then presented with a two-part test trial in which the previously exposed pattern was paired with a novel one. Looking time to each pattern was recorded for 10–20 sec depending on the trial. The position of the two patterns were reversed, to control for side preferences. Looking time was recorded once again for 10–20 sec. The test was scored by comparing the proportion of time the infant looked at the novel vs. the familiar pattern. An alternate method of scoring this test was to compare the amount of time the subject looked at both images vs. neither image, in which case time spent looking away from the targets may be a measure of distractability. We evaluated the subjects both ways.

Playroom motor and behavioral observations began at 15 days of age. The infants were entered into social groups of five or six age-matched peers from the infant colony and placed in an observation playroom for 30 min of daily social interaction. The room

contained shelves at various levels, a ramp, a suspended rope and toys. Motor, postural and special communication behaviors involving the abilities to sit, stand, walk, climb and display various postures and facial expressions were observed in response to other monkeys and to various appartus in the playroom (Sackett et al., '76). The age of onset of 12 motor behaviors and three facial expressions were recorded during 5–min observation periods that occurred twice weekly on each infant. Some of the measures recorded in the playroom were continuations of Neonatal Assessments measures that were observed weekly on each infant. The playroom assessments continued until the infant reached 6 months of age.

Data analysis for each assessment was approached in two ways. First, dose-response relationships between the independent variable MPPEC and the numerous dependent variables including gestational length, growth parameters (weight, height, head circumference) and the scores of each measure on the six developmental tests were analyzed by linear regression. All variables were measured on continuous scales. In addition, comparison of dose cohort means for each dependent variable were performed with one-way ANOVA. This approach, however, could only identify very robust effects in the data set; since the power of the tests was limited by the small group sizes (dose-cohort N's = 4–6). Consequently, a second approach was employed which identified individual animals with delayed performance for each dependent variable. Delayed individuals were detected by transforming each infant's raw score into a normally standardized z score. Delayed individuals were defined as those infants with measured scores greater than 2.57 standard deviations (corresponding to a 99% confidence interval) from the overall mean of the unexposed infants. The tests were scored and the decision made to define an animal as delayed without knowledge of subject exposure. Some individual animals were found to be significantly delayed on nearly every measure.

RESULTS

Figure 1 summarizes all abnormalities of growth, morphology, health, and development as described in the paragraphs below.

Fetal growth and duration of gestation

Animal 33 was the only growth retarded animal and the only liveborn infant in the 4.1 gm/kg DGE dose group (MPPEC = 539 mg/dl). When compared to all exposed and non-exposed male infants in the study, animal 33 had the lowest prenatal and postnatal growth rates and the lowest birthweight. Its postnatal weight gain profile paralleled the age and sex matched growth curve for the colony but measured 160 gm below the curve. Furthermore, animal 33 was the only microcephalic infant in the sample with a head circumference below the 99% confidence interval at birth and at 6 months. The microcephaly was proportionate to body weight. There was no detectable relation-

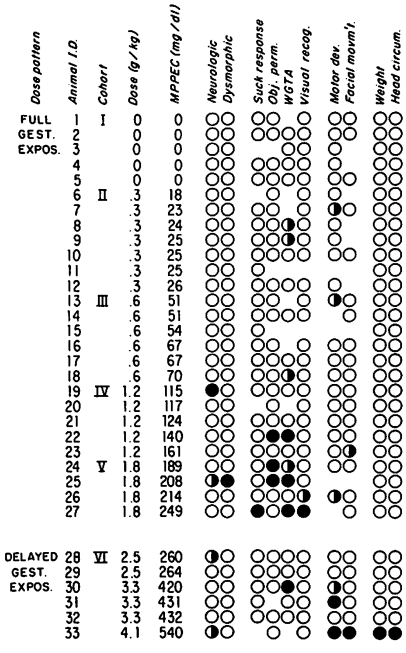

Fig. 1. Individual deviations on developmental and growth measures are compared in infant macaques exposed to ethanol in utero. ● indicates extreme deviations from control means, while ◑ indicates definite but less extreme deviations. Definitions for deviations in each column are found under "Results." Absent circles indicate missing or incomplete data.

TABLE 1. Minor dysmorphic features in animals exposed to alcohol once per week in gestation

Dose group	Animal	Mean MPPEC[1]	Dysmorphia
FGE	12	26	Ptosis
FGE	13	51	Floppy ears
FGE	21	124	Dental anomalies (upper incisors)
FGE	25	208	Flattened philtrum Dental anomalies (upper incisors) Flattened maxilla
DGE	32	432	Unusual auricles Metopic synostosis

[1]MPPEC = maternal peak plasma ethanol concentration.

ship between birth weight, birth length or head circumference and ethanol exposure among the other 32 animals.

A linear regression analysis of postconceptional age for tooth eruption demonstrated a significant dose response for early eruption of each of the four canines with increasing ethanol exposure through the FGE and DGE groups. Ethanol exposure explained 19–24% of the variance in the timing of eruption of each canine (all four *P*-values were $< .01$). The dental eruption was accelerated by 2 to 8 wk relative to controls. Other primary teeth did not show this precocity.

There was no association between duration of gestation and ethanol dose in non-c-sectioned FGE animals. Since most DGE animals were delivered by c-section at the same post-conceptional age of 160 days, it was not possible to relate exposure to their gestational duration except to say that it was in no case more than 8 days shorter than the average 168 days for animals in this study.

Congenital anomalies

No control animals had any major or minor dysmorphic features. Three FGE infants exposed to low or moderately high ethanol doses (MPPEC between 26 and 124 mg/dl) had an isolated minor anomaly (Table 1). Animal 25 (MPPEC of 208 mg/dl) had a cluster of three minor anomalies that have been typically observed in humans with fetal alcohol syndrome. One of the six DGE animals had two minor malformations that were not considered typical of ethanol teratogenesis in humans. No major malformations other than the microcephaly in animal 33 were observed in any animal, nor was a consistent pattern of minor dysmorphic features of the face or overall phenotype discerned.

Health

Three infants developed serious infectious illnesses. At 12 days of age, animal 11 (MPPEC = 25 mg/dl) developed overwhelming septicemia from coxsackie enterovirus, pseudomonas, and staphylococcus aureaus and died at 23 days of age. Animal 12 (MPPEC = 26 mg/dl) and animal 15 (MPPEC = 54 mg/dl) developed chronic diarrhea. Animal 12 survived while animal 15 expired. Infectious illnesses, especially diarrheal illnesses, are common among colony infants, but generally these illnesses are brief and self-limited. No explanation of underlying conditions which might have precipitated these deaths was found at autopsy. Immunologic studies for simean acquired immune deficiency were not being routinely obtained at the time these infants expired.

Animal 19 (MPPEC = 115 mg/dl) had four brief grand mal seizures between 115 and 133 days of life without metabolic or infectious etiology (noted on Fig. 1 as ● in the neurologic abnormality column). Three animals (25, 28 and 33) had strabismus which resolved spontaneously over several months (noted by ◑ on Fig. 1 in the neurologic abnormality column).

Development

No substantial individual deviation was found for any animal among the *neonatal reflex* assessments. All animals began to suck in the test of *nutritive sucking* on the 1st or 2nd day of life except for animal 27, who did not suck until the 5th day ($z = 2.87$) (denoted by ● in Fig. 1). This result was not associated with gestational length below the mean (168 days), nor was it associated with c-section delivery.

The *object permanence* test was scored using postnatal and postconceptional age to

criterion and number of test sessions to reach criterion. Three animals (22, 24, and 25) had consistant significant delays by all three scoring systems and these were denoted by ● in Fig. 1.

Four animals (8, 9, 18, and 24) were significantly delayed on *WGTA* in completing one or two tasks but still completed the entire set of nine tasks prior to the end of the study (denoted in Fig. 1 by ◑). Four animals (21, 25, 27, and 30) were so delayed on the initial *WGTA* tasks that they never completed the battery by the study's conclusion and were hence very significantly deviated (denoted by ● in Fig. 1).

The initial tasks of WGTA are tests of performance while the later tasks assess associative learning. The pattern of difficulty found in all eight abnormal monkeys clearly demonstrated performance difficulties. While associated learning was mildly impaired in four animals it was not tested in the other four who never reached those assessments under the confines of the testing protocol.

When the *visual recognition* test was scored in the usual manner, no animals were found to be aberrant. When the test was assessed as a measure of distractibility, two animals, 26 and 27, stood out as spending excessive time looking away from the targets, varying by more than 2.56 standard deviations from the mean of control animals for times looking away. Animal 27 was the more aberrant of the two (denoted by ● in Fig. 1, while ◑ was given to animal 26).

Among the five measures of *motor function* observed in the playroom only six animals were delayed beyond the 99% confidence interval on one or more tasks. Animals 7, 13, 26 and 30 failed one or two items (◑), while animals 31 and 33 were very deviant, failing four and five tasks respectively (denoted by ●). There were six measures of *facial movements*. One animal, 23, had significant delay on one item (denoted by ◑), and animal 33 had more than three significant delays (●).

DISCUSSION

This study was undertaken to determine the fetal effects of weekly exposure to alcohol, the most common frequent intermittent consumption pattern among American women (Wilsnack et al., '84). Our goal was to obtain data that would correlate dose with specific dysfunctional outcomes of ethanol teratogenesis.

No animal in this study showed all the features of the human fetal alcohol syndrome although facial dysmorphia, growth deficiency and central nervous system dysfunction were all found in 16 of the 28 alcohol-exposed animals. Perhaps the most significant result was the consistency with which FGE animals with MPPEC > 140 mg/dl demonstrated developmental delays, while DGE animals—who were exposed to much higher levels of ethanol after gestational wk 5—were more cognitively intact at 6 months of age.

Among the FGE animals, physical abnormalities included seizures in animal 19 (MPPEC = 115 mg/dl) and significant facial dysmorphogenesis in animal 25 (MPPEC = 208 mg/dl). Spontaneous seizures are very rare in infants in our colony: between 1983 and 1986 only five of 667 (0.7%) macaques had unexplained seizures. The chance occurrence of one infant in 33 having seizures would be 12%. Chernick has described EEG changes as a frequent observation in human infants exposed to moderate and high dose ethanol in utero (Chernick et al., '83). Whether seizures are related to ethanol teratogenesis in this model will require further study.

Animal 25's minor facial anomalies occurred in the premaxillary and philtral regions, a facial zone sensitive to ethanol teratogenesis in humans and in mice. No specific time in gestation has been related to facial alterations in human FAS. Sulik ('84) has demonstrated alteration in this facial zone in mice exposed to ethanol on day 7 of gestation. Newell-Morris and co-authors demonstrated that maxillary and branchial anomalies of the face occurred in the pigtailed macaque exposed to retinoic acid between 20 and 44 days of gestation (Newell-Morris et al., '80). Assuming that ethanol altered the face in roughly the same time period of gestation as retinoic acid, and given that the DGE animals received ethanol from day 33 in gestation without impact to facial form, the period of facial teratogenesis for alcohol would be between gestational days 20 to 32. Animal 25 was exposed to ethanol on days 24 and 31 within this apparent period of vulnerability for facial alteration and was the only FGE animal in the 1.2 or 1.8 gm/kg cohorts exposed to ethanol on those particular days. Further

studies will test the specificity of these days in gestation to facial alteration in the macaque.

All animals with MPPECs above 140 mg/dl in the FGE group were identified as developmentally delayed in some way. Eight of the nine "definitely delayed" scores on the nutritive sucking capability test, object permanence assessment, WGTA, and visual recognition memory assessment occurred in four of these animals. These animals did not demonstrate significant delays in motor and social development as observed in the playroom. Only one of the animals had facial dysmorphia, a finding which strengthens the clinical opinion that human infants gestationally exposed to alcohol may have a behavioral teratogenic effect without a facial anomaly.

The DGE group included the only growth-retarded and microcephalic animal (33) with a MPPEC of 539 mg/dl. Similar retardation in brain growth had been previously reported in an infant macaque exposed to this same dose and dosing schedule (Clarren and Bowden, '82). Decreased body fat is an important component of the growth deficiency in human children with fetal alcohol syndrome (Clarren and Smith, '78). Normal macaque infants have only 2% body fat at term (Newell-Morris and Fahrenbruch, '85) as compared to 15% body fat in term gestation humans (Widdowson, '81) and this may explain why weight deficiency was only seen in very high ethanol exposures in this study.

Two of the three infants with transient strabismus occurred in the DGE group. This form of strabismus has been observed to occur in 4% of macaques infants in our colony (Kiorpes et al., '85). Our three affected infants represent 9% of all study infants or 33% of the DGE infants. The chance occurrance for strabismus in 3 of 33 infants would be 10%. High dose exposure after the 5th wk in gestation may increase the rate of strabismus, but further study will be needed to confirm this observation.

Two factors that could have potentially confounded the behavioral effects of ethanol teratogenesis were caesarian-section delivery and shorter gestational duration. Both factors were present in five of the six DGE infants as a consequence, of elective c-section delivery at 160 days' gestation to circumvent possible perinatal loss in this high risk group. These factors were much less extensive in the FGE group. Neither factor confounded associations of ethanol exposure to developmental delay.

Acceleration in the development of the canine teeth was found as a cohort-related effect independent of FGE/DGE designation. Accelerated tooth eruption has been reported in children exposed in utero to maternal smoking (Rantakallio and Makimen, '83) and in rats with prenatal exposure to methyl mercury (Vorhees, '85; Geyer et al., '85). Early dental eruption has not been previously described with ethanol teratogenesis, but delayed dental eruption has been observed after gestational ethanol exposure (Kelly et al., '87, Vorhees and Fernandez, '86). When a more complete understanding of the determinants of tooth eruption are known and the actions of alcohol upon that system are understood, then perhaps these apparent contradictory results can be reconciled.

In a previous article, we reported that spontaneous abortions in this model were related to ethanol exposures at and above mean MPPEC's of 200 mg/dl (Clarren et al., '87). The data reported here suggest that developmental dysfunction becomes measurable in early infancy with ethanol exposure at and above MPPEC's of 140 mg/dl. Such blood alcohol levels would be achieved in women of average weight (55 kg) consuming approximately 2.5 to 3.0 ounces of ethanol at one time once per week. The data should not be interpreted to mean that weekly dose exposures below 140 mg/dl ethanol are necessarily safe. Marginal developmental delays were identified in the playroom observations and on the WGTA in animals in all of the ethanol exposed cohorts. In addition, cognitive losses might not emerge until the animals were older and beyond the age limits of this study.

This study suggests that very early gestation may be a time when brain tissues are especially vulnerable to alcohol. Generally speaking, women do not suspect they are pregnant within the first month of gestation and may continue a pre-pregnancy drinking pattern that they would not choose to keep while pregnant. Thus, the implications from our study regarding the relationship of early gestational ethanol exposure to cognitive delays are disquieting. Further studies to determine whether detrimental effects of early exposure can be reversed by abstinence in later gestation have been initiated.

ACKNOWLEDGMENTS

We wish to thank Dr. Darrell Williams and Jeff Rockey for their help in breeding the animals and Jerry Ruppenthal, Sherry Savage and the staff of the Infant Primate Research Laboratory for their assistance in the infant assessments. We are indebted to Dr. William Morton and his veterinary staff for performing the caesarian sections and monitoring the health of the animals, and to Dr. Virginia Gunderson who conducted the visual recognition test. Finally, we thank Sarah Phillips for her editorial assistance. This study was supported by USPHS Grants AA05616, RR00166, and HD02274.

Morphometric Analysis of *Macaca nemestrina* Exposed to Ethanol During Gestation

BARBARA SHELLER, STERLING K. CLARREN, SUSAN J. ASTLEY, AND PAUL D. SAMPSON
Department of Pediatrics, School of Medicine (S.K.C., S.J.A); Department of Orthodontics, School of Dentistry (B.S.); Department of Statistics (P.D.S.); the Regional Primate Research Center (S.K.C.); and the Child Development and Mental Retardation Center (S.K.C.), University of Washington, Seattle, Washington 98195

ABSTRACT This study was part of a multidisciplinary investigation of the effects of gestational ethanol exposure in nonhuman primates. Thirty-one pregnant *Macaca nemestrina* were exposed to weekly ethanol doses of 0.0, 0.3, 0.6, 1.2, 1.8, 2.5, 3.3, or 4.1 g/kg maternal weight. Dose cohorts 0.0 through 1.8 were exposed to the initial ethanol dose within 10 days postconception. Dose cohorts 2.5 through 4.1 received their initial dose after the fifth week of gestation. Morphometric analyses performed on cranial radiographs showed that animals exposed to high doses of gestational ethanol had, on average, slightly smaller, distorted crania than control animals. A dysmorphic, flat face characteristic of fetal alcohol syndrome was recognized in one animal of the 1.8 g/kg cohort. The animal that received the highest doses of gestational ethanol was microcephalic. Similar malformations were not seen with low ethanol exposures or in controls. These data suggest a pattern of cranial distortion that may be recognizable and characteristic of ethanol teratogenesis.

Fetal alcohol syndrome (FAS) is a pattern of malformation produced by gestational exposure to ethanol and is defined by: central nervous system dysfunction, growth deficiency, and a specific cluster of minor facial anomalies (Clarren and Smith, '78). Since growth and developmental delays are found in numerous birth defect syndromes, the specific cluster of minor facial anomalies is important in distinguishing FAS. The fact that facial anomalies have been recognized as causally related to prenatal ethanol exposure has given rise to speculation about the mechanism of teratogenesis, and the threshold and spectrum of ethanol teratogenesis at different gestational ages.

This study of facial form in nonhuman primates was part of a multidisciplinary investigation of gestational ethanol exposure. The methods of alcohol administration, handling of the pregnancies, pregnancy outcome results, overall physical condition, and cognitive and developmental performance of the infants have been detailed in previous reports (Clarren et al., '87b, '88). The purpose of the morphometric investigation was to use radiographs to characterize the crania and facial features of control animals and compare them with the features of animals exposed to ethanol during gestation.

MATERIALS AND METHODS

The 31 *Macaca nemestrina* used in this study were exposed prenatally to weekly doses of ethanol. The maternal oral ethanol dose assignments were 0.0, 0.3, 0.6, 1.2, 1.8, 2.5, 3.3, and 4.1 g/kg maternal weight. Those animals assigned to dose cohorts 1.8 g/kg and below received their initial weekly dose within 10 days after conception (referred to as "full gestational exposure" or "FGE"). Animals assigned to cohorts 2.5 through 4.1 g/kg received their initial

[2]Subjects received their initial ethanol exposure between 33 and 46 postconceptional days.

weekly dose between 33 and 46 days postconception (referred to as "delayed gestational exposure" or "DGE").

Standardized lateral cephalometric radiographs of their progeny were taken with the anesthetized animal seated in a cephalostat designed for nonhuman primate research. Lateral radiographs were taken at age 1 ($\bar{x}$ = 221 postconceptional days, range 195–281 postconceptional days), and at age 2 ($\bar{x}$ = 337 postconceptional days, range 285–370 postconceptional days). Frontal radiographs were made after sacrifice, with the preserved specimen heads oriented to a standard plane in the cephalostat. Age at sacrifice ranged from 330 to 381 postconceptional days, with a mean of 356 postconceptional days.

Fifteen additional sex- and age-matched control *M. nemestrina* were obtained from the primate breeding colony that had been the source for the ethanol cohort sample. Criteria for selection included: no intra- or extrauterine exposures to conditions or medicaments that might adversely affect craniofacial growth and ages comparable with those of animals in the cohort sample. These additional control animals had lateral cephalometric radiographs taken that were identical to the fetal ethanol cohort sample.

Table 1 illustrates the distribution of the sample. Each animal's identification number, sex, dose cohort, maternal peak plasma ethanol concentration (MPPEC), and postconceptional age for lateral and frontal radiographs are recorded for each animal included in this project in Table 2.

Identification of landmarks used for digitization was done with a magnifying glass to inspect radiographs illuminated on a viewbox in a dark room. The coordinates of the landmarks were recorded using a digitizing tablet and microcomputer. Figures 1 and 2 illustrate and define the landmark points used in the analyses.

The digitized points were analyzed using morphometric methods developed by Bookstein ('86). The methods quantify mean differences in cranial or facial shape, which may distinguish the experimental group from a control group. Data generated in a study of facial features of humans with FAS have been similarly analyzed with these methods, as introduced by Bookstein ('86).

Landmark analysis was carried out primarily in terms of triangles defined by sets of three landmark points. One edge of each triangle was arbitrarily selected and assigned a standard length with the point coordinates (0,0) and (1,0) in a Cartesian (x,y) system. All information about the shape of the triangle was contained in the relative x,y coordinates of the third point, the shape coordinates (Fig. 3A).

After standardizing a triangle, such as Bregma-Orbitale-Lambda, in the manner described above, shapes were plotted as an x,y scatterplot of the shape coordinates (Fig. 3B). The mean shape for a group of triangles is represented by the average value of its scatter of shape coordinates. The significance of the observed difference in mean shape between ethanol-exposed and unexposed groups was assessed using Hotelling's two-sample T^2 test applied to the bivariate shape coordinate data (Clarren et al., '87a). Multiple triangles describing cranial and facial shape were examined.

Some individual comparisons were made by superimpositions of outlines of the anterior cranial base anatomy. The anterior wall of the sella turcica, anterior contours of the middle cranial fossae, contours of the cribiform plate and the frontoethmoidal crest, and the cerebral surface of the orbital roofs were aligned by eye to achieve the best possible fit. These reference structures are commonly used in orthodontic diagnosis and research, as they are located outside of the face itself (Bjork, '60; Bjork and Skieller, '83).

TABLE 2. Subject number, sex, maternal ethanol cohort, maternal mean peak plasma ethanol concentration, and age at times of radiographs

Subject number	Sex	Maternal weekly ethanol dose (g/kg)	Mean maternal peak plasma ethanol (mg%)	Postconceptional age

[1]Subjects received their initial ethanol exposure between 33 and 46 days postconception.
—, Data not collected.

The amount of facial and cranial growth for an individual may be evaluated by superimposing cephalometric tracings made from radiographs taken at different points in time (Ghafari et al., '87). Tracings of two age- and sex-matched subjects superimposed on the anterior cranial base have been used to qualitatively describe facial and calvarial shape differences between the subjects (Inouye et al., '85).

RESULTS

One FGE animal (no. 25) in the 1.8-g/kg cohort (MPPEC = 208 mg%) was dysmorphic, with a flat philtrum and a flattened midface (Clarren et al., '88). The facial shape coordinates of this animal did not differ statistically from the control group. However, superimposition of the radiographic tracing of animal 25 with an age- which facial characteristics contributed to

the clinical impression of dysmorphic features (Fig. 4). This animal had a dose schedule unique in the cohort; the dosing began on the third postconceptional day, with subsequent weekly doses.

Another animal exhibited microcephaly. This animal (no. 33) was a member of the delayed gestational exposure cohort and was exposed to the highest levels of ethanol in this study (MPPEC = 539 mg%). The head circumference was below the 99th percentile for the species at birth and at 6 months (Sackett et al., '75). The facial structure did not appear abnormal on examination of superimposed radiographic outlines or in terms of facial shape coordinates (Fig. 5).

Comparison of all ethanol-exposed specimens with the controls revealed no statistically significant differences in shape between the groups. Comparison of controls with individual FGE cohorts and with a cohort composed of all DGE animals yielded no significant findings. The small number of subjects in each cohort restricted the power of statistical tests. In subsequent analyses, the four highest FGE (1.8 g/kg) and the six DGE (2.5, 3.3, 4.1 g/kg) subjects were compared with a group combining the 16 low-ethanol exposure subjects with the 20 control animals.

Lateral analysis

There were no clearly significant relationships between facial shape coordinates and classification by ethanol exposure at either age. There was a difference in cranial shape, however, defined by the triangles within the quadrilateral Br-Or-S-L (Table 3). The mean cross-sectional area of Br-Or-S-L was approximately 3.5% smaller in high-dose animals (Table 4). The mean difference was statistically significant ($P \leq 0.04$, one-sided test) on the basis of a random effects regression analysis of log (area) appropriate for longitudinal data, which took into account each subject's sex, age at the times of radiography, degree of ethanol exposure, and the fact that most subjects had data collected at two ages while others were observed only once (Laird and Ware, '82). Figure 6 interprets this mean distortion in cranial shape with respect to approximate registration on Or-S. Mean two-dimensional cranial area in the high-dose animals was reduced by 1.7% compared with controls.

Frontal analysis

Morphometric analysis of multiple triangles describing facial shape and features in the frontal plane revealed no significant alteration of frontal facial features in the high-ethanol exposure group.

Digitization accuracy

Four radiographs were redigitized. The coordinates for homologous points were compared statistically using least squares

analysis; digitization accuracy was determined to be high, with no shape coordinate varying by more than 2.6%.

DISCUSSION

It was hypothesized that a direct relationship would be found between increasing exposures to ethanol and the presence and degree of craniofacial malformations. The most severe craniofacial alterations were expected to occur in the group of animals that had been exposed to the higher weekly dose of ethanol from the beginning of gestation. The animal that was clinically dysmorphic was a member of the 1.8-g/kg cohort, the highest full-gestational dose exposure. The decreased protrusion of the midface, flattened philtrum, and long upper lip of

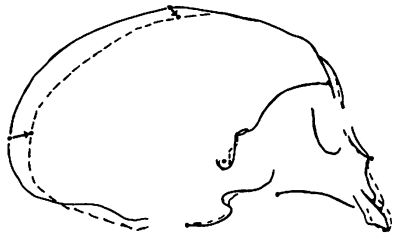

Fig. 6. Superimposition of radiographic tracings using "best fit" on anterior cranial base registered on points S and Or. High-dose ethanol subject compared with age- and sex-matched control. Solid line, control (no. 5) male, 206 postconceptional days. Coordinates of this subject were nearly identical to mean coordinates of the group combining the 16 low-ethanol exposure subjects with the 20 control animals. Dashed line, high-dose ethanol subject (no. 28) male, 206 postconceptional days. Coordinates of this subject were virtually coincident with mean coordinates of the group comprised of the 1.8-, 2.5-, 3.3-, and 4.1-g/kg cohorts. Arrows indicate the direction of distortion for points L and Br in the high-dose ethanol subjects, relative to the registration line S-Or.

animal 25 are all consistent with alcohol teratogenesis (Clarren and Smith, '78; Sulik et al., '81; Vtiz et al., '84). Other animals in the 1.8-g/kg cohort (nos. 24, 26, and 27) had been exposed to weekly plasma ethanol concentrations ranging from 189 mg% to 248 mg% but did not display perceptibly altered facial structures. Their calvaria were on average small and distorted when combined with the other high-exposure groups and compared with controls.

Apparently, early weekly gestational exposure to ethanol with peak plasma ethanol concentrations approximating 200 mg% can have an impact on facial form. Facial anomalies may relate to the specific dose schedule but could relate to other factors in teratogenesis, such as genetic susceptibility, maternal weight gain, or maternal alcohol dehydrogenase activity. Sulik suggested that a critical time period was likely to exist for the associated defects and malformations found in FAS (Sulik, '84). C57BL/6J mice exposed to ethanol doses ranging near 200 mg% on the seventh day of gestation had a 12% incidence of abnormalities of the nasal and upper lip regions that were characteristic of FAS (Sulik et al., '81; Sulik, '84). Newell-Morris and coauthors have demonstrated the craniofacial complex of *M. nemestrina* to be vulnerable to teratogenic influence by retinoic acid between days 20 and 44 of gestation (Newell-Morris et al., '80). Animal no. 25 was uniquely exposed to ethanol on days 24, 31, and 38, within this apparent period of embryonic vulnerability for facial anomalies. The DGE cohort animals received their initial ethanol doses (ranging from 260 mg% to 539 mg%) between days 33 and 46 postconception; no dysmorphic facial features were apparent in the DGE group. Further testing is needed to identify the critical period for the production of facial anomalies.

In this study, animals were sacrificed at age 6 months, which may explain the lack of significant findings in the analysis of facial features. A report detailing facial analysis of children exposed to varying gestational alcohol doses supported the contention that some children difficult to identify with FAS in infancy become more obviously affected later in childhood (Clarren et al., '87a). This will be investigated in a follow-up study in which animals exposed to gestational ethanol will be allowed to live to maturity.

The sole microcephalic animal in this study had been exposed to the highest dose of ethanol. This animal was part of the DGE cohort and had no ethanol exposure until the major period of organogenesis had ended. Microcephaly and scaphocephalic head shape have been reported in *M. nemestrina* exposed to an identical ethanol dose and schedule (Inouye et al., '85). Microcephaly, which is secondary to a diminished rate of brain growth, can be induced by weekly gestational exposure to extremely high doses of ethanol even if it is not administered until the major period of embryogenesis is completed.

In conclusion, a modest cohort ethanol effect was identified in this project, although the finding must be viewed as exploratory, since the analysis of animals

dosed at 1.8 g/kg or more was suggested by examination of the data rather than made as an a priori hypothesis. On average, animals exposed to high doses of prenatal ethanol had slightly smaller, distorted crania than control animals. Weekly exposure to gestational ethanol is therefore adequate to produce calvarial and facial alterations, but a dose-response threshold for dysmorphic effects and the time period critical for the effects have not been clarified. Further investigation using doses up to 1.8 g/kg administered early in gestation is planned to address these questions.

Received 25 May 1989

ASTLEY, S. J. AND R. E. LITTLE. *Maternal marijuana use during lactation and infant development at one year.* NEUROTOXICOL TERATOL **12**(2) 161–168, 1990.—Prenatal marijuana exposure is associated with adverse perinatal effects. Very little is known about the effect of postnatal marijuana exposure on infant development. Postnatal exposure can result from maternal use of marijuana during lactation. Delta-9-tetrahydrocannabinol (THC) transfers and concentrates in the mother's milk and is absorbed and metabolized by the nursing infant. The present study investigated the relationship between infant exposure to marijuana via the mother's milk and infant motor and mental development at one year of age. One hundred and thirty-six breast-fed infants were assessed at one year of age for motor and mental development. Sixty-eight infants were exposed to marijuana via the mother's milk. An additional 68 infants were matched to the marijuana-exposed infants on pre- and postpartum maternal alcohol and tobacco use. Marijuana exposure via the mother's milk during the first month postpartum appeared to be associated with a decrease in infant motor development at one year of age.

Lactation Marijuana Postnatal exposure Infant development

THE reported use of marijuana among pregnant women varies from five to 34 percent (4, 7, 8, 18). Fetal effects associated with prenatal exposure to marijuana include decreased birth weight (10,21) increased frequency of preterm delivery (2,7), increased labor and delivery complications (8,9) and altered visual, tremor and startle responses in neonates (3,6). Many of these findings remain suggestive due to the number of factors associated with marijuana use which are difficult to control in clinical and epidemiologic studies.

In contrast to the volume of literature addressing adverse effects of prenatal marijuana exposure, little attention has been directed towards postnatal marijuana exposure. Infant exposure via the mother's milk is of particular importance in light of the fact that delta-9-tetrahydrocannabinol (THC), the principal psychoactive component of marijuana, transfers into the mother's milk at levels reported at eight times that in maternal blood (17). Not only do nursing infants absorb and metabolize THC, but their exposure occurs at a time when growth and development, particularly glial and myalin formation in the central nervous system, is progressing at a rapid rate.

The purpose of this study was to investigate the relationship between infant marijuana exposure via the mother's milk and infant motor and mental development at one year of age in a predominantly middle class, low-risk population.

METHOD

Subject Selection

The research presented here uses data obtained in a previous prospective investigation of maternal diet, drinking and smoking during lactation on infant growth and development. There were three parts to the original prospective study. First, validity of self-reported alcohol, tobacco and other drug use and the reliability of the maternal interview process was confirmed (13,15). Next, descriptive studies were conducted to contrast the dietary habits and alcohol and tobacco use of lactating and nonlactating women (14, 19, 20). And finally, an infant assessment study was conducted that explored the relationship of alcohol use during lactation and infant development at one year of age (12).

Subjects in the previous prospective study were members of Group Health Cooperative of Puget Sound, a health maintenance organization in Seattle, WA. All prenatal patients receiving care between May 1, 1982 and July 1, 1984 were contacted by the Cooperative in their sixth month of pregnancy regarding possible study participation. An informed consent form with a full explanation of study procedures was provided. Seventy-four percent (5,298) of the prenatal patients responded and completed a mailed screening questionnaire detailing their alcohol and tobacco use both before and during pregnancy, some dietary information, and their plans to lactate. These patients constituted a screened pool.

Three months after delivery, 400 mother/infant pairs had been selected from the screened pool to participate in the previous infant assessment study cited above (12). Selection was based on maternal pre- and postpartum use of alcohol reported in personal interviews that were conducted at one and three months postpartum.

When the sample of 400 had been selected, we found that a substantial number of women reported postpartum use of mari-

[1]Requests for reprints should be addressed to Susan J. Astley, M.S., Department of Pediatrics RD-20, RR314, Health Sciences Building, University of Washington, Seattle, WA 98195.

juana (n = 82). Seventeen additional women who reported marijuana use during pregnancy only were then taken from the screened pool to enrich the sample (n = 417) and provide sufficient power to conduct the pilot study described here. At one year of age, all 417 infants were assessed for motor and mental skills using the Bayley Scales of Infant Development (1).

From among the 417 infants with one-year assessments, those who had been breast-fed for at least two weeks with less than 16 ounces of supplemental formula per day were eligible for the present study. Three-hundred twenty-three of the 417 infants met this criteria. Of these 323 mother/infant pairs, 68 mothers (21%) reported marijuana use during the first and/or third month of lactation. The infants of these 68 mothers represent the "lactation-marijuana-exposed" group in this study. From the remaining 255 breast-fed infants whose mothers did not use marijuana during lactation (lactation-marijuana-unexposed), 68 were matched to the marijuana-exposed group on maternal alcohol and tobacco use during pregnancy and during the first and third months postpartum. The groups were also matched, as nearly as possible, on duration of lactation, prenatal marijuana exposure and month of birth. The two cohorts of infants (marijuana exposed and unexposed during lactation) make up the sample of 136 for the pilot study reported here.

Dependent Variables

The two outcome variables reflecting infant motor and mental development at one year of age were the Psychomotor Developmental Index (PDI) and Mental Developmental Index (MDI) from the Bayley Scales of Infant Development. The Bayley is a widely used infant assessment tool with a standard scoring system and demonstrated validity and reliability. The PDI index provided a measure of the infant's gross motor coordination and finer manipulatory skills of the hands and fingers. The MDI index provided a measure of the infant's problem solving abilities and verbal communication development. The examiners were trained master's level clinicians with specialities in infant development. They were blind to the drug use status of the mother. Interobserver reliability on Bayley scores was maintained at 0.9 or higher.

Independent Variables

Personal interviews were conducted at one and three months postpartum in the original prospective study to gather detailed information on alcohol and tobacco use, exposure to other drugs (prescriptions, over-the-counter drugs, marijuana and other illegal substances), demographic characteristics, obstetric history, lactation status and use of supplemental formula during lactation. The use of drugs during pregnancy was addressed retrospectively in the one-month postpartum interview. Each subject had been assigned a single interviewer for the duration of the study. The interviewers were women of childbearing age, trained to obtain valid and reliable information. Validity of self-reported drug use was confirmed in an earlier pilot investigation on a sample of 108 randomly selected postpartum women. Self-reported drug use was compared to laboratory tests of drug levels present in body fluids; the proportion of questionable self-reports ranged from 0 to 3% depending on the drug (13).

Maternal use of marijuana, cocaine, caffeine and other drugs was measured in terms of how often the substance was used, when it was used and how much was used. Alcohol consumption was categorized into beer, wine and liquor and was measured in terms of frequency of use, modal quantity, and maximum quantity per drinking occasion. These measures were converted to average daily ounces of ethanol ingested in a specified period of time

found the relationship between infant marijuana exposure during lactation and infant development included: 1) Maternal age, height, race, income level, education, marital status, pregnancy history and weight gain, tobacco, coffee, alcohol and psychoactive drug use during pregnancy and lactation and marijuana use during pregnancy; 2) Paternal alcohol and tobacco use before conception and during the postpartum period; 3) Infant gestational age and sex.

Maternal dietary history was gathered in the original study, but previous studies of this population have revealed no association between infant development and maternal nutrition (12,19).

Statistical Analysis

Standard multiple regression analysis was used to determine if infant exposure to marijuana via breast milk explained a significant proportion of the variance in the infant motor and mental development scores, after controlling for confounding and interaction with other independent variables.

The first stage of analysis began with the transformation of the categorical measures of maternal marijuana use into continuous measures that reflected infant exposure. In utero exposure was represented by the number of days the mother used marijuana in each trimester. Infant exposure via the mother's milk was represented by the number of days the mother used marijuana during postpartum months one and three, weighted by the proportion of days she lactated in each month. For example, an infant whose mother reported daily use of marijuana during postpartum month one and stopped breast-feeding halfway through the month would receive an estimated exposure score of fifteen days. An infant whose mother reported marijuana use every other day and breast-fed throughout the month would also receive an exposure score of fifteen days. Women who reported use of less than 16 ounces of supplemental formula during lactation were classified together with women that reported no use of supplemental formula. The effect of supplemental formula use on infant marijuana exposure in this study is addressed in the analysis.

TABLE 3
INFANT MARIJUANA EXPOSURE

Exposed During Gestation	Exposed During Lactation	Number of Subjects
NO	NO	58
YES	NO	10
NO	YES	14
YES	YES	54

Next, potential confounding variables were identified by assessing their association with both infant developmental outcome (MDI or PDI) and maternal use of marijuana during lactation. Chi-square, regression analysis and ANOVA were used, where appropriate, to evaluate associations of each variable with exposure and outcome. We did not, however, rely on statistical significance to identify potential confounders. Any variable that demonstrated a suggestive association with both exposure and outcome was retained as a potential confounder. All secondary variables identified as confounders were regressed simultaneously with infant marijuana exposure during lactation on infant PDI and MDI outcome measures. Backwards and stepwise variable selection was performed with F-to-enter set at $p = 0.05$ and F-to-remove set at $p = 0.10$. Pairwise deletion of missing data was employed. Interaction terms between infant marijuana exposure during lactation and each retained secondary variable were computed. Each interaction term was allowed to enter the equation containing the interaction component variables by stepwise selection to determine if any secondary variable significantly modified the effect of marijuana exposure on infant PDI and MDI. Finally, maternal use of cocaine, alcohol and tobacco during pregnancy and lactation were forced into the final equation, one at a time, to verify that addition of the variable did not change the estimate of the primary independent variable.

Differences in maternal characteristics between the women who did and did not use marijuana during lactation were determined by chi-square or the *t*-test. Contrasts and linear trends of mean MDI and PDI scores, stratified by infant marijuana exposure during gestation and lactation were evaluated with one-way ANOVA.

RESULTS

There were no significant differences between the sociodemographic profiles and infant characteristics of the women who did and did not use marijuana during lactation, as shown in Table 1. Both groups were primarily white, middle class, college-educated women. Age ranged from 18 to 41 with a mean of 28.3 years. Eighty-six percent of the women were married.

The frequency of maternal marijuana use during pregnancy and lactation is presented in Table 2. Twenty to 24 percent of the women in this study reported using marijuana at least once a week during pregnancy or lactation. The usual dose on each occasion was one joint. Five to ten percent of the women who used marijuana reported smoking two to five joints per day. Of the women who reported using marijuana during pregnancy, 84% continued to use marijuana during lactation (Table 3). This strong correlation between maternal pre- and postpartum marijuana use could not be effectively reduced by matching (Pearson correlation coefficient = .59). Matching did, however, effectively reduce the correlations between marijuana use during lactation and the pre- and postpartum use of alcohol and tobacco (Table 4). Alcohol, tobacco and cocaine use during pregnancy and lactation was comparable between the women who did and did not use mari-

juana during lactation. The Pearson correlation coefficients between these variables were all less than .08. There was also no significant correlation between marijuana use during lactation and consumption of coffee.

For descriptive purposes, the mean MDI and PDI scores, stratified by infant marijuana exposure, are presented in Table 5. Higher exposure was defined as exposure to marijuana for more than half of the days of the period. Infants exposed to marijuana for more than half of the days during the first trimester or the first month of lactation had significantly lower mean PDI scores than infants with no marijuana exposure during these periods (one-way ANOVA, $p=0.02$, and 0.008, respectively). Moderate marijuana exposure (exposure for no more than half of the days in a period) only appeared to affect infant PDI in the first trimester. Mean infant PDI scores decreased linearly with increasing marijuana exposure during this period (linear trend, $p=0.005$). Very little change was reflected in the mean mental score.

When the secondary independent variables listed above were examined to determine if they might be the cause of the difference in PDI seen in Table 5, only the measure of maternal marijuana use during pregnancy was a potential confounder. Maternal race (white versus nonwhite) demonstrated a near significant association with both lactation exposure and infant motor development and was retained for further study.

Variables initially regressed on infant motor development (PDI) were maternal race and the number of days that infants were exposed to marijuana during each trimester and the first and third months of lactation. Of these variables, infant exposure to marijuana via the mother's milk during the first month postpartum was the only variable identified by stepwise and backward selection that explained a significant proportion of the variance in infant motor development (Table 6). Five percent of the variance was explained by the infant's exposure to marijuana during this period. Infant exposure expressed as the number of joints smoked by the mother during lactation did not change the results.

The only variables regressed on infant mental development were the number of days that infants were exposed to marijuana during lactation months one and three because no secondary variables were identified as confounders. No significant associations were found.

Exposure to cocaine via breast milk and alcohol during gestation also had a significant adverse effect on infant PDI (Table

7). Inclusion of cocaine and alcohol exposure variables in the above model explained an additional nine percent of the variance in infant PDI scores. Alcohol and cocaine exposure did not confound or interact with the effect of marijuana exposure during lactation on infant PDI, nor did the removal of the five subjects with reported cocaine use during lactation.

Thirty-eight of the 136 women reported use of supplemental formula (less than 16 ounces per day) during the first and/or the third month of lactation. Twenty-two of these women were in the marijuana-exposed group. In this study, women who used less than 16 ounces of supplemental formula during lactation were classified with the women who reported no use of supplemental formula. This classification scheme could result in a slight overestimate of infant marijuana exposure via breast milk, and thus underestimate the strength of the relationship between marijuana exposure and infant development. Restricting the analysis to those women who reported no use of supplemental formula at any time (n=98) did, in fact, strengthen the association between marijuana exposure during the first month of lactation and infant motor development. Eight percent of the variance in infant motor development was explained by the infant's exposure to marijuana during this period, $F(2,87)=7.3$, $p=0.001$. Exposure to cocaine throughout lactation explained an additional six percent of the variance. Alcohol exposure during gestation no longer explained a significant amount of the variance in infant motor development in this subset of infants.

DISCUSSION

In this study sample, daily infant exposure to marijuana via the mother's milk during postpartum month one was associated with a 14 ± 5 point decrease in the Bayley index of infant motor development. This adverse effect on infant PDI was noted in spite of the low-risk status of the study population. The finding persists after controlling for maternal smoking, drinking and cocaine use during pregnancy and lactation.

Marijuana exposure during the first trimester, however, confounded the association between marijuana exposure during the first month of lactation and infant PDI. Stepwise and backwards variable selection procedures identified marijuana exposure during the first month of lactation as the stronger predictor of infant PDI, but the strong correlation between marijuana exposure during the first trimester of pregnancy and the first month of lactation makes it difficult to reliably determine which period of exposure had a stronger influence on infant motor development.

One way to assess the relative importance of independent variables is to consider the increase in r^2 when a variable is entered into an equation that already contains the other independent

variables (16). A large change in r^2 indicates that a variable provides unique information about the dependent variable that is not available from the other independent variables in the equation. The addition of first trimester marijuana exposure to a model containing marijuana exposure during the first month of lactation resulted in a change in r^2 of only .001 (Table 8). On the other hand, the addition of the first month lactation exposure to a model containing first trimester marijuana exposure resulted in a change in r^2 of .023 suggesting that marijuana exposure during the first month of lactation contributes unique information about the variance in infant PDI, above and beyond the information provided by first trimester exposure. Further evidence suggesting a weak or perhaps nonexistent association between first trimester exposure and infant PDI can be seen in the low F value when first trimester exposure is regressed separately on infant PDI.

Dependent variable: PDI (infant Psychomotor Developmental Index from the Bayley Scales of Motor Development).

A linear model provided the best fit of the data, despite the threshold appearance of the relationship between marijuana exposure during the first month of lactation and infant motor development (Table 5). A linear fit is certainly not inconsistent with the results presented in Table 5. When continuous data is presented in a categorized format, an apparent threshold or linear effect can be created simply by virtue of where you decide to divide the categories. Further study, preferably with larger samples will be

necessary to determine the true nature of the association between PDI and marijuana exposure via breast milk.

To date, only one published report has assessed the relationship between infant exposure to marijuana via breast milk and infant development at one year of age (18). In this study, Tennes and her colleagues compared a subset of 27 infants exposed to marijuana via breast milk to 35 breast-fed infants who were not exposed to marijuana. Of the women that reported marijuana use during lactation, twelve used it once a month or less, nine reported weekly use and six used it daily. Prenatal marijuana exposure was not reported for this group. At one year of age the infants were assessed for motor and mental skills using the Bayley Scales of Infant Development. Unlike the present study, no apparent effects of postnatal marijuana exposure were found. The investigators did note, however, that the statistical analyses were limited due to the small sample size and lack of comparability among cases for duration of exposure and dose.

In a study of prenatal effects of marijuana exposure on infant development (2), Fried reported that babies born to women who smoked more than five joints per week during pregnancy demonstrated marked tremors and startles and altered visual responsiveness at two to four days of age. These symptoms attenuated within 30 days. A follow-up study found no association between prenatal marijuana exposure and infant motor development (PDI) at one and two years of age (5). In the present study, prenatal marijuana exposure also failed to be associated with infant motor development when measured at one year of age. Postnatal marijuana exposure, however, did appear to be significantly associated with one-year motor development scores in the present study. Measures of postnatal marijuana exposure were not available in the two studies reported by Fried.

Despite the slight increase in maternal use of marijuana during the third month of lactation in the present study, there was no significant effect on infant PDI associated with marijuana use at that time. It is unlikely that this is due to the decrease in the sample size by eleven subjects in the third month postpartum. The study had the power to detect a difference of eight points in the motor development index with ninety percent certainty in the third month. An increase in the use of supplemental formula also failed to explain the lack of association between infant motor development and marijuana exposure during the third month of lactation. Use of supplemental formula would reduce infant marijuana exposure via breast milk, but exclusion of women who used supplemental formula failed to strengthen the association. This lack of effect on infant PDI may reflect a decrease in developmental vulnerability in postpartum month three.

Maternal use of marijuana during pregnancy and lactation had no detectable effect on infant mental development at one year of age in this study. A lack of association between prenatal exposure and mental development at one and two years of age has also been reported by Fried (2,5). The lack of association seen in all three studies suggests that the neurological areas associated with cognitive function may be less vulnerable to marijuana exposure. Further studies using larger sample sizes, higher exposure and more sensitive diagnostic tools are needed to support this finding.

Daily exposure to marijuana during the first month of lactation was associated with a decrease in PDI score of 14 points, which represents three quarters of a standard deviation in the infants of this sample. It is a difference large enough to be detected by an astute clinician. The long-term implications for child development, however, are unknown. Evaluation of infant mental and motor development is not straightforward, and interpretation of the findings is not always easy.

In summary, although marijuana exposure during lactation was associated with decreased infant motor development, this result should be interpreted cautiously due to the preliminary nature of this study. One cannot infer from the results presented here that marijuana exposure during lactation impairs infant motor development at one year of age, or that prenatal marijuana exposure does not impair motor development. Marijuana exposure during lactation appeared to be a better predictor of infant motor development, but it does not necessarily mean that the relationship is one of cause and effect. Prenatal marijuana exposure, passive exposure to marijuana smoke in the air and the quality of maternal/infant interactions are three factors that could potentially confound the observed association in this study. The difficulty of evaluating infant development and the predictive value of the findings should also be considered. Nevertheless, the deleterious effects of maternal drug use on infant development may not be limited to prenatal exposure; postnatal exposure may be playing a critical role and warrants consideration in future investigations.

Neuroanatomic and Neurochemical Abnormalities in Non-human Primate Infants Exposed to Weekly Doses of Ethanol during Gestation

Sterling K. Clarren, Susan J. Astley, Douglas M. Bowden, Henry Lai, Ann H. Milam, P. Kevin Rudeen, William J. Shoemaker

Ethanol was orally administered once per week to 54 gravid pigtailed macaques (*Macaca nemestrina*) in doses of 0.0, 0.3, 0.6, 1.2, 1.8, 2.5 or 4.1 gm/kg from the 1st week in gestation or in doses of 2.5, 3.3 or 4.1 gm/kg from the 5th week. Mean maternal peak plasma ethanol concentrations (MPPEC's) ranged from 24 ± 6 mg/dl at the 0.3 g/kg dose to 549 ± 71 mg/dl at the 4.1 g/kg dose. Thirty-three live born infants were assessed for abnormalities of physical and behavioral development. Ocular pathology, neuropathologic and neurochemical assessments were done on 31 animals at 6 months postnatal age. Microphthalmia was noted in three of the 26 animals exposed to ethanol. Retinal ganglion cell loss was significantly associated with intra-uterine ethanol exposure. Microphthalmia and retinal ganglion cell loss was observed in both the delayed and full-gestational exposed animals. No structural anomalies were found in the brains via gross inspection or light microscopy. Chemical abnormalities in the striatal nuclei were identified. Striatal dopamine concentrations increased with increasing MPPEC exposure (0–249 mg/dl) among animals exposed weekly to ethanol throughout gestation. Striatal dopamine concentrations decreased with increasing MPPEC exposure (260–540 mg/dl) among animals whose weekly exposure to ethanol was delayed until the 5th week of gestation. The same pattern of association was also noted between MPPEC and ultrastructural alterations in the caudate nucleus. The extent of ultrastructural alterations increased with increasing MPPEC among the full-gestational exposed animals and decreased with increasing MPPEC among the delayed-dose animals.

CENTRAL NERVOUS SYSTEM (CNS) dysfunction is well established as one of the most important clinical results of ethanol teratogenesis. CNS dysfunction is part of the definition of fetal alcohol syndrome (FAS).[1,2] Yet, little is known about where in the brain, when in gestation, or by what mechanisms ethanol-related CNS teratogenic changes occur. This report summarizes an extensive survey of brain chemistry and anatomy performed on 31, 6-month old nonhuman primates (*Macaca nemestrina*). The data are part of the results of a much larger project designed to assess the teratogenic impact of once-per-week alcohol use during pregnancy. Once-per-week alcohol consumption has been found to be the most frequent intermittent consumption pattern for alcohol use by American women.[3]

In the overall project, ethanol was administered orally once a week throughout gestation (from week 1–24) to gravid pigtailed macaques (*M. nemestrina*) in doses of 0.3, 0.6, 1.2, 1.8, 2.5, 3.3, or 4.1 g/kg. A control group received a weekly, oral sucrose solution that was isocaloric and isovolumetric to the highest ethanol dose. The pregnancies were managed normally in all ways aside from the weekly dosing. Weight gain and health were monitored in all gravid animals. The ethanol exposures had a negligible impact on the general health and activity of the mothers, although the animals exposed to the higher ethanol doses (above 1.8 g/kg) were mildly subdued for several hours after each dosing. Previous reports of results from this project have described the general study design, the pregnancy outcomes, and the physical problems and developmental delays of the infants.[4–6]

To briefly summarize those previous reports, pregnancy was followed in 54 females after 116 matings resulting in 33 live born infants. Two infants developed serious infectious illnesses and died within the 1st month of life. Mean maternal peak plasma ethanol concentrations (MPPECs) ranged from an average of 24 ± 6 mg/dl at the 0.3 g/kg dose to 549 ± 71 mg/dl at the 4.1 g/kg dose. The goal of the study was to produce seven viable infants in each dose cohort for assessment of mental and motor development. The proportion of pregnancies that failed within the first 30 days of gestation in the 0.3, 0.6, 1.2, and 1.8 g/kg ethanol cohorts were 67% (14/21), 56% (9/16), 60% (9/15), and 36% (5/14), respectively. The pregnancy failure rates in these cohorts were not statistically different from the rate of 50% in the 14 timed-matings in the study control group, nor were they different from the overall rate of 50% in the primate colony based on more than 1000 timed-matings. At the 2.5 g/kg dose, however, five of six females (83%) experienced pregnancy failure in the first 30 days of gestation. The one animal that was con-

firmed to be pregnant, aborted by the end of the first trimester. Although this increased rate was not significantly different from the control rate, this rate was too high to produce seven viable infants in the time allocated for the study. At the 4.1 g/kg dose, seven of seven (100%) of the pregnancies failed, and this was significantly higher than the rate for the study control group ($p = 0.008$, binomial test). Since the purpose of the study was to produce viable infants for developmental assessment, there was nothing to be gained by continuing the administration of these two fetotoxic doses. In order to study a small sample of infants exposed to very high doses of ethanol and to provide preliminary data for an alternate exposure pattern, the decision was made to delay the administration of high dose ethanol until the 5th week of gestation. The pregnancy failure rates for the delayed exposure group as a whole dropped from 92% (12 of 13) to 52% (12 of 23), as anticipated.

The number of infants in each exposure cohort that was available for neuroanatomic and neurochemical assessment at 6 months of age is presented in Fig. 1 in which full blackened circles denote that the individual deviated by more than two standard deviations from control group means. At least one of the hallmark features of human FAS: facial anomalies, growth deficiencies or central nervous system dysfunction, were found in 57% of the ethanol-exposed animals. No individual animal showed the complete human FAS pattern. Six of the nine animals (67%) exposed to MPPECs at or above 115 mg/dl starting in the 1st week of gestation had clear evidence of a teratogenic impact. While three of the six infants (50%) exposed to higher, delayed doses showed some evidence of a teratogenic effect, none of 11 animals exposed to lower, full-gestational exposures showed comparable effects.

The six animals with full-gestational exposure and MPPECs between 140 and 249 mg/dl had much more severe and consistent cognitive abnormalities than the animals with the delayed gestational exposures, even though the latter were exposed to MPPECs between 260 and 540 mg/dl (Fig. 1).

The study results are consistent with clinical impressions that ethanol related behavioral teratogenesis may occur without accompanying physical anomalies. In addition, the preponderance of abnormalities from ethanol-induced teratogenesis from a once-per-week exposure frequency occurred with MPPECs above 140 mg/dl—an intoxicating dose in humans which can be achieved through the consumption of four to six standard drinks by an average sized woman. Finally, and intriguingly, early gestational exposure to ethanol appeared to be more damaging to cognitive function than later with considerably greater ethanol exposure.

METHODS

After extensive study of their physical and behavioral development, the animals were killed at approximately 6 months of age (329 to 380 days postconception). An initial intramuscular injection of ketamine (10 to 15 mg/kg) was given. If adequate sedation was not achieved, a second (and occasionally a third) dose of ketamine was employed. Once the animal was deeply sedated, an intravenous line was placed in an exposed saphenous vein through which chloral hydrate (40 mg/kg) was infused. Blood pressure was monitored continuously. An adequate surgical level of anesthesia was achieved when the animal exhibited no foot withdrawal reflex and no significant change in blood pressure to deep pressure stimulation. When this level of anesthesia was reached, the optic globes were enucleated with the optic nerves and the brain was removed. The eyes were immediately transferred for study (Dr. Milam's laboratory). The brain was weighed and inspected for gross morphological abnormalities. The cerebellum and brain stem were separated from the cerebrum at the level of the midbrain and the cerebral hemispheres were bisected along the midsagittal plane. The left hemisphere was then placed, mesial surface down, on a frame with a clear Plexiglas bottom. For cutting in coronal plane, the hemisphere was positioned by aligning the anterior and posterior commissures and the massa intermedia. A specially designed, multiblade knife was drawn across the hemisphere producing a series of 5-mm thick cerebral slices. The slices were spread on a dissection board for anatomic identification. Simultaneously, free hand dissection was done of the right hemisphere by a second dissector. That hemisphere was sectioned coronally at the level of the anterior commissure and 5 mm rostrally. Tissues for neurochemical analysis of dopamine, DOPAC, norepinephrine, epinephrine, and serotonin were obtained through dissection from the 5-mm thick slices from the left hemisphere. Structures sampled included the substantia nigra, hypothalamus (with mammillary body), frontal gyrus, calcarine cortex, hippocampus, and hemibrain stem, as well as the right preoptic area and putamen and caudate nuclei. These samples were frozen immediately on dry ice for later analyses (Dr. Shoemaker's laboratory).

The left caudate and putamen were dissected in toto from each brain slice, placed on ice and transferred for immediate assay for dopamine receptors using the ligand-binding technique (Dr. Lai's laboratory).

Samples from the left preoptic area, gyrus rectus, calcarine cortex, right caudate and putamen nuclei, and right cerebellar cortex were placed in Karnovsky's solution for electron microscopic assessment (Dr. Rudeen's laboratory).

Except for portions of the hippocampal gyrus, cerebellum, hypothalamus, and brain stem, which will be utilized in other studies not yet completed, all remaining brain tissues were placed in 10% neutral buffered formalin for neuropathologic study (Dr. Clarren's laboratory). The entire dissection was completed in less than 8 min from the moment the calvarium was removed and the superior sagittal sinus was ruptured.

Tissue sent to each investigator was coded so that the analyses were done without knowledge of the animals' exposure history.

Neuropathology

The right hemisphere was received as two formalin fixed pieces with a 5-mm coronal section missing at the approximate level of the lateral geniculate. The pieces were photographed and sectioned coronally in standard 5-mm slices. After gross inspection and photography, the slabs were embedded in paraffin, cut, mounted, and stained with hematoxylin and eosin as well as luxol fast blue-nissl. The slides were studied in two ways. First, all samples from the same animal were scanned. Then, similar sections from all the animals were compared. Particular attention was paid to detecting cortical irregularities especially in the hippocampus and calcarine areas, white matter loss or gliosis, and neuronal density and structure. Heterotopias were specifically sought.

Ocular Pathology

The globes were slit at the pars plana and placed immediately in 2% paraformaldehyde and 2% glutaraldehyde in 0.13 M phosphate buffer. The gross pathology assessment included measurement of the cornea (horizontal and vertical diameters) and of the globe (horizontal, vertical,

and anterior-posterior diameters). Each globe was opened horizontally and the anterior segment and fundus were examined for abnormalities. A horizontal segment of retina 10 mm wide and 5 mm high was dissected, which included the optic nerve head and the fovea. The tissue was dehydrated, embedded in Sorvall JB-4 methacrylate, and sectioned at 4-μm thickness. Sections were selected that included the fovea pit and optic nerve head and were stained with Richardson's methylene blue-azure II mixture. Ganglion cell counts were recorded from a 1-mm zone of retina extending from the nasal and temporal sides of the fovea pit. The counts were performed at magnification ×40 by three independent investigators. Ganglion cell counts were expressed as normal (7–8 cells deep), mild loss (5–6 cells deep), and marked loss (4 cells deep).

Electron-Microscopic Assessment

Each tissue sampled was fixed in Karnovsky's fixative and trimmed to rectangular blocks approximately 1 × 2 × 1 mm. The tissue blocks were embedded in an Epon 812 resin by standard techniques.[7] The tissues were thin-sectioned with an ultramicrotome and the sections retrieved from the water trough on the glass knife with single-slot copper grids. The grids were placed on formvar films, allowed to air dry then stained with uranyl acetate and lead citrate to enhance the contrast of the tissue. The tissue sections were observed using a Zeiss 10-CR electron microscope. Individual cells from different blocks were selected, photographed and the images printed (final magnification: ×2,550–4,000). To maximize the possibility of finding a structural difference due to ethanol exposure, tissues from the six delayed-dose exposed animals and six full-gestational exposed animals with MPPECs ≥124 mg/dl were compared with tissues from the five control animals. The evaluation involved the subjective estimate of the degree of abnormal appearance of the following cellular parameters: rough endoplasmic reticulum, Golgi bodies, mitochondria, nuclear morphology and heterochromatin pattern, and general cytoplasmic appearance. A scoring system for assessing these ultrastructural alterations of the cell and its organelles was used in which a value of 1 represented the normal appearance without any apparent morphological aberration; 2, a nominal alteration of the normal appearance; 3, a moderately altered appearance; 4, a substantial degeneration in the normal appearance of the cell or its organelles; and 5, a maximal abnormal appearance of cellular structure.

Neurochemical Analysis

The sample vials were removed from the freezer and thawed in a cold water bath. Three milliliters of cold 0.1 M $HClO_4$ was added to each sample, and the tissue was homogenized using a Tekmar TR-10 Tissuemizer adapted with a microprobe. The homogenate was spun for 20 min in a refrigerated Sorvall RC-3 centrifuge at 1,300 rpm. The supernatant was removed and transferred to a 3.5-ml conical bottom assay tube. The remaining pellet was reserved for total protein analysis. One milliliter of 1.5 Tris buffer contaminating EDTA with an adjusted pH of 8.6 was added to each tube along with 50 mg of AAO (acid-washed aluminum oxide). Next, 100 mg/ml of 3,4-dihydroxybenzylanine (DHBA) was added as an internal standard. The tubes were capped, gently shaken for 20 min, centrifuged, and the supernatant aspirated. The remaining AAO was washed with 1 ml of 0.005 Tris buffer, centrifuged and the supernatant again aspirated. This washing was repeated two more times to thoroughly clean the AAO. To extract the catecholamines from the AAO, 200 μl of 0.4 M $HClO_4$ was added to each tube. The tubes were gently shaken for 10 min and then centrifuged. The supernatant was removed, and the samples were transferred to vials and refrigerated until separations were performed.

Epinephrine, norepinephrine, serotonin, dopamine, and DOPAC were separated on an Isocratic liquid chromatography system consisting of a Waters M6000A dual piston pump and a Waters model 712 sample processor equipped with refrigeration unit set at 10°C. An ESA model 5100A coulochem electrochemical detector equipped with an ESA HR 80 column was used for amine detection. A two cell system was employed. The first cell was a +0.04V charge to neutralize the mobile phase while the working detector cell was set at −0.28V for amine detection. A flow of 1 ml/min of monobasic sodium phosphate buffer (pH of 3.6) was used for all separations. With an initial injection of 50 μl of sample, a flow of 1 ml/min allowed for individual isolation of all amines, including the internal standard of DHBA over a 20-min run. The detector response in volts was measured and analyzed by a Water's data module. The area under the curve was determined and compared with standards for quantifying each sample.

The total protein content of each tissue sample was determined from the insoluble pellet obtained from the initial homogenization of the tissue samples. The pellet was resuspended in NaOH, allowed to sit for 24 h and then analyzed using the Bio-Rad Protein Assay method. Protein content was read by a Chemetrics II automated chemistry analyzer.

Dopamine Receptor Assay

Specific binding of ^{3}H-spiroperidol to membranes prepared from brain tissues was assayed by a method described previously.[8] Briefly, fresh brain tissue was homogenized in 10 volumes of a Na-K phosphate buffer (pH of 7.4) with a Polytron homogenizer (3 × 10 sec at setting 5). The homogenate was centrifuged at 40,000 × *g* for 20 min and the pellet was resuspended in phosphate buffer and centrifuged again at 40,000 × *g* for 20 min. The resulting pellet was resuspended in the buffer. Of this homogenate, 100 μl (containing approximately 100 μg of protein) was added to each of a set of test tubes containing various concentrations of ^{3}H-spiroperidol (New England Nuclear; specific activity 25 Ci/mmol) in phosphate buffer. Five ligand concentrations varying from 50–800 pM were used. Binding with each concentration was run in triplicate. Nonspecific binding was determined by addition of 1 μM of d-butaclamol to a similar set of sample tubes. The test tubes and their contents (total volume of 10 ml) were incubated at 37°C for 30 min in a water bath. The incubate was then filtered through a glass filter (Whatman GF/B) under suction. Radioactivity trapped in the filter was measured by scintillation-counting technique with an Omnifluor-toluene scintillant at 40% counting efficiency. Protein concentration of the final tissue homogenate was determined by the method of Lowry et al.[9] using bovine serum albumin as standards. Concentration (fm/mg protein) and affinity (pM) of the receptors were determined by Scatchard analysis.

Data Analysis

Data analysis was approached in two ways. First, formal statistical analyses were carried out to test for associations between ethanol exposure (MPPEC) and each developmental and neurological outcome measure. The χ^2 test and the binomial test were used to assess categorical measures of pregnancy and neurological outcome. Analysis of variance was used to compare mean outcome scores between exposure cohorts. Standard multiple regression analysis was used to determine whether maternal ethanol exposure during pregnancy explained a significant proportion of the variance in infant striatal dopamine, DOPAC, and dopamine receptor concentrations, after controlling for confounding and interaction with secondary variables (ketamine, exposure, and age). Backwards and stepwise variable selection was performed with *F*-to-enter set at $p = 0.05$ and *F*-to-remove set at $p = 0.10$. Interaction terms between maternal ethanol exposure (MPPEC) and each secondary variable were computed. Each interaction term was allowed to enter the equation containing the interaction component variables by stepwise selection to determine if ketamine or age significantly modified the effect of maternal ethanol exposure on each dependent variable. Scatter diagrams of MPPEC^2 terms were entered into each equation and retained if they explained a significant increase in variation, beyond that explained by the straight-line model. Small sample sizes necessarily limit inferences that can be drawn from these assessments.

In addition to the formal statistical assessments that were described above, a more descriptive approach was also employed to identify individual animals that showed evidence of developmental impairment,

and to identify patterns of effect across all infants as they relate to the level and timing of intra-uterine ethanol exposure. For each animal, the raw score for each outcome measure was transformed into a normally standardized z-score based on the corresponding mean and standard deviation in the unexposed animals. Affected animals were defined as those infants with z-scores >2 standard deviations. The results of this assessment are presented in Fig. 1 as an extension of the figure as previously published.[5]

RESULTS

Neuropathology

A small but statistically significant decrease in brain volume (3%) was detected in the 12 animals who received delayed or full-gestational exposures to MPPECs at or above 140 mg/dl. True microcephaly was only noted in one animal exposed to an MPPEC of 540 mg/dl administered after the 5th week of gestation.[6] No gross malformations were found in any brain specimen. No abnormalities of cerebral cortices or nuclei, glia, or neurons were confirmed by observation of the brain samples prepared for review with the light microscope.

Ocular Pathology

Tortuosity of retinal blood vessels, a noted feature in humans with FAS, was not observed in this series of nonhuman primates. Three of the animals showed bilateral microphthalmia (globe diameters of 17 mm or less in all three meridia), including one animal whose mother was exposed to 0.6 g/kg ethanol, one animal whose mother was exposed to 1.2 g/kg ethanol and one from the delayed dose group (Fig. 1). Microcornea (both diameters 9 mm or less) was observed only in the left eye of animal number 19, an infant whose mother was exposed to 1.2 g/kg ethanol. Mild ganglion cell loss was also noted in the left eye. The right eye of this animal had a normal sized cornea (11 × 10 mm), but had marked ganglion cell loss.

The mean diameters for each meridia across the left and right globes of the five control animals were 18.2 ± 0.6, 18.0 ± 0.7, and 18.6 ± 0.5. Three of these animals had normal ganglion cell numbers while the other two had mildly reduced ganglion cell numbers bilaterally. Marked loss of retinal ganglion cells was observed in five of the 26 ethanol-exposed animals, including one from the 0.3 g/kg ethanol exposed group, one from the 1.2 g/kg ethanol exposed group, two from the 1.8 g/kg ethanol exposed group, and one from the delayed dose group. The pattern of marked ganglion cell loss was always found in only one retina with mild ganglion cell loss in the opposite retina. Mild ganglion cell loss was found in all of the other ethanol exposed animals. In the majority (19) of these monkeys, the mild ganglion cell loss was bilateral; in the other two, mild ganglion cell loss was unilateral and the opposite retina had normal ganglion cell counts. The frequency of mild to marked ganglion cell loss in the ethanol-exposed animals (100%) was significantly greater than the frequency of ganglion cell loss in the controls (40%, $\chi^2 = 11.1$, $p = .0009$ with Yates correction).

Fig. 1. This figure is extended from a previous publication[5] with the addition of two columns depicting ocular pathologic changes. Individual deviations on developmental and growth measures are compared in infant macaques exposed to ethanol in utero and control infants. ●, indicate extreme deviations from control means, while ◑, indicate definite, but less extreme deviation. Only marked retina ganglion cell losses are displayed. Animal 19, who had marked retina ganglion cell loss also had microcornea. Animals 11 and 15 were not available for neuroanalysis; both animals developed serious infectious illnesses and died within the 1st month of life.

Electron-Microscopic Assessment Results

Electron micrographic assessments revealed important anatomical differences among cells from animals exposed to different doses of ethanol during gestation. To assure a focus on neurons, only cells that demonstrated either somatic synapses or multipolar processes were selected for investigation. Cells that were thought to be glial cells were not photographed and were excluded from the evaluation. The normal appearance of a neuron in the caudate nucleus included a round nucleus with peripherally clumped heterochromatin. Organelles in the cytoplasm were evenly distributed and the abundant numbers of mitochondria contained lamellar cristae. Rough endoplasmic reticulum (ER) had a regular array with evenly spaced cisternae

which frequently filled much of the cytoplasm with organized stacks of membranes and polysomes. Intracellular vesicles were usually present.

In contrast, the organelles and cytoplasmic organization of neurons in the nucleus from animals that were exposed to ethanol in utero, had a different appearance (Fig. 2). The cytoplasm of many cells lacked the usual distribution and number of cellular organelles. The most striking differences were in the appearance of the ER. The cisternae of the ER appeared swollen and distended, which resulted often in an oval or round vacuolar appearance rather than flat membranous stacks. The mitochondria showed a variety of structural changes particularly in the loss of cristae, suggestive of a degenerative condition. This is consistent with mitochondrial abnormalities found in rat pups exposed to a 20% ethanol solution during gestation.[10] Vesicles were present in the cytoplasm of these cells, and normal appearing Golgi were present with regularly arranged membranous stacks. However, some areas showed Golgi membranes that did not appear organized but were distended, disordered, and vesiculated. In some of the cells, the nucleus appeared crenated or stellate shaped whereas this appearance was absent in cells from control animals. As seen in Fig. 3, the intracellular dysmorphism score as previously defined, appeared elevated among animals with MPPECs between 214 and 264 mg/dl, including two animals who were not exposed to ethanol until the 5th week of gestation. Animals receiving full gestational exposure to lower doses of ethanol (MPPECs 124–208 mg/dl) and animals receiving delayed exposures to higher levels of ethanol MPPECs 420–540 mg/dl) had dysmorphism scores similar to those of control animals. Assessments of the cells in other brain areas are not yet completed.

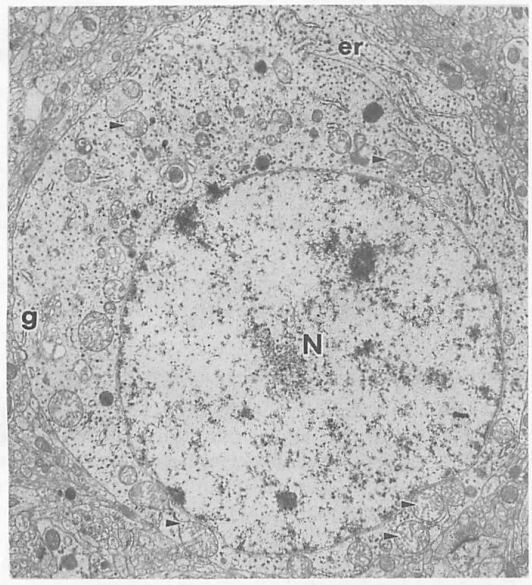

Fig. 2. Photograph of a neuron from the caudate nucleus of a monkey whose mother was exposed weekly to 1.8 g/kg of ethanol throughout pregnancy (magnification ×4,000). Note the relatively sparse amount of peripheral heterochromatin in the nucleus (N). The cytoplasm contains abundant numbers of organelles in this cell, but many of the mitochondria have unorganized cristae (arrow heads). A Golgi body (g) is present, but appears disordered. The cisternae of the rough endoplasmic reticulum (er) is swollen and in some areas it is vacuolar.

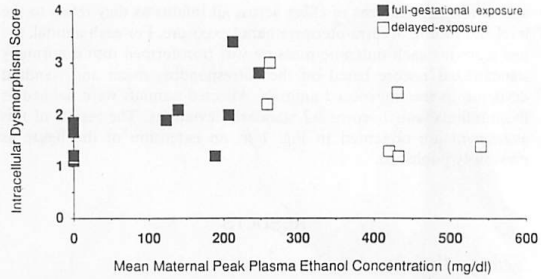

Fig. 3. Infant intracellular dysmorphism score as it relates to maternal MPPEC and timing of ethanol exposure. The intracellular dysmorphism score reflects the extent of intracellular structural alteration observed in the cells of the caudate nucleus. A score of 1 represents no apparent morphological aberration, while scores of 2, 3, 4, and 5 reflect nominal, moderate, substantial, and maximal alteration in structure, respectively. The extent of structural alteration appeared elevated among animals exposed in utero to maternal MPPECs between 214 and 264 mg/dl, including two animals whose ethanol exposure was delayed until the 5th week of gestation.

Neurochemical Analysis

Associations were found between MPPECs dopamine and DOPAC concentrations in the striatal nuclei. Ethanol exposure did not appear to influence dopamine concentrations in other brain areas or epinephrine, norepinephrine, or serotonin concentrations.

Influence of Age and Ketamine Exposure on Striatal Dopamine Concentrations. Dopamine concentrations in the caudate and putamen nuclei were found to vary significantly by animal age and ketamine exposure at the time of death. When final age (days postconception) and ketamine exposure (mg/kg) were regressed on putamen and caudate dopamine concentrations (ng/mg protein), age explained 38% of the variance in putamen dopamine concentration [$F(1,28) = 17.4$, $p = 0.003$] and 16% of the variance in caudate dopamine concentration [$F(1,28) = 5.2$, $p = 0.03$]. Ketamine explained an additional 15% of the variance in the putamen [$F(2,27) = 15.2$ $p < 0.0001$], and 19% of the variance in the caudate [$F(2,27) = 7.2$, $p = 0.003$]. Striatal dopamine levels increased with increasing age from 329 to 380 days postconception (Fig. 4). Striatal dopamine concentration decreased with increasing ketamine exposure in what appeared to be a threshold effect at exposures ≥21 mg/kg (Fig. 5). Thirty of the 31 animals were entered into this regression analysis; one subject had an invalid dopamine assay.

The mean total ketamine doses across all infants was 19 ± 9 mg/kg with a range of 9 to 43 mg/kg. The mean

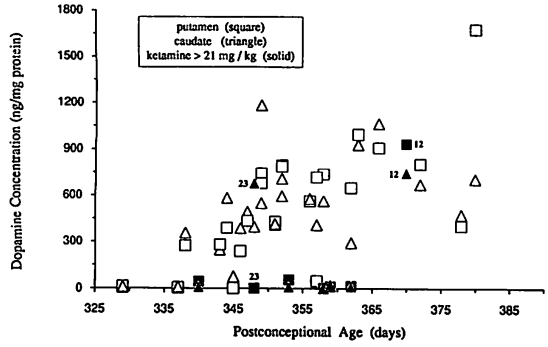

Fig. 4. Striatal dopamine as it relates to postconceptual age. The cuadate and putamen dopamine concentrations (ng/mg protein) for each animal are presented as they relate to postconceptual age at killing. Striatal dopamine concentration increased with increasing age from 329 to 380 days postconception. Total ketamine exposures ≥21 mg/kg are associated with markedly reduced dopamine concentrations. Animal No. 12 was the only animal to receive a high total ketamine exposure that was delivered in a series of small doses.

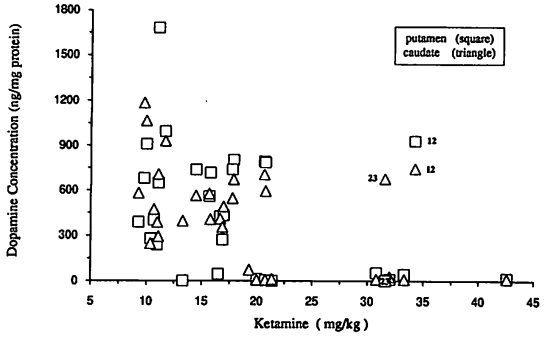

Fig. 5. Striatal dopamine as it relates to ketamine exposure. The caudate and putamen dopamine concentrations (ng/mg protein) for each animal are presented as they relate to total ketamine exposure at the time of killing. Striatal dopamine concentrations decreased with increasing total ketamine exposure in what appeared to be a threshold effect at exposures ≥21 mg/kg. Animal No. 12 was the only animal to receive a high total ketamine exposure that was delivered in a series of small doses.

caudate and putamen dopamine concentrations across all subjects in both pattern groups were 439 and 452 ng/mg protein, respectively; the medians were 473 and 400, respectively. Seven infants received total ketamine doses ≥21 mg/kg. Of these seven infants, five (71%) had caudate dopamine levels below 50 ng/mg protein and six (85%) had putamen dopamine levels below 50 ng/mg protein. Animal 12 was the sole subject with a total ketamine exposure above 21 mg/kg and measureable dopamine concentrations in both caudate and putamen. It should be noted that this animal had a unique ketamine exposure. While its total ketamine dose was 34 mg/kg, the drug had been delivered in a series of small aliquots over 30 min. Of the 23 infants with ketamine exposures less than 21 mg/kg, only four (17%) had putamen dopamine concentrations below 50 ng/mg protein and only two (8%) had caudate dopamine concentrations below 50 ng/mg protein. Ketamine exposure was unrelated to age, the level of maternal ethanol exposure or the timing of ethanol exposure.

To simplify the interpretation of the dopamine assay data, the animals were divided into two groups, those exposed to ethanol weekly througout gestation ($n = 25$) and those whose weekly ethanol exposure was delayed until the 5th week of gestation ($n = 6$).

Striatal Dopamine, DOPAC, and Dopamine Receptor Concentrations among Animals Exposed to Ethanol throughout Gestation. Among the animals exposed to ethanol throughout gestation, MPPEC explained 13% of the variance in putamen dopamine concentration after adjustment for the effect of age and ketamine exposure [$F(5,19) = 10.5$, $p = 0.0001$] (Table 1). MPPEC, expressed as a second order polynomial, provided the best fit of the data. Putamen dopamine increased with increasing MPPEC, increased with increasing age and decreased with increasing ketamine exposure. There was a significant interaction between MPPEC and final age. This interaction reflected the unequal age distribution at the time of death along the continuum of MPPEC. The age range was much broader among the animals exposed to MPPECs ≤100 mg/dl (329–380 days) compared with animals exposed to MPPECs >100 mg/dl (348–362 days). MPPEC, final age and ketamine exposure, together explained 74% of the variance in putamen dopamine concentration.

Similar results were found when MPPEC, final age, and ketamine exposure were regressed on caudate dopamine levels among the infants exposed to ethanol throughout gestation (Table 1). Caudate dopamine concentrations increased linearly with increasing MPPEC. MPPEC explained 17% of the variance in caudate dopamine levels after adjustment for age and ketamine exposure [$F(4,19) = 6.4$, $p = 0.002$]. Caudate dopamine levels increased with increasing age and decreased with increasing ketamine exposure. Once again, there was a significant interaction between MPPEC and age, reflecting the unequal distribution of age with increasing MPPEC. MPPEC, age, and ketamine exposure explained 57% of the variance in caudate dopamine levels.

DOPAC concentrations correlated significantly with dopamine concentrations in the putamen (Pearson correlation coefficient = 0.45, $p = 0.03$). A much weaker correlation between dopamine and DOPAC was found in the caudate (Pearson correlation coefficient = 0.32, $p = 0.12$). Ketamine exposure and final age did not appear to influence the DOPAC concentrations. Adequate assays for DOPAC concentration were only obtained in 17 of 25 full gestation exposed subjects.

Dopamine receptor levels (fm/mg protein) in the caudate increased gradually with increasing MPPEC (0–250 mg/dl) and increasing age (329–380 days) (Table 2). MPPEC explained 22% of the variance in caudate dopamine receptor levels. Final age explained an additional 32% of the variance [$F(3,19) = 11.3$, $p = 0.0002$]. There

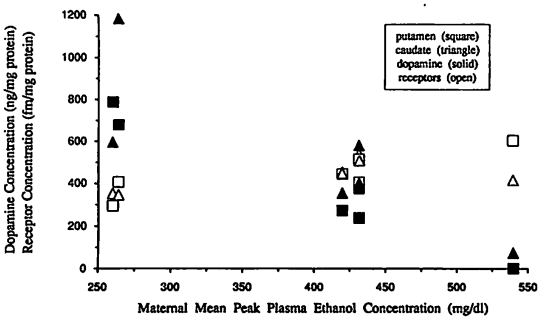

Fig. 6. Striatal dopamine and dopamine receptor concentrations as they relate to maternal MPPEC among the delayed-dose infants. Striatal dopamine and dopamine receptor concentrations for the delayed-dose infants are presented as they relate to MPPEC. Dopamine levels appear to be decreasing with increasing MPPEC, while dopamine receptor levels appears to be increasing.

was a significant interaction between age and MPPEC. Ketamine exposure appeared to have no influence on receptor levels. In contrast, MPPEC, age and ketamine exposure appeared to have no influence on putamen dopamine receptor levels (Table 2).

Striatal Dopamine, DOPAC and Dopamine Receptor Concentrations among Delayed-Dose Animals. Among the six high-dose animals (MPPEC = 260–540 mg/dl) whose ethanol exposure was delayed until the 5th week of gestation, putamen and caudate dopamine levels decreased linearly with increasing MPPEC (Fig. 6 and Table 3). MPPEC explained 95% of the variance in putamen dopamine [$F(1,4) = 83.1$, $p = 0.0008$) and 68% of the variance in caudate dopamine [$F(1,4) = 8.7$, $p = 0.04$]. The putamen and caudate dopamine concentrations for the two delayed-dose animals exposed to MPPECs of 260–264 mg/dl were comparable of 189 to 249 mg/dl *throughout* gestation. Striatal dopamine levels were not influenced by ketamine exposure (9–20 mg/kg) or final age (338–353 days) in the delayed-dose group. This lack of effect is probably due to the narrow range of each of these parameters within this group.

Putamen and caudate dopamine receptor levels (fm/mg protein) appeared to increase with increasing MPPEC among the six delayed-dose animals (Fig. 6 and Table 4). MPPEC explained 74% of the variance in putamen dopamine receptor levels [$F(1,4) = 11.1$, $p = 0.029$] and 88%

$F(2,3) = 10.6, p = 0.04$ $R^2 = 0.86$					

of the variance in caudate dopamine receptor levels [$F(2,3) = 10.6, p = 0.04$]. MPPEC, expressed as a second-order polynomial, provided the best fit of the caudate receptor data. Age and ketamine exposure appeared to have no influence on the striatal dopamine receptor levels in the delayed-dose animals.

DOPAC concentrations were available on five of the six delayed-dose animals. There was no significant correlation between DOPAC and dopamine concentrations in either the putamen or caudate. Scatter plots of DOPAC versus dopamine did, however, suggest that DOPAC concentrations were paralleling dopamine levels in the caudate.

DISCUSSION

Weekly exposure to ethanol during gestation, even very heavy exposure, did not produce obvious structural disorganization of the central nervous system. A number of subtle abnormalities were detected, which could be important clues towards the final delineation of ethanol's effect on the structure and function of the developing brain. The most striking pathologic abnormalities was found in the eyes. Several of the ethanol-exposed animals had ocular anomalies comparable with those recognized in humans with FAS,[11] including asymmetrical microphthalmia in three animals, microcornea in one animal, and marked loss of retinal ganglion cells in five animals. The frequency of ocular abnormalities appeared to increase with increasing MPPEC among both the delayed and full-gestational exposure animals. Ocular abnormalities rarely occurred in both eyes. The discrepancy between eyes may suggest that relatively small windows in gestational time may exist in primate eyes for expression of the deleterious effects of ethanol. This would be analogous to the situation reported in a mouse model for ocular anomalies in FAS.[12] Microcornea and marked retinal ganglion cell loss were observed together in animal 19, exposed to the 1.2 g/kg dose throughout gestation, while microphthalmia and marked retinal ganglion cell loss were only observed together in animal 33 who had been exposed to the very highest level of ethanol exposure after the 5th week of gestation.

Morphometric counts of retinal ganglion cells have not been performed to our knowledge in humans with FAS. All of the animals exposed to ethanol showed at least mild decrease in ganglion cell numbers. This agrees with observations in rats exposed to intrauterine ethanol where mild decreases in numbers of myelinated axons were found in the optic nerve.[13] Although these ganglion cell losses were often mild, there was a very significant difference in frequency of ganglion cell loss between controls and ethanol exposed animals. The reason for marked asymmetry of the counts between the eyes of the same animals is not known.

The loss of retinal ganglion cells should have been associated with laminar abnormalities in the lateral geniculate and the calcarine cortex. Abnormalities in those brain areas were not positively identified but neither were they fully excluded. The technique of single section sampling of brain areas was selected in this project as a

reasonable and cost effective screening procedure. Obvious structural abnormalities were anticipated in some animals as previously reported in humans and nonhuman primates.[14,15] Unfortunately, such a sampling technique cannot reliably distinguish a true subtle defect in laminar structure from an artifact in the angle of section. Serial sectioning of brain areas at high risk for teratogenic alteration should be done in the future if studies of this type are repeated.

We were surprised to find that very high ketamine exposures were associated with decreased dopamine levels. This ketamine effect was independent of prenatal alcohol exposure and age. What appeared to be a "threshold effect" at ketamine doses ≥21 mg/kg contrasts with the results presented by Sung et al. (1973) and Ylitalo et al. (1976),[16,17] who both assessed brain dopamine concentrations following ketamine injection in rats. Ylitalo noted that after injection of 100 mg/kg ketamine intraperitoneally, brain dopamine content was unchanged at 15 min, 1 hr, and five hr after administration. The striatal HVA content, however, was increased by about 55% ($p < 0.05$) at 15 min and 1 hr after administration, suggesting an increased turnover of dopamine. Sung[16] also reported a lack of change in brain dopamine concentrations at 1, 2, 4, and 6 hr after administration of 20 and 40 mg/kg ketamine in rats. He did note, however, that ketamine did affect the rate of decline of dopamine after inhibition of tyrosine hydroxylase with DL-a-methyltyrosine methyl ester hydrochloride (aMT) suggesting that ketamine may increase the rate of dopamine synthesis. In another study using a primate species (*C. aethiops*), Bacopoulos noted that the concentration of dopamine metabolites in brain regions was not altered by doses of 10 mg/kg ketamine.[18] The influence of high ketamine exposure on striatal dopamine concentrations, observed in this study, warrants further investigation.

The striatum receives its dense dopaminergic input primarily from the substantia nigra (nigrostriatal system).[19,20] Although secure identification of the neuron cell bodies in the striatum that evidenced degeneration was not possible, it is probable that these cells received dopamine afferents from the substantia nigra.

Among the animals exposed to MPPECs between 0 and 249 mg/dl throughout gestation, striatal dopamine concentrations appeared to *increase* with increasing MPPEC. In contrast, striatal dopamine concentrations *decreased* with increasing ethanol exposure among the animals in the delayed gestation exposure cohort. In the striata of the delayed gestation exposure cohort, a reciprocal relationship was observed between the concentrations of dopamine and that of dopamine receptors. In the other groups, caudate dopamine receptors increased with increasing dopamine concentrations, but putamen dopamine receptors did not vary at all with dopamine concentration. One might also expect that DOPAC concentration would parallel dopamine concentration. This was found to be the case in putamen measurements in the full gestation exposure cohorts, but not in the caudate. DOPAC did not vary with dopamine exposure in the striata of delayed gestation exposed animals either. No easy explanation for these disparate observations is forthcoming.

It was not anticipated that a teratogen like ethanol would produce abnormally high levels of a neurochemical like dopamine when exposure occurred in one dosing paradigm and abnormally low levels of the same neurochemical when exposure occurred in a different dosing paradigm. Further study into the validity of this observation is necessary. If this observation is confirmed, it may help to explain the clinical diversity in degree and types of behavior and cognitive deficit found in children with alcohol-related birth defects.

In conclusion, this study emphasizes that normal physical features and only subtle neuroanatomic and neurochemical alterations may be associated with abnormal behavioral development in nonhuman primates exposed to ethanol in utero. By extension, the work supports the position that human infants exposed to ethanol in utero cannot safely be said to be "unaffected" because of a normal appearance, normal head circumference, or normal brain imaging study. Further work in delineating infant teratogenic risk from moderate and intermittent ethanol exposure is still vitally needed for maternal counseling and development of appropriate risk categories for infant follow-up.

ACKNOWLEDGMENTS

We are grateful to Cliff Astley for surgical assistance, to Ingrid Klock and Faridah Dahlan for assistance with ocular pathology, to Debra Sherman for assistance with the electron microscopic study, and to Sonja Tijmann for secretarial support.

Holoprosencephaly in a Fetal Macaque *(Macaca nemestrina)* Following Weekly Exposure to Ethanol

JOSEPH R. SIEBERT, SUSAN J. ASTLEY, AND STERLING K. CLARREN
Departments of Pathology (J.R.S.) and Pediatrics (S.J.A., S.K.C.), Child Development and Mental Retardation Center (S.K.C.), Regional Primate Center (S.K.C.), University of Washington, Seattle, Washington 98195

ABSTRACT Previous studies in rodents have indicated that the facial changes of fetal alcohol syndrome (FAS) closely resemble those of a mild form of holoprosencephaly. In order to examine this relationship in non-human primates, we evaluated a 133-day gestation macaque *(Macaca nemestrina)* with holoprosencephaly, median cleft lip and palate, and encephalocele. The mother had been given ethanol once per week (1.8 g/kg body weight) from weeks 2 to 19 postconception. Diagnosis of holoprosencephaly was made following ultrasound evaluation for polyhydramnios and delivery of the female fetus by caesarean section. Another fetus of identical age was delivered by caesarean section for use as a control. Both fetuses were studied by anthropometric, gross, radiographic, and histologic techniques. In the fetus exposed to alcohol, no extracranial anomalies were identified and the karyotype was normal. The brain was micrencephalic, with absent olfactory bulbs, tracts, optic nerves and chiasma, fused frontal lobes, and a single, dilated lateral ventricle; a parietooccipital encephalocele consisted of thin, dysplastic cortex bordering the ventricle; the cerebellum was dysplastic and superiorly displaced. Within the craniofacial complex, anophthalmia was bilateral; premaxillary components were absent, palatal shelves separate, the maxillae closeset, and the ethmoid bone small and deformed. Most of these defects are similar to those encountered in humans with holoprosencephaly and support the hypothesis of shared etiologic and pathogenetic relations between the facial anomalies of fetal alcohol syndrome and holoprosencephaly.

Studies in mice indicate that the changes of fetal alcohol syndrome (FAS) closely resemble those associated with mild forms of holoprosencephaly (Sulik and Johnston, '82; Sulik et al., '84). Several authors have indicated that the frontonasal anomalies in human FAS may also be seen as part of the facial dysmorphology associated with holoprosencephaly (Pfeiffer et al., '79; Jellinger et al., '81; Majewski, '81; Ronen and Andrews, '87). While no consensus has been achieved, the issue remains an important one. To identify alcohol as an etiologic agent responsible for holoprosencephaly in humans would broaden the teratogenic range of alcohol and possibly further the understanding of mechanisms responsible for the development of holoprosencephaly.

CASE REPORT

As part of a continuing study of the teratogenic effect of binge drinking in different periods of gestation, 28 pregnant pigtail macaques *(M. nemestrina)* were randomized to one of four cohorts. Three cohorts received ethanol once per week (1.8 g/kg body weight by nasogastric tube) for the first 3 or 6 weeks of gestation, or for the complete 24-week gestation; the fourth cohort received a sucrose solution that was isocaloric and isovolemic to the ethanol solution. One mother

TABLE 1. Comparison of somatic and craniofacial features[1]

Feature	Exposed	Control
Gestational age (days)	133	133
Sex	Female	Male
Body weight (g)	218	292
Crown-rump length (mm)	135	160
Foot length (mm)	53	60
Head length (mm)	53	63
Head width (mm)	40	49
Outer orbital distance (mm)	23	30
Inner canthal distance (mm)	6	7
Brain weight (g)	24	57

[1]Measures obtained after formalin fixation. See text for discussion.

in the 24-week exposure cohort developed polyhydramnios; her peak plasma ethanol concentration was 211 mg/dl, and she had previously given birth to three normal infants. Ultrasound examination in the 18th week demonstrated maldevelopment in the brain of the fetus. Caesarean section was performed at 133 days gestation and the female fetus died shortly thereafter. A karyotype was subsequently normal. An untreated male fetus of identical gestation (and different mother) was later delivered by caesarean section and used as a control. Both animals were studied by anthropometric, gross, radiographic, and histologic techniques.

RESULTS

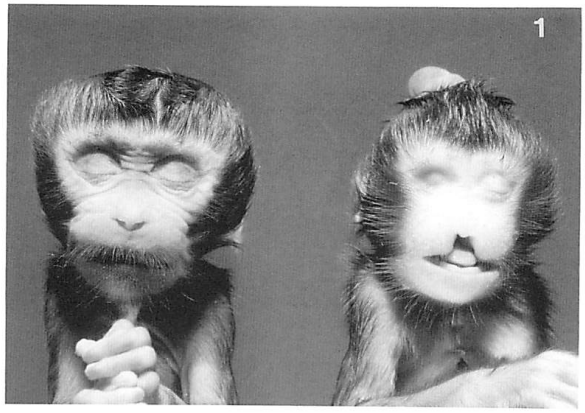
The fetus exposed to alcohol was smaller than the control animal, as evidenced by decreases in body weight, crown-rump length, and foot length; the head was considerably smaller in length and biparietal width, and outer orbital and inner canthal distances were reduced (Table 1). A median cleft lip and palate were evident, the snout was flattened and eyelids asymmetric, and a parietooccipital encephalocele protruded through the calvaria (Figs. 1, 2). Radiographically, the premaxilla and upper central and lateral incisors were absent; the palate was cleft and the ethmoid complex small and deformed; and the medial orbital walls were intact (Fig. 3). A gross dissection of facial tissues revealed absence of the orbicularis oris in the region of the cleft. Histologic examination of the craniofacial complex confirmed the radiographic findings and in addition revealed bilateral anophthalmia; eyelids, conjunctiva, extraocular muscles, glands, and nerves were well-formed and focally edematous (Fig. 4).

The brain of the treated animal was severely microencephalic (Figs. 5, 6; Table 1). The frontal poles were fused and an encephalocele protruded from the convexity; olfactory bulbs, tracts, optic nerves, and chiasma were absent; and the lateral ventricles existed as a large, confluent space which extended to and occasionally ruptured through the cortical surface. In the left temporal pole, a distended subarachnoid space bordered areas of nodular cerebral dysplasia and cortical thinning. A defect in occipital cortex was apparent; the cerebellum and brainstem were displaced superiorly. Microscopic examination showed severe dysplasia of cerebrum and cerebellum.

DISCUSSION

To our knowledge, this is the first report of holoprosencephaly and associated changes of the craniofacial complex in a non-human primate. In addition, only two instances of naturally occurring cleft lip and palate in macaques are known (Hendrickx and Prahalada, '86). One pigtail macaque *(M. nemestrina)* was born at the Regional Primate Center, Seattle, WA, in 1983, and although retarded, lived nearly 3 years; the animal had a novel karyotype (42,XY/43,XY, + variable), termed *mosaic variegated trisomy* (Vigfusson et al., '86). A rhesus monkey *(M. mulatta)* with cleft lip and palate was described by Swindler and Merrill ('71) and likewise survived a number of years, serving as a breeder at the Primate Field Station in Medical Lake, WA. Autopsy information was unavailable for the two animals, but we surmise that neither had holoprosencephaly—at least of the severe variety—because of the length of survival and reasonably intact neurologic function.

The present case manifests a rare form of holoprosencephaly associated with anophthalmia, exencephaly (encephalocele), and anterosuperior displacement of posterior fossa tissues. Anophthalmia has been produced experimentally by a variety of agents, including ethanol, and has been reported in some cases of holoprosencephaly (Hogan and Zimmerman, '62; Warkany, '71; Torczynski et al., '77; Cook et al., '87; Siebert et al., '90). The condition represents a failure of optic vesicle outgrowth or, in holoprosencephaly, damage to prechordal mesoderm or anterior neural plate during or possibly prior to gastrulation. The association of holoprosencephaly and exencephaly/anence-



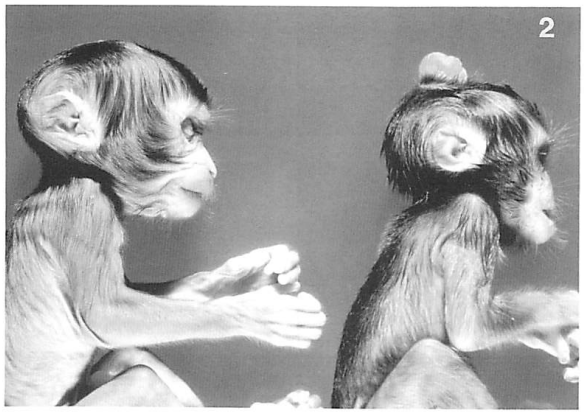


Fig. 1. Frontal view of fetal macaques *(Macaca nemestrina)*. Gestational age of control **(left)** and treated **(right)** animals was 133 days. Median cleft lip and encephalocele are apparent in treated animal.

Fig. 2. Lateral view of control **(left)** and treated **(right)** fetuses. Note encephalocele and flattened snout in the latter animal.

phaly has been reported in a small number of humans, but those individuals had severe deficits in components of the anterior and middle cranial fossae (Lemire et al., '81; Siebert et al., '81). Disruption of posterior fossa tissues probably arose from tethering by the encephalocele during early development. Changes in the craniofacial skeleton of the present case are also considerably milder than those in more severe forms of holoprosencephaly, such as cebocephaly, ethmocephaly, and cyclopia (Kokich et al., '82; Souza et al., '90). Reasons for these differences are unknown, although dosage, time of exposure, nutrition, and genetic predisposition are presumably among the more important factors.

The somatic changes observed in the present case represent a severe reduction in growth that is almost certainly due to the prenatal administration of ethanol. Differences in body size between the treated and

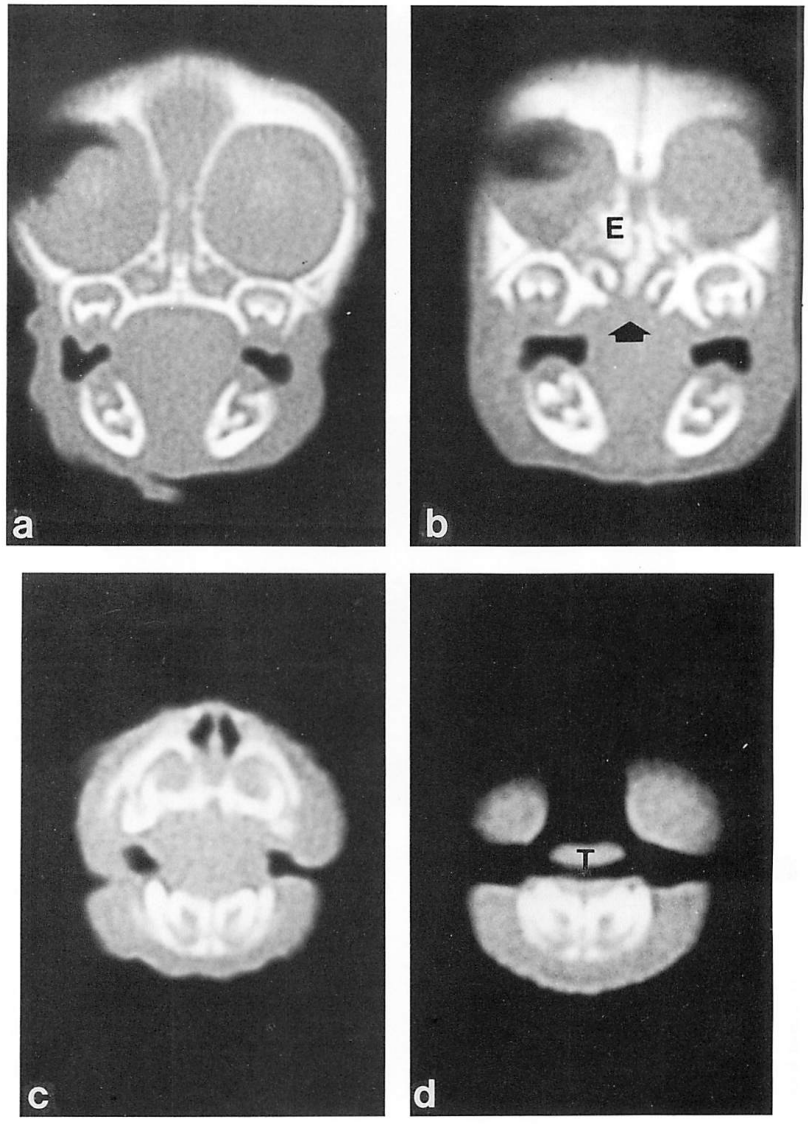

Fig. 3. Computed tomographic scans of control **(a,c)** and treated **(b,d)** fetuses. A dysplastic ethmoid bone (E) and cleft palate (arrow) are visible in b; in d, a median cleft lip, with absent central and lateral incisors, is seen above the tongue (T).

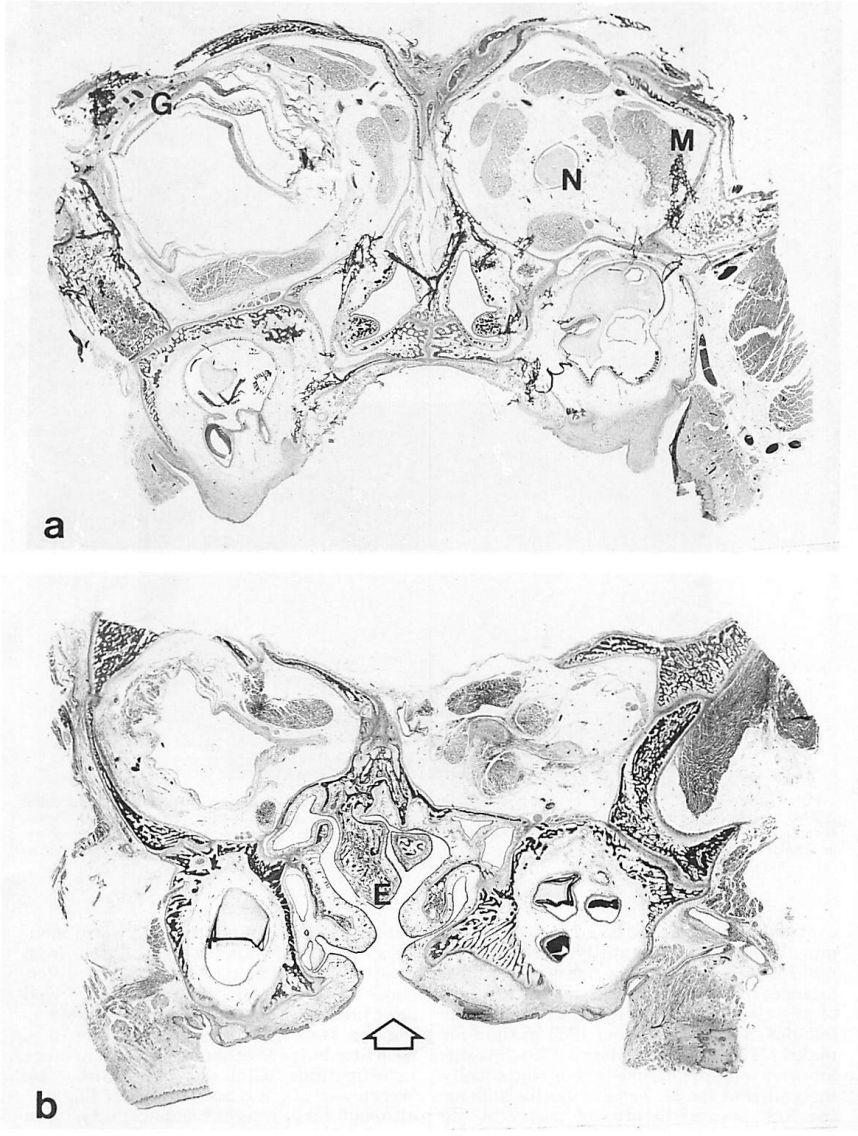

Fig. 4. Microscopic view of the craniofacial complex, sectioned coronally through the orbits, of control (**a**) and treated (**b**) animals. In both, orbital cavities are lined by conjunctiva and contain extraocular muscles (M), nerves (N), and glands (G); serial sections revealed globes in the control animal only. Cleft palate (arrow) and dysplastic ethmoid bone (E) are evident in b. Masson's trichrome stain. Original magnification ×6.

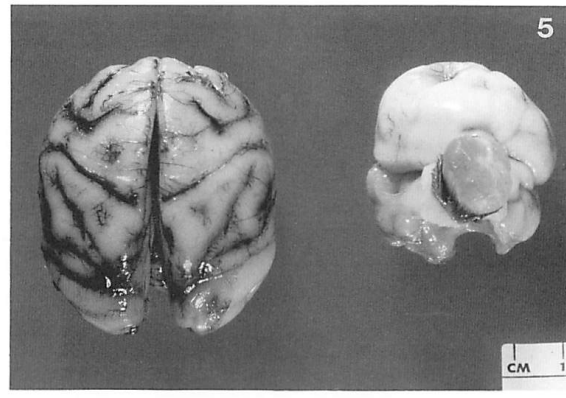

Fig. 5. Superior view of control **(left)** and treated **(right)** brains. Note single frontal lobe (top of figure), encephalocele, and occipital defect in the brain exposed to alcohol.

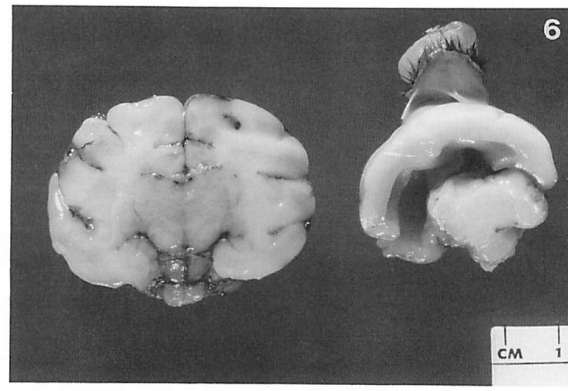

Fig. 6. Coronal sections of control **(left)** and treated **(right)** brains. Encephalocele, fused cerebral cortex, single ventricular cavity, and superiorly displaced cerebellum and brainstem are apparent in the treated brain.

control animals cannot be attributed to sexual dimorphism. Prenatally, male and female *M. nemestrina* show no significant differences in linear measures, and at 133 days of gestation, the expected body weight for females is actually higher (333 g) than for males (313 g) (Newell-Morris, '79). Sex differences remain non-existent or statistically insignificant for *M. nemestrina* throughout the first several months of postnatal life (Sirianni and Swindler, '85). This follows the growth pattern of other old world monkeys, apes, and humans—and differs from most other mammals—in that sex differences fail to become pronounced until well after infancy (Laird, '67; Bogin, '88). Reductions in body and head size at term have been attributed to ethanol exposure in other investigations (Clarren and Smith, '78; Webster et al., '83; Streissguth et al., '85), although birth weight has not always been reduced in macaques exposed to high doses

prenatally (Clarren and Bowden, '82; Bowden et al., '83).

The clinical appearance of the frontonasal complex in mild forms of holoprosencephaly is quite similar to that of FAS. Subtle changes, such as wide inner canthal distance relative to palpebral fissures, short nose relative to midface length, indistinct, elongated philtrum, flat medial midface, and thin vermilion border of the upper lip, as well as the more overt findings of cleft lip and/or palate, are common to both conditions (DeMyer et al., '64; Cohen et al., '71; Jones et al., '73; Clarren and Smith, '78). The midface and anterior cranial base are reduced in both holoprosencephaly and FAS, and associated with choanal narrowing and a hypoplastic ethmoid bone (Johnson, '79; Siebert, '81; Frias et al., '82; Clarren et al., '87). The similarity in phenotypes raises the question of whether the two disorders have a common formative pathway. Put somewhat differently, do subtle anomalies of the frontonasal region (e.g., the facial changes of FAS) represent mild forms of holoprosencephaly? This appears to be the case in the rodent, where the administration of ethanol to pregnant mice produces holoprosencephaly and craniofacial changes equivalent to those in human forms of FAS (Sulik et al., '82; Sulik and Johnston, '83). These observations imply identical or at least overlapping modes of pathogenesis (i.e., Siebert, '83; Siebert et al., '85), although precise mechanisms need to be elucidated.

Previously, diabetes mellitus has been the only non-chromosomal disorder positively associated with holoprosencephaly in humans (Barr et al., '83). Other cases of holoprosencephaly have been associated with maternal alcohol abuse in humans, but only a few have been verified, particularly those reported by Jellinger et al. ('81), Ronen and Andrews ('87), and Bönnemann and Meinecke ('90). In light of the prevalence of FAS, it seems that cases of holoprosencephaly in alcohol-abusing mothers should be more common and easier to document. This is not the case, however. A variety of explanations are possible: It may be that alcohol teratogenesis in non-human primates and humans occurs at highly specific times or dosages. This has been demonstrated in several studies of rodents (Sulik and Johnston, '82; Webster et al., '83; Sulik et al., '85). In addition, Cohen ('89) has pointed out that the comparative rarity of holoprosencephaly in FAS is to be expected, because holoprosencephaly is itself so rare. According to this view, if the prevalence of holoprosencephaly as a fetal alcohol effect were to increase 100 times, it would be observed in only 1 out of every 100–1,000 cases of FAS.

What are the implications of this study for humans? The model demonstrates that a single bolus of alcohol administered weekly initiates teratogenesis in the macaque. In this regard, the experiment mimics binge drinking as it occurs in the human. A dosage of 1.8 g/kg body weight in the macaque is the equivalent of 7 fluid ounces of whiskey, 23 ounces of wine, or 59 ounces of beer in a 55-kg woman (Dubowski, '76). These observations have obvious ramifications for basic scientists, medical workers, and, of course, for society. Despite the accumulating evidence for alcohol teratogenesis, it nevertheless seems unclear if the substance positively causes holoprosencephaly in humans. Both epidemiologic and individual case studies will therefore be necessary to resolve the issue. In the meantime, the appearance of the disorder in rodents and nonhuman primates requires that our suspicions remain high.

ACKNOWLEDGMENTS

Discussions with Doctors Ellsworth C. Alvord, Jr., Denis R. Benjamin, Joel E. Haas, Cheng-Mei Shaw, and Kathy K. Sulik were most valuable. We are also grateful to Suzanne H. Conrad for assistance in ultrasound examinations and to Cliff A. Astley, who provided surgical assistance. This work was supported by U.S. Public Health Service grants AA05616, RR00166, and HD02274.

Analysis of Facial Shape in Children Gestationally Exposed to Marijuana, Alcohol, and/or Cocaine

Susan J. Astley, PhD; Sterling K. Clarren, MD; Ruth E. Little, ScD;
Paul D. Sampson, PhD; and Janet R. Daling, PhD

ABSTRACT. The association between fetal marijuana and/or alcohol exposure and facial features resembling fetal alcohol syndrome was investigated in a sample of 80 children. Standardized lateral and frontal facial photographs were taken of 40 children, 5 to 7 years of age, whose mothers reported frequent use of marijuana during the first trimester of pregnancy and 40 children whose mothers reported no use of marijuana during pregnancy. The marijuana-exposed and unexposed children were group-matched on alcohol exposure prior to and during pregnancy, sex, race, and age at the time of assessment. The photographs were assessed clinically by a study staff dysmorphologist and morphometrically by computerized landmark analysis. Fetal alcohol syndrome-like facial features were not associated with prenatal marijuana exposure in this study sample. No consistent patterns of facial features were identified among the marijuana-exposed group. Maternal consumption of two or more ounces of alcohol per day, on average, in early gestation was found to be associated with fetal alcohol syndrome-like facial features identified both clinically and morphometrically. Cocaine use reported by 13 of the 80 women was independently associated with mild facial dysmorphic features of hypertelorism and midfacial flattening. The results demonstrate the usefulness of this diagnostic technique for quantifying anomalies apparently unique to fetal alcohol syndrome and for targeting clusters of anomalies in new conditions for future evaluation. *Pediatrics* 1992;89:67–77; *marijuana, cocaine, alcohol, facial morphology, fetal alcohol syndrome, fetal exposure.*

Delta-9-tetrahydrocannabinol, the principal psychoactive component of marijuana, is known to cross the placental barrier in humans[1] and therefore has the potential for adversely affecting fetal development. Marijuana is estimated to be used by 1 in every 10 pregnant women. A few studies have presented evidence suggesting an association between fetal marijuana exposure and facial anomalies that resemble those seen in fetal alcohol syndrome (FAS).[2–4] Facial anomalies associated with FAS include a hypoplastic philtrum, thin upper lip, a short nose relative to the midface length, short palpebral fissues, and a flattened maxillary region. The results of these studies suggested that features compatible with FAS may not be specific to alcohol. Small sample sizes, questionable reliability of exposure, other drug use, and/or limited diagnostic sensitivity have precluded drawing firm conclusions from these studies.

In this study, the association between first-trimester fetal marijuana exposure and FAS-like facial anomalies was investigated in photographs of 40 children exposed frequently to marijuana during the first trimester of gestation. The exposure data had been collected prospectively and the association between marijuana and alcohol exposure was effectively eliminated by group-matching. Diagnosis of facial form was assessed clinically by a dysmorphologist and morphometrically by landmark analysis. The sensitivity of the morphometric diagnostic tool has been confirmed in studies of craniofacial malformation[5,6] and has effectively delineated the FAS face in a study sample half the size of the current study population.[4]

METHODS

Subjects

Subjects in the present study were selected from among 1100 mother-infant pairs who participated in a Seattle-based prospective study (1982 through 1987) investigating the effect of maternal diet, drinking, smoking, and marijuana use during lactation on infant growth and development. There were three parts to the original prospective study. First, validity of self-reported alcohol, tobacco, and other drug use and the reliability of the maternal interview process was confirmed.[7,8] Next, descriptive studies were conducted to contrast the dietary habits and alcohol and tobacco use of lactating and nonlactating women.[9–11] And finally, two infant assessment studies were conducted to investigate the influence of alcohol and marijuana use during lactation on infant development at 1 year of age.[12,13]

The subjects' mothers in the original prospective studies were members of Group Health Cooperative of Puget Sound, a Health Maintenance Organization in Seattle, Washington. All prenatal patients receiving care between May 1, 1982, and July 1, 1984, were contracted by the Cooperative in their sixth month of pregnancy regarding possible study participation. Seventy-four percent (5298) of the prenatal patients responded positively and completed a mailed screening questionnaire detailing their alcohol and tobacco use both before and during pregnancy, some dietary information, and their plans to lactate. These patients constituted the screened pool.

A total of 1100 women were selected from the screened pool to participate in one or more of the previous prospective studies. At 6 weeks after delivery, a detailed personal interview was conducted in each woman's home to obtain information on diet, drinking, smoking, and other drug use during pregnancy and the first postpartum month. Additional information on maternal demographics and reproductive history was collected. Similar data were collected in interviews conducted at 3 and 12 months postpartum. Neonatal status (birth weight, birth length, head circumference, gestational age, and Apgar scores at 1 and 5 minutes) was abstracted from the infants' medical records.

Among the 1100 mothers, 61 reported using marijuana at least once per week during the first trimester of pregnancy and 933 reported no use of marijuana at any time during pregnancy. The children of these 61 mothers made up the exposed cohort in the present study. An equal number of children unexposed to marijuana were selected from the group of 933 by group-matching to the exposed cohort on the following characteristics: reported maternal alcohol consumption during the month prior to pregnancy and during pregnancy and the infant's sex, race, and birth date. Group-matching was performed by stratifying the 933 children simultaneously by sex, age (divided into 6-month groups), race (black, nonblack), and maternal alcohol consumption (AA score: absolute ounces of alcohol per day) both before and during pregnancy, grouped as follows ($AA < 0.05$; $0.05 \leq AA \leq 1.9$; and $2.0 \leq AA \leq 4.0$). Matches were randomly selected from the appropriate groups with the aid of a random number chart. Letters of invitation were sent to the 61 exposed subjects regarding possible study participation. Informed consent was obtained after a full explanation of study procedures. When an exposed subject was successfully located and enrolled in the study, a letter of invitation was sent to the mother of a group-matched unexposed subject. Of the 61 marijuana-exposed mother-child pairs who were eligible for participation in the study, we were able to locate and enroll 40.

Data Collection in the Original Prospective Study

Detailed information on maternal use of alcohol, tobacco, marijuana, cocaine, and other licit and illicit drugs during pregnancy was collected by personal interview at 1 month postpartum. Demographic characteristics and obstetric history were also collected. The interviewers were women of childbearing age, trained to obtain valid and reliable information. Information about maternal use of alcohol in the month prior to conception was collected in a mailed screening questionnaire completed during the sixth month of pregnancy. Use of marijuana and/or cocaine in the month prior to pregnancy was not recorded in this study. Validity of self-reported drug use was confirmed in an earlier pilot investigation of 108 randomly selected postpartum women. Self-reported drug use was compared to laboratory tests of drug levels present in body fluids. The proportion of questionable self-reports ranged from 0% to 3% depending on the drug.[7]

Information about maternal use of marijuana and cocaine was recorded in terms of how often the substance was used (days per week) and how many "joints" or "snorts" were taken per day when the substance was being used. This information was recorded for each trimester. Alcohol consumption was categorized into beer, wine, and liquor and was recorded in terms of frequency of use (days per week), modal quantity, and maximum quantity per drinking occasion in the month prior to conception and during each trimester. These measures were converted to average daily ounces of absolute alcohol ingested per day (AA score).[14]

Assessment of Facial Photographs

Photographic Procedure. An informed consent with a full explanation of study procedures was provided for the parent or guardian and an assent form was provided for the child. Facial form was assessed from standardized frontal and lateral facial photographs. The children were between 5 and 7 years of age at the time of the photograph. A placard with the child's study number and a 2-cm rule was included in each photograph to provide a measure of scale. The children were asked to hold a comfortable pose with their mouths closed while the photographer positioned herself to obtain frontal and lateral pictures with no detectable rotation. The photography session took approximately 20 minutes.

A set of 5 × 7- and 2 × 3-inch, black and white prints were made of each frontal and lateral view. The photographs within each set were printed to scale, within 1 mm accuracy, so that distance measures taken directly from the photographs would be comparable across all the subjects. The larger prints were used for digitization of facial landmarks and measuring distances between landmarks while the smaller prints facilitated the clinical evaluation, permitting scanning of the entire group of photographs at one time.

Clinical Assessment of the Photographs. The photographs of all 80 children were examined and scored by the study staff dysmorphologist (S.K.C.). The photographs were first evaluated for the presence of FAS-like facial features and then for any other pattern of anomaly. Specific attention was given to short palpebral fissues, absent or diminished philtrum, thin upper lip, short nose relative to the midface height, and flattening of the maxillary region. The assessments were performed without knowledge of exposure history. The measures recorded from the 5 × 7 photographs of each child include midface height (entrocanthion to upper lip), nose length (entrocanthion to subnasale), intercanthal distance, palpebral fissure length, philtrum and midface contour (scored as "not," "somewhat," or "definitely flat"), upper lip (scored as "not," "somewhat," or "definitely thin"), and ptsosis (present, absent).

Based on the above measures and the dysmorphologist's overall impression of the child's face, each child was classified into one of the following five groups: (1) no unusual features; (2) unusual features, but not the face of FAS; (3) possible FAS-like face; (4) probable FAS-like face; or (5) definite FAS-like face.

Computerized Morphometric Assessment of the Photographs Using Landmark Analysis. A set of 23 facial landmarks were located and marked on the 5 ×.7 photographs of each child (Fig 1, Table 1). These are the same landmarks that were used in the previous study by Clarren et al.[4] The relative location of the 23 landmarks was entered into a data base with the use of a computer digitizing tablet (MacTablet).

An analysis of facial shape was carried out using methods developed by Bookstein.[15-19] The analysis began with the examination of triangles defined by sets of three landmarks; the mean shapes of these triangles were compared between the exposed and unexposed groups. For example, if a short midface was the facial characteristic of interest, then the triangle resulting from the three facial landmarks 1, 4, and 12 might describe that characteristic (Fig 2). The triangle would be standardized by arbitrarily selecting one edge, for example 1-4, as the baseline and assigning it a standard length of one unit on a Cartesian (x, y) coordinate system (Fig 2). The shape of the triangle would be described by the x and y "shape coordinates" of the third landmark (number 12). The x, y shape coordinates for the triangles of each exposed and unexposed subject could then be displayed in a scatterplot and the mean shape coordinates for each group would be computed as the average (or centroid) of the scatter of shape coordinates within each group (Fig 3). In this hypothetical example, the mean location of landmark 12′ for the exposed group is closer to the baseline 1-4 than the mean location of landmark 12 for the unexposed group. Hotelling's T^2 statistic would be used to determine whether this observed difference in mean shape between the two groups of triangles is significant.

After identifying which triangle(s) had significantly different mean shapes between two groups, a description of how the triangles differed was formulated using tensor analysis. The difference in shape between two triangles can be characterized by a pair of directions at 90°: those for which measured distances show the greatest and least relative charge (expansion or contraction). This pair of directions, drawn to depict the magnitude as well as the direction of shape change, are called "tensor axes" (Fig 4). Tensor

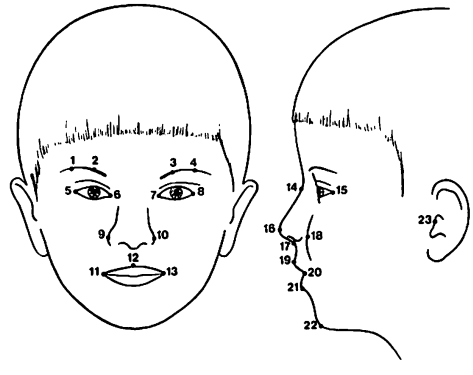

Fig. 1. Twenty-three facial landmarks were identified on the frontal and lateral photographs of each child.[4] The coordinates associated with each landmark were entered into a data base by computer digitization. The landmark definitions are presented in Table 1.

TABLE 1. Definition of the Facial Landmarks*

Landmark	Common Name	Definition
		Frontal view
1, 4		Intersection of the eyebrow curve and a vertical line through the exocanthion
2, 3		Intersection of the eyebrow curve and a vertical line through the midpoint of the palpebral fissure
5, 8	Exocanthion	Lateral intersection of upper and lower eyelids
6, 7	Entrocanthion	Medial intersection of upper and lower eyelids
9, 10		Most lateral points on alar curvature
11, 13	Cheilon	Lateral intersection of upper and lower vermilion
12		Midpoint of upper vermilion border
		Lateral view
14	Nasion	Point of maximum curvature over nasal bridge
15	Exocanthion	Lateral intersection of upper and lower eyelids
16	Pronasale	Point of maximum curvature over nasal tip
17	Subnasale	Intersection of columella and philtrum
18		Point of maximum curvature of soft tissue fold from zygoma
19		Border of upper vermilion and philtrum
20	Cheilon	Lateral intersection of upper and lower vermilion
21		Border of lower vermilion and lower lip
22	Gnathion	Point of maximum curvature of chin
23		External auditory opening

* The facial landmarks are illustrated in Fig. 1.[4]

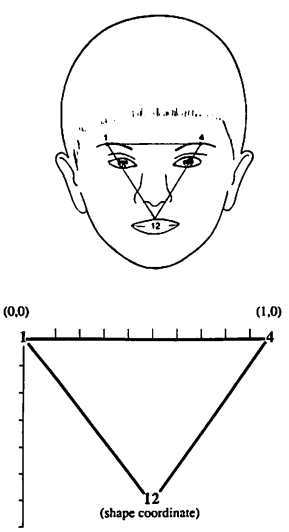

Fig. 2. The triangle formed by the three facial landmarks 1-4-12 is standardized on a cartesian (x, y) coordinate system. Landmark number 12 represents the x, y shape coordinates for this triangle.

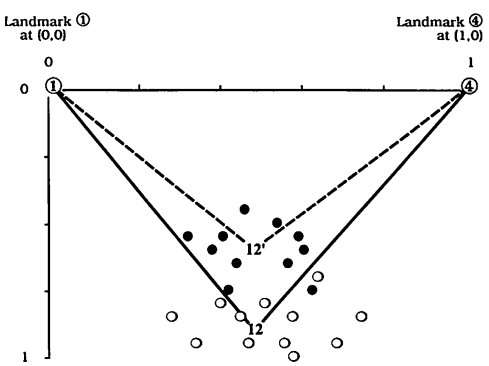

Fig. 3. The shape coordinates (landmark 12) of the exposed (●) and unexposed (O) subjects are displayed as a scatterplot in this hypothetical example. The scatterplot graphically illustrates the position of the midpoint of each child's upper vermilion border (landmark 12) relative to the position of landmarks 1 and 4 on the eyebrows. The *mean* shape coordinates for each group are represented by the average (or centroid) of the scatter of shape coordinates within each group. The locations of the mean shape coordinates for the exposed and unexposed groups are represented by 12′ and 12, respectively. The observed difference in shape between these two mean triangles would be assessed using Hotelling's T^2 statistic.

analysis of landmark data has been described in detail in several publications by Bookstein.[15,16,20] Its application to the study of FAS has also been described.[4,19,21] The use of tensor axes to describe shape change between individual triangles can be extended to describe shape change across the entire set of landmarks using the method of biorthogonal grids.[18,20,22,23] No single triangle of landmarks can be studied independently of the configuration of landmarks around it. Indeed, pictures of tensor axes for triangles can be misleading.[19] Biorthogonal grids (as demonstrated in Fig 8A) depict tensor axes which vary smoothly from place to place over the image. A grid consists of two families of curves which intersect everywhere at 90°. These intersecting curves indicate the directions of greatest (relative) expansion and contraction for a smooth mapping of one landmark configuration into another.

Statistical Analysis

In a previous study,[4] the mean facial shape coordinates associated with triangles 1-4-12, 22-14-19, and 19-23-14 were found to be significantly associated with high levels of prenatal alcohol exposure. These particular triangles were first analyzed to determine whether they differentiated the marijuana- or the alcohol-exposed groups from the unexposed groups in this study. Other triangles, with shapes not so clearly related to FAS, were next evaluated. Because of the exploratory nature of that assessment, formal tests of hypotheses were not emphasized.

The independent and interactive effects of fetal marijuana and alcohol exposure on the x and y coordinate values describing facial shape were assessed by multivariate analysis of variance.[24] Within the context of multivariate analysis of variance, Hotelling's T^2 statistic was used to test explicitly for differences in mean shape between the marijuana- and alcohol-exposed and unexposed groups. To test whether shape changes across all possible triangles, as depicted in the biorthogonal grid, could be described by a simple linear (or homogeneous) model of deformation, another variant of Hotelling's T^2 statistic was used.[19] Under this model, the tensor axes for shape change are the same for all possible triangles.

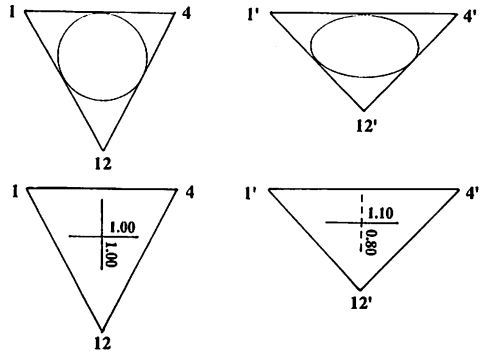

Fig. 4. The transformation of one triangle into another transforms[18] a circle inscribed in the first triangle into an ellipse in the second. The axes (or tensors) of the ellipse, rescaled and oriented homologously in triangle (1-4-12), lie along the directions in which that triangle is most stretched and most compressed by the transformation. The magnitude of the stretching and compression is reflected in the length of the axes. In this hypothetical example, the "deformed" triangle 1'-4'-12' representing the mean shape of the exposed group resulted from a 10% horizontal expansion and a 20% vertical contraction of the "normal" triangle 1-4-12 representing the mean shape of the unexposed group.

Differences in maternal characteristics and infant outcomes between the marijuana- and alcohol-exposed and unexposed groups were evaluated by χ^2 and the t test, where appropriate. Multiple regression analysis was used to evaluate associations between marijuana and alcohol exposure on birth outcome measures and distance measures recorded from the photographs.

RESULTS

Study Population

Of the 61 marijuana-exposed children who were eligible for participation in this study, we were able to locate and enroll 40. These subjects had been last contacted 5 to 7 years previously, when they participated in the original prospective study. Of the 21 mother-child pairs that were not enrolled, 9 could not be located, 2 had moved out of state, 9 were contacted but did not want to participate in the study, and 1 infant had died of sudden infant death syndrome. The mothers of the 40 children who were enrolled in the study differed from the mothers of the 21 children who did not participate in that they were heavier users of marijuana, alcohol, and tobacco and were less likely to have attended college.

From among the 933 eligible nonexposed subjects, the mothers of 70 children were contacted in order to locate and enroll 40 group-matched subjects. Of the 30 subjects who were not enrolled, 24 could not be located, 1 had moved out of state, and 5 expressed no interest in participating in the study. The 40 children with no reported exposure to marijuana were effectively group-matched to the marijuana-exposed group on preconceptional and prenatal alcohol exposure, sex, race, and birth date. Women who reported use of marijuana were, however, more likely to be younger and to be in a lower income bracket and were less likely to be married or to have attended college (Table 2).

Among the 40 marijuana users, 15 reported using marijuana one to two times per week, 11 reported using it three to four times per week, and 14 reported using it every day (Table 3). Fifteen of the women reported smoking marijuana two to five times per day on the days when they used marijuana. The highest reported use of marijuana by one woman was 10 times per day, every day throughout pregnancy to alleviate nausea.

Twelve (15%) of the 80 mothers reported drinking 2 to 4 oz of alcohol per day in the month prior to conception. Ninety-eight percent of the women reported drinking less than ½ oz of alcohol per day during pregnancy. Alcohol consumption prior to and during pregnancy was effectively matched between the marijuana-exposed and unexposed groups (Table 3). Thirteen of the 80 women reported use of cocaine during pregnancy. Cocaine use was more prevalent among the marijuana users.

There were no discernible differences in neonatal status between the marijuana-exposed and unexposed groups (Table 4).

Clinical Assessment of the Photographs

The relationship between maternal use of marijuana in the first trimester of pregnancy and the clinical identification of FAS-like facial characteristics among the children is presented in Table 5. The likelihood of identifying FAS-like facial features among the marijuana-exposed and unexposed groups was essentially the same. Children exposed to marijuana in the first trimester were not more likely to be classified by the dysmorphologist as having FAS-like facial features (as assessed by χ^2). Two children in the marijuana-exposed group were classified as having a probable FAS-like face; the mothers of these children reported consuming 1 or 2 oz of alcohol per day in the month prior to conception. One child in the group unexposed to marijuana was classified as having a probable FAS-like face; the mother had a low AA score in the month prior to pregnancy (0.2 oz/d) but did report two episodes of binge drinking during pregnancy (consumption of five or more drinks per occasion). The lack of association between marijuana and FAS-like facial features was not attributable to differences in sex, race, or age between the two groups. Evaluation of the photographs for facial patterns unrelated to FAS identified a few children with isolated, unusual features but failed to find any consistent patterns that differentiated the marijuana-exposed from the unexposed children.

In contrast, when the 80 children were stratified according to their mother's reported use of alcohol in the month prior to conception, the presence of thin upper lips and somewhat flat philtrums increased in frequency (although not significantly so) with increasing fetal exposure to alcohol (Table 5). It should be noted that maternal use of alcohol in this study population was relatively low compared to the levels of alcohol consumption that have previously been associated with FAS facial features in children. Fetal alcohol syndrome facial alterations have previously been associated with maternal consumption of at least 4 oz of alcohol per day[4,25]; only one child in the current study was exposed to this level of maternal consumption. No child was classified by the dysmor-

phologist as having a definite FAS-like face. The proportion of children classified as having a "probable" FAS-like face increased with increasing maternal consumption of alcohol, but the increase was subtle and could have occurred by chance. Marijuana and cocaine use were equally distributed among the women who reported consuming less than 2 oz of alcohol per day prior to pregnancy and the women who reported consuming 2 oz or more per day.

Computerized Morphometric Assessment of the Photographs

In the present study, the shapes of triangles 1-4-12, 22-14-19, and 23-14-19 (previously found to be associated with prenatal alcohol exposure) did not differentiate, to a statistically significant degree, the children exposed to marijuana during the first trimester from the children with no reported exposure to marijuana during gestation. This lack of association persisted even when the exposed group was restricted to those exposed every day. In addition, we were unable to identify any triangles or patterns of minor abnomalies, not previously related to FAS, that differentiated the marijuana-exposed group from the unexposed group. The apparent lack of association between fetal marijuana exposure and facial dysmorphology in this study was not attributable to differences in sex, race, or age between the exposed and unexposed groups.

Shape differences in two of the three triangles previously associated with fetal alcohol exposure[4] were significantly associated with maternal consumption of alcohol in the month prior to conception *among the male children* in this study. It should be noted that in the present study population, alcohol and cocaine exposure was higher among the boys than the girls (Table 6). The sex of the child was also strongly correlated with facial size in this study population. As a result, it was necessary to perform the computerized morphometric assessment separately on the boys and girls. Upon doing so, the mean shape coordinates associated with triangles 22-14-19 and 19-23-14 were found to differentiate boys whose mothers reported consuming ≥ 2 oz of alcohol per day in the month prior to conception (n = 10) from boys exposed to lower levels of alcohol (n = 38) at modest significance levels ($T^2 = 6.65$, $P = .048$ and $T^2 = 6.33$, $P = .054$, respectively) (Fig 5). The tensor axes for this deformation suggested that boys with higher exposure to alcohol had relatively shorter midfaces. This finding was also evident in the measures of midface height recorded directly from the photographs (Table 7). The size of the study population was too small to stratify the alcohol results by marijuana exposure and perform formal tests of significance. Identification of the marijuana-exposed cases on the scatterplot of shape coordinates did, however, confirm that marijuana exposure was not confounding the apparent alcohol effect.

The shape of triangle 23-21-22 also differentiated the boys whose mothers reported consuming 2 to 4 oz of alcohol per day in the month prior to conception

(n = 10) from the boys whose mothers consumed less than 2 oz per day (n = 38) ($T^2 = 10.02$, $P = .01$) (Fig 6). The deformation in the triangle suggested that higher alcohol exposure was associated with retrognathia.

Triangle 22-14-17 (Fig 7) also differentiated the boys whose mothers reported consuming ≥ 2 oz of alcohol per day in the month prior to conception (n = 10) from the boys exposed to less than 2 oz of alcohol per day (n = 38) ($T^2 = 7.92$, $P = .028$). The direction of deformation in this triangle suggested that relative nose lengths were shorter among the boys exposed to higher levels of alcohol. This triangle did not differentiate between the girls with comparable exposures. This finding was corroborated in the distance measures taken directly from the photographs of all 80 children. When nose length, measured directly from the photographs, was regressed on ounces of alcohol consumed per day in the month prior to conception, a significant inverse relationship was noted (Table 7). The sex of the child also influenced nose length, with boys having longer noses than girls. An interaction term between sex and alcohol suggested that the effect of alcohol on nose length differed among the boys and the girls, which is consistent with the results of the digitized analysis of triangle 22-14-17.

Only 2 of the 32 mothers of girls reported consuming 2 oz or more of alcohol per day in the month prior to conception. Although shape changes were not apparent in our analyses of triangles, the sample size was far too small to draw conclusions.

The tensor axes in Figs 5, 6, and 7 appear similarly oriented. A biorthogonal grid was constructed using mean coordinates of lateral landmarks 14 through 23 to summarize the deformational contrasts between the 10 boys whose mothers reported consuming ≥ 2 oz of alcohol/day in the month prior to conception and the 38 boys with less exposure (Fig 8, A). The change in mean shape, as depicted by the biorthogonal grid, describes a shortening of the midface region, especially along the upper midline and retrusion of the chin, relative to the baseline 14-23. The shifts in the 10 mean landmarks between the exposed

and unexposed groups were parallel and for the most part had magnitudes proportional to their mean distances from the baseline (14-23) as would be expected if the overall shape change between groups was linear (or homogeneous) (Fig 8, B).[19] A significant linear shape change across all 10 landmarks was confirmed (F statistic on 2 and 31 *df* = 4.96, *P* = .013). In addition, an F statistic for nonlinearity was computed (F = 1.08 on 14 and 33 *df*, *P* = .40) confirming that the transformation across all triangles was adequately described by a simple (linear) global model. In other words, the directions of expansion and contraction were relatively consistent across all triangles mapped within the boundaries of these 10 landmarks. The linear component of this model explained 50% of the shape change between the two groups.

In the process of evaluating exposure to cocaine as a potential confounder for the facial patterns associated with alcohol exposure, patterns of facial anomalies associated with cocaine exposure were revealed. The mean shape coordinates associated with triangles 23-14-19, 23-14-17, and 23-14-22, all reflecting midface flattening or retrusion, were found to differentiate boys exposed to cocaine during the first trimester (n = 9) from the boys with no exposure to cocaine during pregnancy (n = 38) at modest significance levels (T^2 = 6.44, *P* = .053; T^2 = 8.78, *P* = .019; T^2 = 7.91, *P* =.028, respectively) (Fig 9). Exposure to cocaine on three or more days throughout gestation

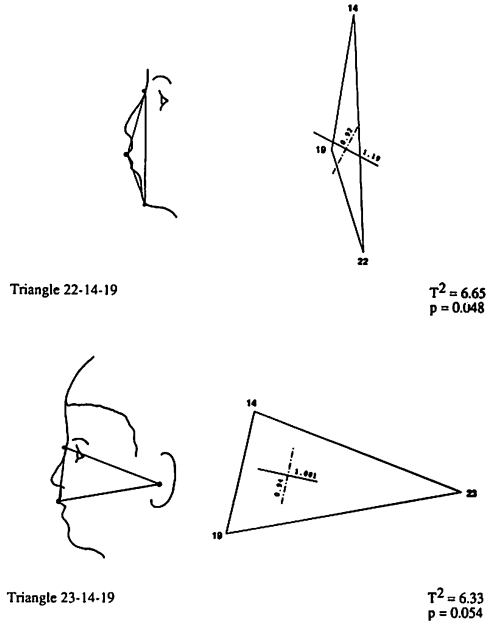

Fig. 5. Two lateral triangles (22-14-19 and 23-14-19) that were found to be associated with prenatal alcohol exposure in a previous study[4] were also found to be associated with fetal alcohol exposure among the boys in the current study. Boys whose mothers reported consuming ≥ 2 oz alcohol/day in the month prior to conception (n = 10) are contrasted with boys whose mothers reported lower alcohol consumption (n = 38).

in 4 boys was associated with increased intercanthal distance relative to palpebral fissure length when compared with the 44 boys with less or no exposure to cocaine ($T^2 = 11.6$, $P = .0065$). Three of these 4 boys received 3 to 9 days of exposure in the first trimester. No associations were observed among the three girls, all of whom were exposed to cocaine only once, in the first trimester. Separate analyses were performed for boys and girls because, as with the alcohol exposure, cocaine exposure was higher among the boys (Table 6) and the sex of the child was strongly associated with facial size. The effects associated with cocaine exposure were not attributable to variation in alcohol, marijuana, or tobacco exposure. The cocaine associations revealed in the landmark analyses were corroborated by the distance measures taken directly from the photographs.

DISCUSSION

In the current study, fetal marijuana exposure was not found to be associated, to a statistically significant extent, with facial features compatible with FAS. A few epidemiologic and clinical studies, however, have presented evidence suggesting an association between prenatal marijuana exposure and the presence of congenital malformations[26-31] or more specifically, features compatible with FAS.[3,4] The inconclusive nature of these reports can be attributed to one or more of the following factors: weak diagnostic sensitivity, questionable reliability of exposure, inadequate sample size, and/or strongly correlated covariates.

Only one of those studies, to our knowledge, reported a significant association between FAS-like facial features and maternal use of marijuana during pregnancy. In that prospective cohort study of 1690 mother-infant pairs, Hingson et al[2] reported that women who smoked marijuana during pregnancy were five times more likely than nonusers (95% confidence interval = 2.0 to 12; $P = .001$) to deliver a child with FAS-like features. The newborns were examined at 2 to 3 days of age by one of four pediatricians who then completed an anomaly checklist. The authors noted that marijuana use in their study population was strongly correlated with alcohol use. The authors also noted that children of women who averaged two or more drinks daily were not more likely to have FAS-like features when compared with children of women who reported no use of alcohol. Their reported lack of association between FAS-like features and maternal consumption of two to four drinks per day is consistent with other clinical studies. Fetal alcohol syndrome-like features are typically associated with chronic maternal alcoholism.[4] Combining the group that reported consuming two to three drinks per day with the group that reported consuming four or more drinks per day may have weakened the association with FAS-like features. In our digitized analysis of facial form, boys whose mothers reported consuming four or more drinks per day (2 oz or more of alcohol per day) prior to concep-

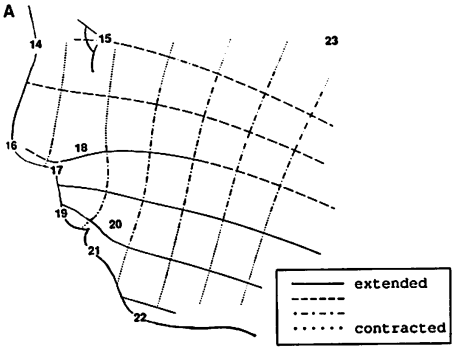

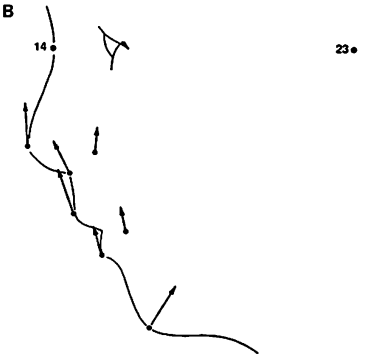

Fig. 8. A, Biorthogonal grid depicting the difference in mean shape between the 10 boys exposed to maternal alcohol consumption of 2 oz or more per day early in pregnancy and the 48 boys exposed to lower levels of maternal alcohol consumption. The grid describes a shortening of the midface region and retrusion of the chin relative to the baseline 14-23. B, Observed shift in the 10 mean lateral landmarks between the exposed and unexposed groups relative to the baseline 23-14.

tion were significantly different from those exposed to lower levels. When the women who reported consuming two drinks per day (1 oz of alcohol) were combined with those who consumed four or more drinks per day, the differences between the two exposure groups (<2 compared with ≥2 drinks) were no longer significant.

In the current study, maternal consumption of as little as 2 oz of alcohol per day, very early in gestation, was associated with FAS-like facial features. Fetal alcohol syndrome-like facial features were not associated with our measures of maternal use of alcohol during pregnancy. Reported use of alcohol during pregnancy was very low in this study population and was comparable in the marijuana-exposed and unexposed groups. Previous studies have suggested that reported use of alcohol in the month prior to conception is a better estimate of the mother's true alcohol consumption during the first 6 to 8 weeks of pregnancy, prior to confirmation of pregnancy. It is during this time period that facial development is most susceptible to teratogens.[32,33]

The deformations depicted by triangles 22-14-19, 22-14-17, 23-14-19, and 23-21-22 and the distance measures recorded directly from the photographs suggested that the children with higher alcohol exposure had shorter noses relative to midface height and were retrognathic. Both of these features are consistent with the FAS facial phenotype. In the current study, the triangular deformations and the distance measures taken directly from the photographs also confirmed that midface length was shorter among the children with higher alcohol exposure. In the literature, the midface is often described as being long relative to the nose. In this study, because all photo-

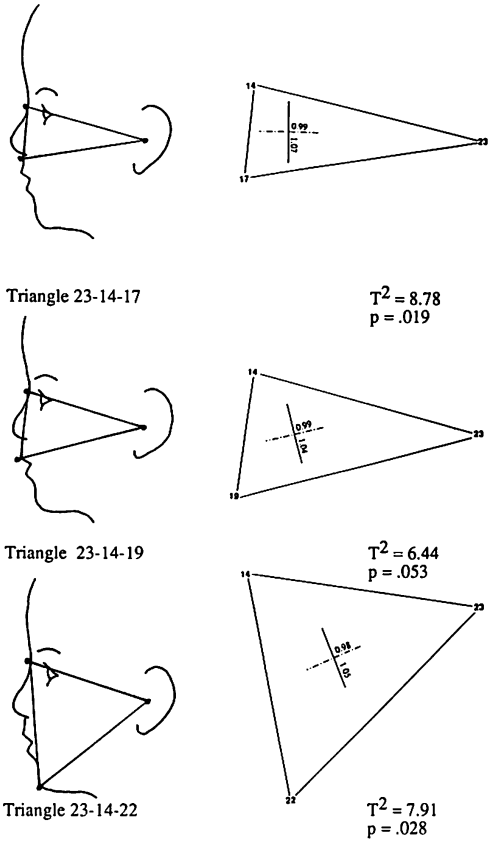

Fig. 9. Midface retrusion associated with first-trimester fetal cocaine exposure among boys. Boys with 1 to 9 days of first-trimester cocaine exposure (n = 9) are contrasted with boys with no cocaine exposure (n = 38).

graphs incorporated a measure of scale, we were able to record real measures of size across all photographs. It appeared that both nose length and midface height decreased with increasing alcohol exposure. In the boys, the mean nose lengths decreased from 3.53 cm to 3.42 cm to 3.25 cm as maternal alcohol consumption increased from (0 to 0.9) to (1 to 1.9) to (2 to 4) oz/d. Correspondingly, mean midface length decreased from 5.51 cm to 5.44 cm to 5.21 cm within each group.

Although triangles 22-14-19 and 23-14-19 were predictive of alcohol exposure in both the current study and the previous study by Clarren and colleagues,[4] it should be noted that the description of shape change for these triangles, as depicted by the directions of the tensor axes, differed. Direct comparisons between the "affected" groups in the two studies cannot be made because of differences in race, sex, and level of alcohol exposure. In the previous study, the group of eight children, among whom significant shape changes were detected, were exposed to 4 oz or more of alcohol per day, were 75% black, and consisted of both boys and girls. A permutation test was used to confirm that there was a significant shape change in these two triangles attributable to ethanol exposure and not to racial differences.

In contrast, in the present study, the group of 10 children among whom significant shape changes were found were exposed to only 2 to 4 oz of alcohol per day and were all boys, and only 10% were black. The shapes of triangles 22-14-19 and 23-14-19 were significantly different between blacks and whites, independent of alcohol exposure. The directions of the tensor axes, attributable to race, roughly match those attributed to alcohol in the previous study. In the current study these two triangles also identify significant contrasts between alcohol-exposed and unexposed groups, independent of race. To determine whether the direction of deformation attributable to alcohol seen in this predominantly white population is the same among a black population, a study sample of exposed and unexposed blacks will need to be assessed.

Two limitations in this study that could have contributed to a false-negative association between marijuana and FAS-like facial features were the reliability of reported drug use and lack of information on use of marijuana in the month prior to conception. Both of these limitations may have resulted in an underestimation of marijuana exposure. In the original prospective study, laboratory drug testing was not performed on all study participants. Instead, validity of self-reported drug use was investigated in a pilot study that preceded the original study. Self-reported drug use was compared to laboratory tests of drug levels present in body fluids in a random sample of 108 postpartum women. The proportion of questionable self-reports ranged from 0% to 3% depending on the drug.[8] These results are encouraging and probably suggest that if drug use has been underreported in this study population, it is unlikely to account for the complete lack of association found between marijuana exposure and FAS-like facial features. Estimating marijuana exposure during the first few weeks of gestation from reports of first trimester use may also have underestimated exposure. Prepregnancy levels of maternal marijuana use may have provided more accurate estimates of fetal exposure in the first 6 to 8 weeks when women are often unaware of their pregnancies. Although actual use of marijuana during the period of facial organogenesis will remain unknown in this study population, a study by Fried and colleagues[34] did find that of three "soft drugs" used by pregnant women (alcohol, nicotine, and marijuana), marijuana use by heavy users was the least reduced between prepregnancy and the first trimester.

To our knowledge, facial alterations associated with fetal cocaine exposure have not been previously reported. The teratogenic potential of cocaine has been documented in both the human[35–37] and animal literature,[38] but contrasting reports do exist.[39–43] Variations in the level and timing of exposure and differences in species susceptibility make it difficult to draw conclusions at this time.

The changes in facial form associated with cocaine exposure in our study population were subtle. Fetal cocaine exposure in this population was associated with increased intercanthal distance and increased midface retrusion. For all practical purposes, these findings would have gone unnoticed. The results should be interpreted cautiously. One cannot infer from the results presented here that fetal cocaine exposure adversely affects craniofacial development. Larger, prospectively designed studies will be required to substantiate these preliminary findings. In light of the prevalence of cocaine use among pregnant women, these preliminary findings strongly support the need for further investigation.

In summary, no dysmorphic facial anomalies were found associated with maternal marijuana use during the first trimester. Several methodologic aspects of this study lend credence to these results. The most sensitive period for the induction of facial malformations lies between the 2nd and 12th weeks of embryonic development.[33] The population we studied received relatively heavy exposure to marijuana during this vulnerable time period. Information on marijuana, alcohol, tobacco, and other drug use during pregnancy was collected prospectively in personal interviews conducted at 1 month postpartum, and the correlation between maternal alcohol and marijuana use during pregnancy was effectively eliminated by group-matching. On the other hand, facial features compatible with FAS were associated with maternal consumption of alcohol in the month prior to conception, substantiating the sensitivity of this diagnostic approach in identifying established syndromal features, even in a relatively small sample.

ACKNOWLEDGMENTS

Funding for this project was provided by the University of Washington Alcohol and Drug Abuse Institute.

We are grateful to Group Health Cooperative of Puget Sound and Children's Hospital and Medical Center in Seattle, Washington, for their assistance with this project. A special thanks is extended to all the mothers and children who participated in the study.

Pregnancy Outcomes After Weekly Oral Administration of Ethanol During Gestation in the Pig-Tailed Macaque: Comparing Early Gestational Exposure to Full Gestational Exposure

STERLING K. CLARREN AND SUSAN J. ASTLEY
Division of Embryology, Teratology and Congenital Defects, Department of Pediatrics (S.K.C., S.J.A.); Regional Primate Research Center (S.K.C.); Child Development and Mental Retardation Center (S.K.C.), University of Washington, Seattle, Washington 98195

ABSTRACT An oral dose of 1.8 g/kg ethanol given once per week throughout gestation to gravid pig-tailed macaques *(Macaca nemestrina)* has been established previously as teratogenic. This study was designed to use this nonhuman primate model to mimic a common problematic human circumstance in which women intermittently abuse alcohol into early pregnancy, realize that they are in fact pregnant, and then want to know the chance that the conceptus is harmed. In order to evaluate this situation, gravid macaques were assigned to one of four dosing cohorts. Animals were given the 1.8 gm/kg dose of ethanol once per week for the first 3, 6, or 24 weeks (full gestation) of pregnancy. Control animals received an isocaloric, isovolemic sucrose solution once per week for 24 weeks. The pregnancies were carefully monitored and the infants were comprehensively evaluated for the first 24 months of life. This paper describes the pregnancies while subsequent papers will describe the infants.

Peak plasma ethanol levels ranged from 175 to 250 mg/dl. Weekly maternal exposure to this intoxicating dose of ethanol, starting early in pregnancy, did not influence risk of pregnancy failure during the first 30 days of gestation but appeared to be associated with an increased risk of abortion occurring between gestational days 30 and 160. Of the pregnancies that were successfully carried to full term, the potentially teratogenic dose of ethanol did not alter pregnancy outcome in any clinically significant way.

INTRODUCTION

Clarren and colleagues reported the development of the first successful binge dosing model for fetal alcohol effects in a nonhuman primate in 1982 (Clarren and Bowden, '82) and then used it to determine the teratogenic threshold for ethanol after once-per-week gestational exposure. The results have been reported in four parts: the methodology and pregnancy outcomes (Clarren et al., '87), the clinical and behavioral assessments of the infants (Clarren et al., '88), a morphometric analysis of the infants' craniofacial shape (Sheller et al., '88) and a neuropathologic and neurochemical assessment of the infants' brains (Clarren et al., '90).

In brief, these studies used gravid female pig-tailed macaques *(Macaca nemestrina)* that were assigned to dosing cohorts and received 0.0, 0.3, 0.6, 1.2, or 1.8 g/kg of ethanol throughout gestation (weeks 1 through 24) or 2.5, 3.3, or 4.1 g/kg of ethanol during weeks 5–24 of gestation (these higher doses were always associated with nonviable pregnancies when given from week 1). The

infants that resulted from these pregnancies were examined clinically, neurologically and morphologically and assessed by a battery of developmental and cognitive tests. It was determined that exposures which produced mean maternal peak plasma ethanol concentrations (MPPEC) above 140 mg/dl were behaviorally teratogenic and resulted in poor performance on at least part of the psychometric test battery. Behavioral teratogenesis was present in the absence of growth or physical anomalies which corroborate observations in humans that isolated behavioral abnormalities may be a fetal alcohol effect (Streissguth et al., '84). In addition, the infant animals with exposure to mean MPPEC above 140 mg/dl from the first week in gestation were much more severely impaired than animals that were not exposed to ethanol until after the fifth week of gestation, even though the maternal peak plasma ethanol concentrations were much higher (260–540 mg/dl). These results could be seen as "good news" and "bad news" for women who drink during pregnancy. The good news would be that behavioral teratogenesis from weekly drinking, a common drinking pattern among women (Wilsnack et al., '84), was only measurable at levels of ≥140 mg/dl. An average-sized female would have to consume approximately six standard drinks (or 3 ounces of absolute alcohol) to reach a peak plasma ethanol concentration of 140 mg/dl. The bad news would be that the first weeks of pregnancy, a period when many women do not suspect that they are pregnant, may be a period of special vulnerability for ethanol induced fetal brain damage.

The current project was conducted to further assess behavioral and physical teratogenesis associated with early, weekly ethanol exposure, followed by later gestational abstinence. The exposure pattern used in this investigation was designed to mimic a common human situation. That is, women who drink in their usual nonpregnancy pattern find themselves several weeks pregnant and then wonder how much damage may have been done and how much recovery or lack of further damage may occur if alcohol consumption is discontinued. The methodology for this project and the pregnancy outcomes are discussed in this paper. The resultant infant animal development will be presented in subsequent papers.

MATERIALS AND METHODS

Twenty-seven adult female pig-tailed macaques *(Macaca nemestrina)* were selected for this project from the breeding colony of the Regional Primate Research Center at the University of Washington. The criteria for selection were identical to those in the previous study (Clarren et al., '87). The dams had to have a normal physical exam, stable weight, normal complete blood count, normal urinalysis, and normal serum laboratory battery. They were between 5 and 15 years of age with a history of producing at least one viable infant in the previous two years with no unusual history of negative pregnancy outcomes (spontaneous abortions, stillbirths or early neonatal deaths). Eleven equally healthy sires were selected for use in this project from the colony's pool of breeding males.

Timed mating was accomplished by breeding the females at peak tumescence of the vulvar tissues, the period of peak fertility in the animal's menstrual cycle. A laparoscopy procedure was performed within 36 hr of breeding to observe a corpus luteum and confirm ovulation. The laparoscope was inserted through a small incision in the abdominal wall after the animal was anesthetized with intramuscular ketamine of 10 mg/kg. The procedure was generally accomplished in 10–20 min, and the animal was usually fully alert after 1 hr.

When ovulation after copulation was positive, the dam was randomly assigned to one of four dosing cohorts and began its weekly receipt of ethanol or sucrose (control) solution. The ethanol dosage of 1.8 g/kg was selected because of its previously established teratogenic potential. One group of dams received the ethanol dose diluted by volume in four parts of water once-per-week throughout gestation (full gestation equals 24 weeks). A second group received a sucrose solution, isocaloric and isovolemic to the ethanol solution, weekly through gestation. The third group received the ethanol solution for the first three weekly doses and then the sucrose solution through week 24, while the fourth group received the ethanol solution for the first six weekly doses and then the sucrose solution through week 24. The breeding, cohort assignment, and dosing continued until at least seven confirmed pregnancies were followed in each cohort.

Dosing was performed exactly as it was in

the previous study with all animals dosed once a week on the same day of the week (Clarren et al., '87). As animals became available for study, they were dosed on the next scheduled dosing day. This method allowed for exposures across all gestational days. As in the previous study, the animals were maintained in individual cages adjacent to compatible animals in rooms with a general low level of activity helping to minimize stress. They were fed 40 biscuits of Purina Monkey Chow once daily at 3:00 PM and supplemented with apple wedges. Leftover biscuits were counted each morning to monitor food intake. There were no problems with food refusal by the animals. On the day prior to dosing, the animal's food was removed at 5:00 PM in preparation for dosing at 8:00 AM the following morning. The food was removed 15 hours prior to dosing to reduce the variability of plasma ethanol uptake and elimination that results from food consumption (Kalhorn et al., '86). On the morning of dosing, each animal was removed from its cage, without sedation, and weighed. The volume of ethanol or sucrose was calculated and prepared. The resting pulse was recorded. The uterine height was estimated by measuring the external abdominal distance between the top of the symphysis pubis and the palpated uterine fundus. The test solution was then slowly and carefully delivered over a 5-min period through a soft nasogastric catheter (8 Fr.). After dosing, the animal was returned to its cage and observed periodically. Food was reintroduced at 5:00 PM on that day.

Pregnancy was confirmed by uterine palpation 30 days after copulation. Negative palpations at 30 days meant that the female had either not become pregnant or had suffered a direct or indirect embryo toxic event. Animals that were pregnant at 30 days continued to receive a weekly dose of ethanol or sucrose solution until a birth or abortion occurred. When a female was rebred in the project, she was randomly assigned to a different dosing cohort. Females were removed from the breeding pool after a maximum of four negative palpations at 30 days presumed gestation or after two positive pregnancies.

When the dams were within 15 days of their estimated date of delivery, they were watched for signs of labor every 30 min around the clock via a closed-circuit video camera. When labor became active, a study staff member was called to attend the birth. A decision to perform a cesarean section was made if the fetus maintained a consistent breech position after 160 days gestation or if the pregnancy went beyond 180 days gestation without any signs of labor.

Pregnancy outcomes were classified, as in the last study, as follows:

1. *Not pregnant at 30 days gestation.* A corpus luteum was observed by laparoscopy within 36 hr of conception, but a negative palpation was recorded at 30 days gestation. This could represent a failure in conception, a failure in implantation, or an early embryo toxic event.
2. *Abortion.* A spontaneous or therapeutic termination of pregnancy from 30 days confirmed gestation to 160 days gestation.
3. *Stillbirth.* Delivery of a nonviable fetus after 160 days gestation.
4. *Breech birth.* A birth resulting in a nonviable infant due to undetected breech positioning.
5. *Viable infant.* A liveborn infant who survived the perinatal period.

Within 1 month postpartum, the rate of ethanol uptake and elimination in plasma was determined for each dam that gave birth to a viable, full-term infant. A plasma ethanol curve was also generated on the dam that gave birth to a 133-day-old fetus with holoprosencephaly. Determination of plasma ethanol levels were delayed until after birth to minimize handling of the animals during pregnancy. A series of blood samples were collected by recapturing the unsedated animals at 40, 100, 120, 150, and 400 min after administration of a single oral dose of 1.8 g/kg of ethanol. Each 1 ml blood sample was mixed with 1 mg EDTA and chilled on ice. Within 1 hr, the plasma from each sample was transferred to a 0.5-ml microcentrifuge tube and stored at −70°C. Plasma ethanol levels were determined by gas chromatography (Baselt, '87) within 24 hr of acquisition.

RESULTS

Eighty-nine breedings in 27 females and 11 males resulted in 35 pregnancies confirmed by palpation at 30 days gestation. The proportion of negative 30-day palpations ranged from 54% to 65% across the four dose cohorts (Table 1). The variation across the cohorts was not statistically sig-

TABLE 1. Pregnancy confirmation at 30 days gestation among pig-tailed macaques undergoing weekly oral exposure to 1.8 g/kg ethanol or sucrose solution

nificant as assessed by ANOVA. The proportion of animals with negative 30-day palpations observed in this study were similar to the proportions observed in the previous study among the animals exposed weekly to ≤1.8 g/kg. They were also comparable to the overall colony rate of 50% for time-mated pregnancies. Of the 54 matings that resulted in negative 30-day palpations, 47 of the females were tumescing (cycling) within 40 days of ovulation, suggesting that the vast majority of the negative palpations were due to failed conceptions prior to maternal exposure to ethanol. The data extend our conclusions from our previous study that the dose of ethanol which produces behavioral teratogenesis is not an early embryo toxic dose.

Seven of the 35 confirmed pregnancies ended in abortion (Table 2). The abortions occurred in five females, all assigned to ethanol cohorts. The abortions occurred on days 66, 75, 81, 84, 85, 99, and 133 of gestation. The dams were exposed to ethanol weekly through gestational days 31, 25, 23, 43, 21, 45, and 131, respectively. In the previous study one in seven (14%) confirmed control pregnancies ended in an abortion as compared with three of nine (33%) pregnancies exposed weekly to 1.8 g/kg throughout pregnancy. In this study, zero of seven control pregnancies ended in abortion, while seven of 28 (25%) pregnancies exposed to ethanol ended in abortion. Although the rate of abortion was higher in the ethanol cohorts in both studies, the sample sizes were small and the contrasts between the ethanol exposed and unexposed groups in each study were not statistically significant as assessed by χ^2.

One of the seven abortions was a therapeutic abortion. A dam in the 24-week cohort was found to be developing polyhydramnios at 124 days gestation. During the evaluation of this problem, a diagnostic ultrasound at 131 days gestation suggested severe hydrocephalus and possible encephalocele. As a result, a therapeutic cesarean section was performed at 133 days gestation; a female fetus with holoprosencephaly, exencephaly, and an unusual face with median cleft lip and premaxillary agenesis was found. This case has been presented in a separate publication (Siebert et al., '91). The mother of that fetus was exposed to 1.8 g/kg ethanol weekly from day 12 through day 131 of pregnancy with a peak plasma ethanol concentration of 211 mg/dl. One other dam in the study was exposed to ethanol on the same days of pregnancy with a postpartum peak plasma ethanol concentration of 209 mg/dl. A full-term viable female infant was born without complication. The dam that gave birth to the fetus with holoprosencephaly had previously given birth to three viable healthy infants, including one female that was assigned to the control cohort in this study. A different sire was involved in each of her four pregnancies.

Of the remaining 28 gravid females, two more experienced complications during pregnancy. One dam in the 3-week cohort gave birth to a nonviable infant because of undetected breech positioning, and one dam in the 24-week cohort developed an adverse reaction to the alcohol or the intubation procedure characterized by an immediate post intubation production of thick oral pharyngeal secretions. Dosing was discontinued in the tenth week of pregnancy after the second adverse reaction. A viable infant was born to this dam and was evaluated devel-

[1]Holoprosencephaly and therapeutic abortion.

opmentally but was not entered into any of the ethanol cohort analyses presented in this manuscript, since the dose exposure was unique.

When the 89 mated pairs were divided into three breeding outcome groups (not pregnant at 30 days gestation, abortions or full-term gestations) maternal and paternal age, parity, gestational age at first exposure to ethanol and mean maternal heart rate during the first 30 days of gestation were comparable across the groups (Table 3). Although all seven monkeys that aborted were exposed to ethanol, the proportion of ethanol exposed monkeys in each of the three breeding outcome groups was not significantly different as assessed by χ^2. Dosing was performed once a week on the same day of each week, resulting in seven different gestational exposure patterns, i.e., animals were dosed on gestational days 1, 8, 15, etc., 2, 9, 16, etc., through pattern 7, 14, 21, etc. The earliest exposure to ethanol took place on the third day of gestation; the latest initial exposure took place on the thirteenth day of gestation. The seven exposure patterns were equally represented in each of the four cohorts. Breeding outcomes appeared to be unrelated to the pattern or initial day or week of ethanol exposure in this small group of animals.

In summary, of the 35 confirmed pregnancies, 26 viable infants were born into the four planned cohorts; seven each into the control, 3-week and 24-week exposure cohorts, and five infants into the 6-week exposure cohort. The mean duration of gestation across the four cohorts ranged from 172 to 177 days; the average for the colony is 171 ± 12 days (Table 4). Mean maternal weight gain during pregnancy appeared to decrease with increasing duration of exposure to ethanol (Table 4). Although there were no significant contrasts between cohorts, there was a significant linear trend (one-way ANOVA: $F = 4.9$, $P = .04$). The dams in the control group experienced an average weight gain of 45%, while the dams in the 3-week cohort experienced a 37% weight gain on average and the dams in the 6- and 24-week cohorts achieved a 32% weight gain on average. All of the animals gained weight far better than colony dams as a whole; the average weight gain in pregnancy in the colony is 13% (G.P. Sackett; personal communication). The birthweight centiles for the colony are generated from all births recorded at the Regional Primate Research Center, adjusted for sex, gestational age, and the generation of the dam in the colony. The colony centiles are generated predominantly from infants whose mothers were group-housed in small family units during pregnancy. The dams in this study were placed under more optimal conditions throughout pregnancy, i.e., single-cage housing in a low stress environment with daily monitoring of food consumption. Birthweight centiles would be expected to be higher under these conditions, but not necessarily as high as those observed. The slower weight gain was unrelated to food consumption, maternal age, parity, prepregnancy weight, length of gestation, infant sex, or birthweight.

Among the 26 pregnancies that resulted in viable infants, the mean maternal heart rate throughout pregnancy, across all four cohorts was 148 ± 16 beats per minute (bpm) (Table 4). Maternal heart rates were typically higher during the first few weeks of handling (199 ± 38 bpm) but were comparable across the four cohorts and reduced considerably as the animals became familiar with the dosing procedure. Neither the animals' heart rates nor physical demeanor suggested that the weekly dosing, without sedation, was particularly stressful. For

comparison, the mean heart rate of ketamine sedated gravid *Macaca nemestrina* (N = 268), housed under identical conditions with no experimental intervention was 175 ± 30 beats per minute (G.P. Sackett: personal communication).

The plasma ethanol curves demonstrated that the animals achieved peak plasma ethanol concentrations of 175–250 mg/dl, with a mean of 223 ± 28 mg/dl (Table 4). Peaks occurred as anticipated about 120 min after ingestion (Fig. 1). The rates of ethanol uptake and elimination were comparable across all exposed animals and were comparable to the plasma ethanol curves generated from the gravid animals in the previ-

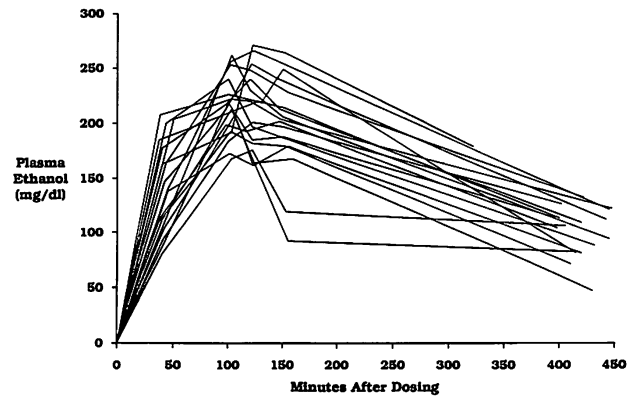

Fig. 1. Plasma ethanol uptake and elimination following a single oral dose of 1.8 g/kg ethanol in each dam that gave birth to a liveborn infant. Plasma ethanol levels were determined within 1 month postpartum.

ous study (Clarren et al., '87) that received 1.8 g/kg ethanol weekly throughout gestation. Most plasma ethanol concentrations remained above 100 mg/dl 400 min after dosing (mean = 104 ± 28 mg/dl across all exposed animals). We chose to monitor plasma ethanol uptake and elimination in the postpartum period to minimize handling of the animals during pregnancy. To confirm that the plasma ethanol curves during the pre- and postpartum periods were comparable, three animals who had plasma ethanol levels measured during pregnancy in the previous study were available during the present study (three years later) for measurement of plasma ethanol levels in the nonpregnant state (Fig. 2). The animals were given a single dose of 1.8 or 2.5 g/kg ethanol to match the dose they received in the previous study. The plasma ethanol levels measured during and after pregnancy overlapped remarkably, suggesting that postpartum measures of plasma ethanol levels may be used as valid estimations of plasma ethanol levels during pregnancy.

DISCUSSION

The primary purpose of this research project was to evaluate ethanol teratogenesis in nonhuman primate infants. The data in this paper are presented to assure the reader that alternate causes for anomaly in these gestations were considered and controlled.

These results confirm and extend our observations from previous work (Clarren et al., '87) that weekly maternal exposure to an intoxicating dose of ethanol (1.8 g/kg), starting early in pregnancy, did not influence the risk of pregnancy failure in the first 30 days of gestation but appeared to be associated with an increased risk of abortion occurring between gestational days 30 and 160. Of the pregnancies that were successfully carried to full term, the potentially teratogenic dose of ethanol did not alter pregnancy outcome in any clinically significant way. There was a statistically significant decrease in the rate of maternal weight gain with increasing duration of exposure, but the mean weight gains in each of the four exposure groups still far exceeded the average maternal weight gain during pregnancy among colony animals. There was no other clinical evidence of maternal ill health or toxicity. No clear explanation for this observation was forth coming.

Theoretically, embryonic exposure to a teratogenic substance in the early implantation period should cause such ubiquitous damage that abortion rather than malformation would be the expected outcome. Following this line of reasoning, some clinicians may have reassured women that if

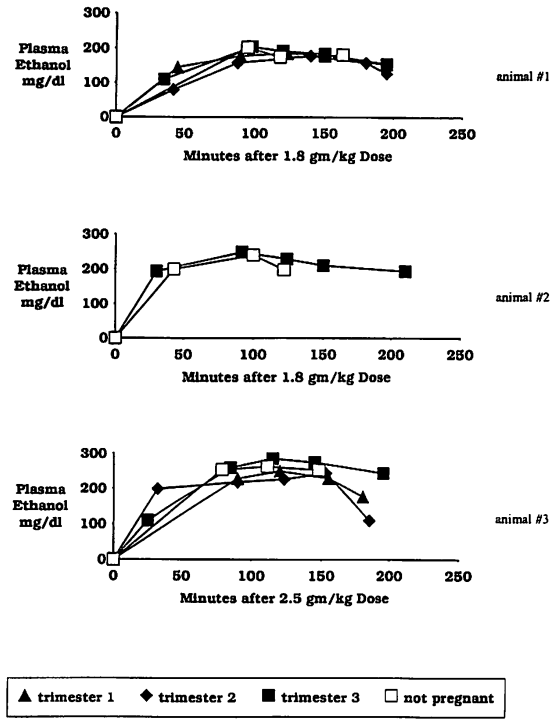

Fig. 2. Plasma ethanol uptake and elimination during and after pregnancy in three pig-tailed macaques *(Macaca nemestrina)* after a single oral dose of 1.8 or 2.5 g/kg ethanol.

they stopped drinking within a few weeks of conception and continued to carry their fetus it was likely that the environmental substance had not produced a teratogenic effect. The data in the present study do not wholly support this type of advice. The apparent increased risk of abortion among these ethanol exposed animals is consistent with the concept of abortion as a teratogenic outcome after early gestational exposure and is consistent with several epidemiologic reports (Harlap and Shiono, '80; Sokol et al., '86; Kline et al., '80). On the other hand, success in carrying a pregnancy to full term does not confirm that the infant has escaped the teratogenic impact of the early gestational exposure. As will be shown in the next paper in this series summarizing infant outcomes, early gestational exposure followed by later gestational abstinence did lead to significant cognitive/behavioral teratogenesis in the offspring.

ACKNOWLEDGMENTS

We wish to thank Mark Murchison and the entire staff of the Regional Primate Research Center's Field Station in Medical Lake, Washington, for their help in the selection and breeding of the animals. Special thanks is extended to Rick Shain and Jerome Gray at the Regional Primate Research Center (RPRC) in Seattle, Washington, for

their knowledgeable and compassionate handling of the adult animals during dosing. We thank Dr. Suzanne H. Conrad for performing the fetal ultrasound and Cliff Astley, RPRC staff surgeon, for performing the caesarian sections. This study was supported by USPHS grant AA05616.

Critical Gestational Periods and Threshold Doses for Ethanol Teratogenesis

Sterling K. Clarren, M.D., and Susan J. Astley, Ph.D.
Children's Hospital and Medical Center, University of Washington

Fetal toxicity or teratogenicity involves the passage of substances and/or their metabolites through the gravid female into the developing embryo or fetus. The teratogenic process can be measured by increased fetal wastage and as abnormal outcomes in surviving infants such as overall growth deficiency, major or minor malformations, or central nervous system dysfunction (defined by neurologic, cognitive, or behavioral aberration). These abnormal outcome measures vary in their specificity for the embryo/fetus as compared to the child or adult. Malformation is a unique embryonic response to toxicity. Alterations in growth could occur as a toxic response in the fetal period as well as throughout childhood. Brain dysfunction might occur after toxic exposure at any age. The mechanisms of teratogenesis involve disruption in a series of growth-related activities which are seemingly unique to the prenatal period of life. Organogenesis involves primary cellular differentiations, cellular inductions, cell interactions, secondary cellular differentiations, cell migration, cellular proliferation, and selective cell death.

Teratogenesis might occur through disruption in any or all of these systems globally or in specific embryonic developmental fields. These disruptions might occur through inner cellular mechanisms altering protein synthesis or regulation, or at the level of the cell membranes. Alternatively, disruption could occur through secondary mechanisms like aberrations in placental/fetal blood flow or deranged hormonal balance. The teratogenic potential of a substance to produce anomalies through interference in one or more of these tasks of organogenesis is determined by dosage and mediated through gestational timing of exposure, rates of maternal and fetal metabolism, and possibly by genetic "resistance" of the fetus to the teratogen.

Ethyl alcohol is now well established as a mammalian teratogen. In humans, ethanol can produce all types of teratogenic outcomes: fetal wastage, growth deficiency, major and minor malformations, and neurologic, cognitive, and behavioral dysfunction. One specific ethanol-related teratogenic outcome is fetal alcohol syndrome (FAS), in which growth deficiency for height and weight, brain dysfunction, and a specific set of minor anomalies of the face are combined (Clarren and Smith 1978).

FAS was first described in the early 1970s (Jones et al. 1973). Since then, numerous studies in man and animals have demonstrated that FAS is invariably linked to in utero exposure to ethanol and its metabolites and not to other possible problems in the alcoholic milieu, such as nutritional deficits, smoking, vitamin deficiencies, other substances of abuse, etc. (Schenker et al. 1990). Still, dose-response information for ethanol teratogenesis in human gestation has developed very slowly, and very little is yet known about the precise mechanisms of ethanol teratogenesis.

The study of these basic questions in man has been hampered for numerous reasons. Fetal dose exposure can only be roughly approximated in humans from maternal consumption histories. Even if women can accurately remember the amounts of alcohol consumed during pregnancy, it is essentially impossible to relate this consumption to exact timing in gestation. Further, peak blood alcohol concentrations and rates of ethanol metabolism and excretion will vary and will depend on the rate of consumption, the size (weight) of the mother, the coconsumption of food, the mother's genetic determinants for ethanol metabolism, the existence of liver disease, and day-to-day variations in alcohol metabolism.

Measurement of fetal response to ethanol may be as problematic as accurate measurement of exposure. Determining growth dysfunction or the presence of major malformations is relatively straightforward, but minor malformations may be overlooked or poorly described. It often takes years of careful and extensive sequential testing with appropriate controls before it is clear that an individual has subtle but important aberrations in attention or learning abilities that represent alcohol-related birth defects. The ultimate study of mechanisms of ethanol teratogenesis in humans would require the sequential analysis of affected embryos and fetuses—a situation that is and will remain impossible for all practical purposes.

Over the last decade many small-laboratory-animal models have been developed for ethanol teratogenesis. Models like those developed by West et al. (1990) or Riley (1990) have been used to develop dose-response data and will be used in the future to study the mechanisms of teratogenesis. Yet rodents metabolize ethanol much more rapidly than humans, their gestations are far more rapid, and their brains far less complex. In order to verify that these models are in fact assessing systems that are analogous to humans, a nonhuman primate model can be used.

Methods and Results

We have developed a model for ethanol teratogenesis in the pigtailed macaque *(Macaca nemestrina)* and have used this model to study dose-response principally for brain dysfunction after weekly gestational exposure and the neuroanatomic and neurochemical underpinnings of this dysfunction (Clarren and Bowden 1982).

Our initial studies involved the oral administration of ethanol once per week to gravid pigtailed macaques in doses of 0.3, 0.6, 1.2, 2.5, 3.3, or 4.1 g/kg. A

control group received a sucrose solution which was isocaloric and isovolemic to the highest ethanol dose. Pregnancy was followed after 116 possible timed matings in 54 females.

The pregnancies were carefully monitored such that the control pregnancies and alcohol-exposed pregnancies were similar in all ways except exposure. The day before each dosing session the animals were weighed and the volume of ethanol or sucrose solution was calculated. The animals were denied access to food after 5:00 p.m. in preparation for dosing at 8:00 a.m. the next morning. At dosing, each unsedated animal was brought from its cage and examined. The resting pulse was recorded and the uterine height was measured. The test solution was then slowly delivered via a soft nasogastric tube. The animal was then returned to its cage. Once in every 8 weeks of the 24-week gestation, the dosing procedure was followed by a series of blood samples drawn by femoral venipuncture to determine the curve of ethanol metabolism. In the animals given 0.3 or 0.6 g/kg of ethanol, the animals were recaptured such that blood samples could be obtained 2, 10, 30, 60, and 150 minutes after dosing. In animals given 1.2, 1.8, or 2.5 g/kg of ethanol, blood samples were obtained at 30, 90, 120, 150, and 210 minutes after dosing. In the animals receiving 3.3 or 4.1 g/kg ethanol doses, the blood samples were obtained 30, 90, 120, 150, and 300 minutes after dosing. The samples were spaced so that the peak plasma ethanol concentration (PPEC) could be reasonably established with a reasonable amount of animal handling.

The timing of gestation was established by a laparoscopic finding of a corpus luteum within 36 hours of mating and confirmation of pregnancy by palpation at 30 days gestation. A positive laparoscopic evaluation and subsequent negative 30-day palpation would have indicated a "pregnancy failure" possibly due to a failure in conception, an early embryotoxic event, or an implantation failure. Any spontaneous termination of pregnancy from the time of positive palpation at 30 days to 160 days gestation was called a "spontaneous abortion" in this study while the delivery of a nonviable fetus after 160 days gestation was termed a "stillbirth."

The pregnancy failure rates among animals receiving between 0.3 and 1.8 g/kg of ethanol varied from 36% to 67%. These rates were not statistically different from the study control cases. At the 2.5 g/kg dose and above, no viable infants were produced (Tables 1 and 2). In order to bring some animals to term at these higher dose exposures, a second dose exposure pattern was established in which dosing was delayed until the sixth week in pregnancy and then a dose of 2.5, 3.3, or 4.1 g/kg was given weekly. There was no significant increase in spontaneous abortions from confirmation of pregnancy to term in any group except the group receiving the delayed 4.1 g/kg dose, in which 80% of pregnancies ended in abortion ($p = .008$, binomial test). However, it was noted that among control animals and those with ethanol doses of 1.2 g/kg or less (PPEC $\leq$161 mg/dL), only two of 27 (7%) animals aborted while nine of 21 (43%) animals aborted with PPECs above these levels.

Table 1. Pregnancy failure at 30 days gestation in pigtailed macaques after weekly exposure to ethanol

Dose assignment (g/kg ethanol)	Dams bred (*n*)	30-day pregnancy failures	
		n	%
Delayed dose[a]	23	12	52
Sucrose treated	14	7	50
0.3	21	14	67
0.6	16	9	56
1.2	15	9	60
1.8	14	5	36
2.5	6	5	83
4.1	7	7*	100

[a]No exposure to alcohol or sucrose within the first 30 days of gestation.
*$p = 0.008$ (binomial test).

Table 2. Pregnancy outcome after confirmation of pregnancy in pigtailed macaques undergoing weekly exposure to ethanol

Dose cohorts *(g/kg ethanol)*	Confirmed pregnancies	Spontaneous abortions	Breech stillbirths	Viable infants
Sucrose control	7	1	1	5
0.3	7	—	—	7
0.6	7	1	—	6
1.2	6	—	1	5
1.8	9	3	2	4
2.5	1	1	—	—
2.5[a]	3	1	—	2
3.3[a]	3	—	—	3
4.1[a]	5	4*	—	1
Totals	48	11	4	33

[a] Delayed dose, i.e., no exposure to alcohol in the first 30 days of gestation.
*$p = 0.002$ (binomial test).

Among the female macaques who carried their infants to term, ethanol was well tolerated. Even at the very high 4.1 g/kg exposures, which resulted in PPECs above 500 mg/dL, the animals never became ill or comatose. Rather, the animals would simply sit quietly in their cages after dosing until later on in the day, when they would return to their usual behavior patterns. Aside from the day of dosing, the animals ate normally and gained weight normally through gestation. No serious illness occurred.

When the animals were within 15 days of their estimated full term gestation (172 days), they were transferred to a labor and delivery suite where they were monitored for signs of labor every 30 minutes around the clock by closed-circuit television. When signs of active labor were observed, a member of the delivery team was called to attend the birth.

A total of 33 live-born infant macaques resulted from 48 confirmed pregnancies in 116 matings. Twenty-seven of the animals had been exposed to sucrose or an ethanol solution each week from week 1 to week 24 of pregnancy and were

referred to as FGE (full gestational exposure) animals. Six additional animals had been exposed to the even more substantial ethanol solutions from week 6 to week 24 of pregnancy and were referred to as DGE (delayed gestational exposure) animals.

Each animal was extensively assessed for growth, malformation, and brain function on a battery of tests which extended over the first 6 months of life. Then, at 6 months, each animal was sacrificed so that another battery of neuroanatomic and neurochemical studies could be carried out. While the results of these assessments are summarized here, they are discussed in more detail elsewhere (Clarren et al. 1988, Sheller et al. 1988, Clarren et al. 1990).

The newborn infant exam included ascertaining the Simian Apgar score at 5 and 10 minutes after birth. Additionally, the infants were assessed for rooting, sucking, grasping, eye blinking, and righting reflexes. Birth weight was recorded.

The morning after delivery, a more thorough physical examination of the infant was performed which included measurements of body proportion, pigmentation, head molding, fontanelle size, overriding sutures, facial symmetry, and tooth eruption. Food intake and signs of ill health like sudden fluctuations in weight, diarrhea, or temperaments were noted daily. Each infant had at least one thorough examination for major and minor anomalies by a dysmorphologist.

In addition to regular weights, each animal was measured at regular intervals for foot length, crown rump length, and head length, width, and circumference. Standard frontal and lateral cephalometric radiographs and photographs were obtained at 1 and 6 months of age.

The animals were initially housed in isolettes and weaned to individual cages in a large general infant animal housing suite. Each animal was housed with a parental surrogate (a diaper) until 140 postnatal days of age. There was a daily social experience with a group of like-aged peers in an observation playroom.

Six infant developmental/behavioral measures were employed. Assessments requiring subjective ranking of behavior and/or performance were conducted by testers for whom inter- and intraobserver reliability was high. All testers were blind to the infants' alcohol exposure. The following tests were included:

Neonatal reflex assessments included noting resistance to passive movement of limbs, the strength of grasping, and the presence or absence of the rooting, sucking, and snorting reflexes; observing the infants' auditory startle response, visual orientation and tracking, and the onset of species-specific facial expressions; and testing the leg and arm placing reflex and the clasping and righting reflexes. This assessment was made on the day after birth and twice a week thereafter for 3 weeks.

Nutritive sucking capability was measured from birth to 9 days of age through a device which established the age at which the infant was capable of sucking, the total number of sucks per session, and mean length, amplitude, and velocity of each suck.

The *Object Permanence Assessment* documented the development of object permanence conceptualization from weeks 2–16 based on the procedure devel-

oped by Piaget for human infants (Flavell 1977). The procedure measured the infant's ability to locate and grasp an object (toy) and then, at a later age, the ability to locate the object under conditions of full view, partial hiding, and full hiding behind a screen or in a covered well.

The *Wisconsin General Testing Apparatus* was used to measure early infant learning strategies from 4 to 6 months of age (Harlow 1959). The tests measure an infant's ability to form a systematic pattern of responses while searching for a hidden reward either under or within colored boxes. The tests become more challenging with age.

The *Visual Recognition Memory* test was developed as an early measure of infant intelligence, documenting memory development in the first months of life (Fagan 1977). Visual recognition is measured by recording the proportion of time an infant visually fixates on a familiar object rather than novel two-dimensional abstract patterns. Preferential fixation on a novel pattern demonstrates that an infant can distinguish between two patterns and can remember a pattern previously seen. Human and nonhuman primate infants at risk for intellectual impairment have been shown to direct a lower proportion of their looking time to novel stimuli than do normal infants (Fagan and Singer 1983, Gunderson et al. 1987). Several studies have demonstrated a strong correlation between early visual recognition memory and later cognitive development (Fagan and McGrath 1981, Rose and Wallace 1985).

Playroom motor and behavioral observations were used to further document motor and social development. At 15 days of age the infants were entered into social groups and played daily in a playroom under observation. Motor, postural, and special communication behaviors involving the ability to sit, stand, walk, climb, and display various postures and facial expressions were observed in response to other monkeys and to various apparati in the playroom (Sackett et al. 1976).

Data analysis for each assessment was approached in two ways. First, dose-response relationships between the independent variable (maternal PPEC) and the numerous dependent variables including gestational length, growth parameters (weight, height, head circumference), and the scores for each measure for each of the six developmental tests were analyzed by linear regression. All variables were measured on continuous scales. In addition, comparisons to dose cohort measures for each dependent variable were performed with one-way ANOVA. Since this approach could identify only very robust effects in this small data set, a second approach was employed which identified individual animals with delayed performance for each dependent variable. Delayed individuals were detected by transforming each infant's raw score into a normally standardized Z score. Delayed individuals were defined as those infants with measured scores greater than 2.57 standard deviations (beyond the 99% confidence interval) from the overall mean of the unexposed infants. The tests were scored and the decision made to define an animal as delayed without knowledge of the subject's exposure.

The results of these studies are presented in Figure 1. Each animal is identified

Figure 1. Individual deviations on physical, growth, and developmental parameters are compared in infant macaques exposed to ethanol in utero. Definitions for deviation as denoted by a blackened or half-blackened circle are found in the text. Empty circles indicate normal results, and empty spaces indicate missing or incomplete data (from Clarren et al. 1990).

by individual number, dose cohort, and mean maternal PPEC. While the ethanol exposure in each cohort increased in step increments, variation in maternal metabolism of ethanol produced a continuous array of PPECs. An empty circle on the figure means that a test was completed with normal results, a half-blackened circle means abnormality of approximately 1.5 to 2.5 standard deviations from control means, and a fully blackened circle means deviation beyond 2.5 standard deviations.

Four animals were noted to be neurologically impaired: animals 19, 25, 28, and 33. Animal 19 had four brief grand mal seizures without a metabolic or infectious etiology. The other three animals identified with half-blackened circles in the "neurologic" column had strabismus. Spontaneous seizures are very rare in colony infants and have occurred 0.7% of the time. The chance of one infant in 33 having seizures is 12%. Chernick et al. (1983) described electroencephalogram changes as frequent in human infants exposed to moderate- or high-dose ethanol in utero. Transient infantile strabismus occurs spontaneously in 4% of colony infants. The three affected infants in this study represent 9% of all study infants or 33% of DGE infants and 4% of FGE infants. Strabismus is noted in FAS infants. Further work will be needed before these neurologic abnormalities can be conclusively related to in utero ethanol exposure in this model.

No control animal had any major or minor dysmorphic features. Single minor anomalies were found in three FGE infants and two minor anomalies were found in one DGE infant. This is probably random variation. Only one animal, 25, had a cluster of three minor anomalies typically observed in humans with fetal alcohol syndrome. The anomalies in that animal were carefully evaluated through radiographic morphometric analysis and are described elsewhere (Sheller et al. 1988).

Only animal 33, the lone surviving infant of the DGE 4.1 g/kg dose group (mean maternal PPEC = 539 mg/dL), was growth deficient and microcephalic. The microcephaly was proportionate to body weight. Morphometric analysis performed on cranial radiographs showed that animals exposed to high doses of gestational ethanol had, on average, slightly smaller and distorted crania than control animals (mean two-dimensional cranial area reduced by 1.7% in FGE, 1.8 g/kg animals and DGE animals compared to controls).

No single test of development selected a large group of animals as abnormal, nor were any cohort effects found through analysis of single assessments. However, when the individual animals were assigned individual scores for deviation and plotted on Figure 1, it became clear that the test battery when taken as a whole identified all FGE animals with mean maternal PPEC above 140 mg/dL and three of six DGE animals as abnormal compared to control and lower FGE exposed animals. The scoring of the cognitive/developmental test had been done as follows:

The Object Permanence Assessment was scored using postnatal and postconception age to criterion and number of test sessions to reach criterion. Animals 22, 24, and 25 had consistent delays by all three scoring systems and received full blackened dots.

Four animals, 8, 9, 18, and 24 were delayed significantly on the Wisconsin General Testing Apparatus in completing one or two tasks within this test sequence but were able to complete the full set of nine tasks before 6 months of age. These animals were assigned half-blackened circles. Four other animals, 21, 25, 27, and 30, were so delayed on early Wisconsin tasks that they could not complete the test set by the end of the testing period. These animals were given full blackened circles.

When the Visual Recognition Memory test was scored in the usual manner, no animals were deviant. When the test was assessed as a measure of distractibility, two animals, 26 and 27, stood out as spending excessive time looking away from the targets, varying by more than 2.56 standard deviations from the mean of control animals for time spent looking away. Animal 27 was more deviant than 26.

Animal 27 was also the only animal that did not suck normally by the second day of life, and did not suck until day 5 ($Z = 2.87$).

Finally, among the five measures of motor function observed in the playroom, only six animals were delayed beyond the 99% confidence interval on one or more tasks. Four animals, 7, 13, 26 and 30, failed one or two items and received half-blackened circles, while animals 31 and 33 failed four or five tasks.

The DGE group included the only growth-retarded and microcephalic animal (33) with a mean maternal PPEC of 539 mg/dL. Similar retardation in brain growth had been previously reported in an infant macaque exposed to this same dose and dosing schedule (Clarren and Bowden 1982). Decreased body fat is an important component of the growth deficiency in human children with fetal alcohol syndrome (Streissguth et al. 1984). Normal macaque infants have only 2% body fat at term (Newell-Morris and Fahrenbruch 1985) compared to 15% body fat in term gestation humans (Widdowson 1981), and this may explain why weight deficiency was seen only in very high ethanol exposures in this study.

All animals with mean maternal PPECs above 140 mg/dL in the FGE group were identified as developmentally delayed in some way. Eight of the nine "definitely delayed" scores on the nutritive Sucking Capability test, Object Permanence assessment, Wisconsin General Testing Apparatus, and Visual Recognition Memory assessment occurred in four of these animals. These animals did not demonstrate significant delays in motor and social development as observed in the playroom. Only one of the animals had facial dysmorphia, a finding which strengthens the clinical opinion that human infants gestationally exposed to alcohol may have behavioral teratogenic effects without facial anomalies.

In order to assess the neuroanatomic and neurochemical underpinnings of these cognitive deficits, each animal was sacrificed at 6 months of age. The brain and eyes were removed after sedation with intramuscular Ketamine followed by deep general anesthesia with intravenous chloral hydrate. Each brain was weighed and inspected for gross morphologic abnormalities and then rapidly dissected in a standard fashion for distribution to one of several laboratories. The eyes were transferred for pathology and retina cell counts (Dr. Ann H. Milam's laboratory,

Department of Ophthalmology, University of Washington School of Medicine, Seattle). Cerebral dissection first yielded tissues from the right hemisphere, including samples from the substantia nigra, hypothalamus, frontal gyrus, calcarine cortex, hippocampus and hemibrain stem, the right preoptic area, and the putamen and caudate nuclei. These samples were frozen immediately to be later analyzed for dopamine, DOPAC, norepinephrine, epinephrine, and serotonin (Dr. William J. Shoemaker's laboratory, Neurobiology Laboratory, Department of Psychiatry, University Health Center, Farmington, CT). The left caudate and putamen were dissected in toto from each brain slice, placed on ice, and transferred for immediate assay for dopamine receptors using the ligand-binding technique (Dr. Henry Lai's laboratory, Department of Pharmacology, University of Washington School of Medicine, Seattle).

Samples from the left preoptic area, gyrus rectus, calcarine cortex, right caudate and putamen nuclei, and right cerebellar cortex were placed in Karnovsky's solution for electron microscopic assessment (Dr. P. Kevin Rudeen's laboratory, Departments of Anatomy and Neurobiology, University of Missouri School of Medicine, Columbia). Except for portions of the hippocampal gyrus cerebellum, hypothalamus, and brainstem, which are still under study by Dr. James West (Department of Anatomy, University of Iowa School of Medicine, Ames), the remaining brain tissues were placed in 10% neutral buffered formalin for neuropathologic study (Dr. Clarren's laboratory).

The complete methods for each of these analysis are available elsewhere (Clarren et al. 1990). Data analysis was again approached in two ways. First, formal statistical analyses were carried out to test for associations between ethanol exposure (as measured by maternal PPEC) and each neuroanatomic or neurochemical outcome measure. The chi-square and binomial tests were used. Analysis of variance was used to compare mean outcome scores between exposure cohorts. Multiple regression analysis was used to assess the multivariant influences of maternal PPEC, age and ketamine exposure on the estimation of striatal dopamine, DOPAC and dopamine receptor concentrations. Small sample sizes necessarily limited inferences that could be drawn from these assessments.

In addition to the formal statistical assessments, a more descriptive approach was also employed to identify individual animals that showed evidence of developmental impairment and to identify patterns of effect across all infants as they related to the level and timing of intrauterine ethanol exposure. This approach was helpful in describing the results of the eye pathology. For each animal, the raw score for each outcome measure was transformed into a normally standardized Z score based on the corresponding mean and standard deviation in the unexposed animals. Affected animals were defined as those infants with Z scores > 2.5 standard deviations.

No gross malformations were found in any brain specimen. No abnormalities of cerebral cortices or nuclei, glia, or neurons were confirmed by observation of the brain samples prepared for review with the light microscope.

Tortuosity of retinal blood vessels, a noted feature in humans with FAS, was

not observed in this series of nonhuman primates. Three of the animals, 17, 23, and 33, had bilateral microphthalmia (globe diameter less than 18 mm in all three meridians). Microcornea was observed in the left eye of animal 19. Finally, marked loss of retinal ganglion cells was observed in five of the ethanol-exposed infants, 12, 19, 24, 25, and 33. The pattern of marked ganglion cell loss was always found in only one retina, with mild ganglion cell loss in the opposite retina. Mild ganglion cell loss was found in all of the other ethanol-exposed animals. In the majority (19) of the monkeys, the mild ganglion cell loss was bilateral; in the other two, mild ganglion cell loss was unilateral and the opposite retina had normal ganglion cell counts. The frequency of mild to marked ganglion cell loss in the ethanol-exposed animals (100%) was significantly greater than the frequency of ganglion cell loss in the controls (40%, chi-square = 11.1, $p = 0.0009$ with Yates correction).

Electron micrographic assessments revealed important anatomical differences among cells from animals exposed to different doses of ethanol during gestation. The most striking differences between alcohol-exposed and nonexposed neurons were in the appearance of the endoplasmic reticulum. The cisternae of the endoplasmic reticulum appeared swollen and distended, which resulted in an oval or rounded vacuolar appearance rather than flat membranous stacks. The mitochondria showed a variety of structural changes particularly in the loss of cristae, suggestive of a degenerative condition. This is consistent with mitochondrial abnormalities found in rat pups exposed to a 20% ethanol solution during gestation (Baruah and Kinder 1987). Vesicles were present in the cytoplasm of these cells, and normal-appearing golgi were present with regularly arranged membranous stacks. In some cells, the nucleus appeared related or stellate shaped, whereas this appearance was absent in cells from control animals. The slides from all animals were reviewed without knowledge of exposure and assigned a score for ultrastructural alteration: 1 = normal, 2 = nominally abnormal, 3 = moderately altered appearance, 4 = substantial degeneration in normal appearance of the cell or its organelles, and 5 = maximum abnormal appearance. As seen in Figure 2, the intracellular dysmorphism score appeared elevated among animals, with mean maternal PPECs between 214 and 264 mg/dL in both FGE and DGE groups (animals 26,27, 28, and 29).

Associations were found between mean maternal PPECs, dopamine, and DOPAC concentrations in the striatal nuclei. Ethanol exposure did not appear to influence dopamine concentrations in other brain areas or epinephrine, norepinephrine, or serotonin concentrations. Dopamine concentrations in the striatum varied significantly by animal age and ketamine exposure at the time of sacrifice; however, these factors were accounted for in the analysis (Clarren et al. 1990). Among FGE animals exposed to alcohol, mean maternal PPEC explained 13% of the variance in putamen dopamine concentration [$F(5, 19) = 10.5, p = 0.0001$] and 17% of the variance in the caudate [$F(4, 19) = 6.4, p = 0.0002$]. DOPAC concentrations correlated significantly with dopamine concentrations in the putamen (Pearson correlation coefficient = 0.45, $p = 0.03$). A much weaker correla-

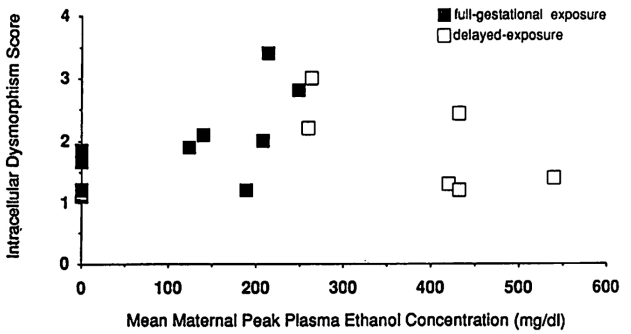

Figure 2. Infant intracellular dysmorphism score as it relates to mean maternal PPEC and timing of ethanol exposure. The intracellular dysmorphism score reflects the extent of intracellular structural alteration observed in the cells of the caudate nucleus. Scores of 1, 2, 3, and 4 reflect normal, minimal, moderate, and substantial alteration in microstructure (from Clarren et al. 1990).

tion between dopamine and DOPAC was found in the caudate (Pearson correlation coefficient = 0.14, $p = 0.14$).

Dopamine receptor levels (fm/mg protein) in the caudate increased gradually with increasing maternal PPEC in FGE animals and increasing age at sacrifice (329–380 days). Maternal PPEC explained 22% of the variance in caudate dopamine receptor levels. In contrast, maternal PPEC had no apparent influence on putamen dopamine receptor levels.

Among the six high-dose animals in the DGE group, putamen and caudate dopamine levels decreased linearly with increasing maternal PPEC. Maternal PPEC explained 95% of the variance in putamen dopamine [$F(1,4) = 83.1, p = 0.0008$] and 68% of the variance in caudate dopamine [$F(1, 4) = 8.7, p = 0.4$].

Putamen and caudate dopamine receptor levels (fm/mg protein) appeared to increase with increasing maternal PPEC among the six delayed-dose animals. Maternal PPEC explained 74% of the variance in putamen dopamine receptor levels [$F(1, 4) = 11.1, p = 0.029$] and 88% of the variance in caudate dopamine receptor levels [$F(2, 3)$ 10.6, $p = 0.04$].

Discussion

This study was undertaken to determine the fetal effects of weekly exposure to ethanol, the most common frequent intermittent consumption pattern among American women (Wilsnack et al. 1984). The goals of the projects were to obtain data that would correlate dose exposure with specific dysfunctional outcomes,

relate phenotypic variables like growth deficiencies and malformation to cognitive and behavioral performance, and relate brain performance to brain structure.

The data suggest that spontaneous abortion is related to weekly ethanol exposures when mean maternal PPEC exceeds 200 mg/dL. In a prospective study of 1200 pregnancies, Sokol et al. (1986) reported an increase in abortions among "heavy drinking" women but did not clarify the specific consumption levels. Kline et al. (1980) reported a case-control study comparing the drinking histories of 626 women who aborted spontaneously with 632 women who carried their pregnancies to at least 28 weeks gestation. Harlap and Shiono (1980) prospectively assessed 32,000 pregnancies and reported a doubling of spontaneous abortions in the second trimester, 14% as compared to 29%, for women drinking one to two standard drinks per day on average. In both of these latter quantitative studies, average alcohol scores were derived by estimating weekly consumption in terms of fluid ounces of absolute alcohol and dividing by seven to obtain an average daily ethanol consumption in ounces per day (Jessor et al. 1968).

The majority of macaques that aborted had mean PPECs above 200 mg/dL. An average-size woman would achieve a comparable PPEC by consuming seven to nine standard drinks containing a total of 2.5 to 4.5 ounces of absolute ethanol (Clarren et al. 1987). Such a weekly amount converts to an average alcohol score of between 0.4 to 0.6, which is comparable to an average alcohol score calculated from the human observations for ethanol exposure and spontaneous abortion by Kline et al. (1980) and by Harlap and Shiono (1980), 0.3 and 0.5, respectively.

Malformations and brain dysfunction became measurable in exposed macaque offspring in early infancy with ethanol exposures at or above 140 mg/dL. This does not mean that weekly dose exposures below 140 mg/dL ethanol were necessarily safe. Marginal developmental delays were identified in the playroom observations and on the Wisconsin General Testing Apparatus in animals in all of the ethanol-exposed cohorts. In addition, further cognitive loss might not emerge until animals become older—at ages beyond the limits of this study. Further, the animals exposed to this dose of alcohol from the first week of gestation were more severe and consistently abnormal than animals exposed to higher doses later on in gestation. This means that exposure to ethanol in humans prior to awareness of pregnancy may be especially harmful. This conclusion is consistent with the findings of Streissguth et al. (1984), who found that cognitive anomalies in children exposed to alcohol in utero were more closely associated with periconceptual maternal drinking than later gestational drinking.

No animal in this study showed all the features of human fetal alcohol syndrome, although every component was seen in some alcohol-exposed animal, with brain problems being the most common.

In the past there has been speculation that "partial" FAS or "possible fetal alcohol effects" might be due to teratogens other than alcohol itself. Our work strengthens the position that these anomalies are related to alcohol teratogenesis directly. It is probable that there is no single dose-response relationship for ethanol

teratogenesis, but rather each abnormal outcome in brain structure or function, morphology, and growth has its own dose-response and gestational timing parameters. FAS should not be seen as the only, most severe, or most important alcohol-related birth defect. It is simply the easiest to recognize.

It is likely that brain dysfunction in our study arose from aberrations in many brain areas. What is important to emphasize here is how subtle the brain findings were at autopsy in spite of clear cognitive deficits in the animals. Up to now only strikingly abnormal brains have been described in the literature as associated with FAS (Clarren et al. 1987). In all probability, most fetal brain damage from alcohol is at the microscopic anatomic or neurochemical level. Computerized tomograms or magnetic resonance images may only rarely image these defects. If *early* gestational exposure to ethanol can lead to obvious behavioral deficits associated with subtle structural damage, it means that ethanol is interfering with brain at a most primitive time in the formation of neural ectoderm. For teratogenesis at that moment to result in only the subtlest of anatomic alteration suggests that the mechanism of damage is in early cellular induction, a time when cells are programmed for later function but their differentiation cannot be detected by current techniques.

Our work helps crystallize human observations with significant implications for epidemiologic studies of the full prevalence of alcohol-related birth defects. Without clinical markers only carefully controlled prospective studies will ever be able to estimate the prevalence of fetal alcohol-induced brain damage. Clinicians will never be able to conclusively prove that isolated brain damage in an individual patient was related to ethanol exposure.

Our studies imply a complex message for public awareness campaigns aimed at preventing alcohol-related birth defects by targeting high-risk populations. On the one hand, measurable brain damage from weekly exposure to alcohol was only consistently found when PPECs exceeded 140 mg/dL. This is the same PPEC West et al. (1990) found related to structural brain teratogenicity for ethanol in rats. The average-size woman would need to consume five to seven drinks each containing 15 cc of absolute ethanol to achieve such a PPEC. This would suggest that real drunkenness could be targeted as a high-risk weekly drinking behavior associated with teratogenesis. On the other hand, damage may be occurring very early in pregnancy prior to the awareness of conception. Since teratogenesis occurs at levels of consumptions far lower than toxic levels, damaged fetuses are likely to be carried to term and their brain damage will only be detected years later. This would imply that if ethanol-related birth defects are to be effectively reduced, warning campaigns could target high-risk drinking behaviors but would need to focus on the *potentially* pregnant women.

Cognitive and behavioral deficits in nonhuman primates associated with very early embryonic binge exposures to ethanol

Sterling K. Clarren, MD, Susan J. Astley, PhD, Virginia M. Gunderson, PhD, and Dee Spellman, BS

From the Division of Congenital Defects, Department of Pediatrics, the Regional Primate Research Center, the Child Development and Mental Retardation Center, and the Departments of Epidemiology and Psychology, University of Washington, Seattle

This study was undertaken to evaluate teratogenesis associated with early weekly ethanol exposure followed by later gestational abstinence. Ethanol, 1.8 gm/kg, was orally administered weekly to gravid nonhuman primates *(Macaca nemestrina)* for the first 3, 6, or the entire 24 weeks of pregnancy. Control animals received weekly sucrose solution as did the 3- and 6-week cohort animals in subsequent weeks. Thirty-five viable infants were assessed for growth, malformations, and behavioral and cognitive dysfunction. Animals in the 6-week and 24-week cohorts were uniformly abnormal in behavior and inconsistently abnormal in physical development relative to the control animals. Animals in the 3-week cohort were equivocally normal. These results demonstrate ethanol's capacity to produce behavioral teratogenesis (brain dysfunction) in isolation from physical anomalies in the rest of the body. The results strongly suggest that binge drinking in the first 6 to 8 weeks of pregnancy (a period when women may not know that they are pregnant), followed by later gestational abstinence, is as dangerous to the fetus as exposure throughout gestation. (J PEDIATR 1992; 121:789-96)

A previous study of ethanol teratogenicity in nonhuman primates *(Macaca nemestrina)*[1] demonstrated that (1) cognitive and behavioral abnormalities can occur without accompanying physical anomalies, (2) once-a-week drinking that is not necessarily "alcoholic" can induce fetal brain damage, and (3) early gestational exposure may be more damaging to cognitive function than later and considerably greater ethanol exposure. This last finding is consistent with a report in the human-studies literature that found decreased cognitive function to be more strongly correlated with reported alcohol consumption around the time of conception than with reported alcohol consumption during pregnancy.[2]

ANOVA	Analysis of variance
MPPEC	Mean peak plasma ethanol concentration
WGTA	Wisconsin General Testing Apparatus

This apparent association between early ethanol exposure and cognitive impairment is puzzling because traditional teratologic theory suggests that subtle behavioral deficits not associated with dysmorphic features or obvious structural changes in the brain should be related to late gestational exposure, not early exposure. Moreover, many women are unaware of their pregnancy in the first weeks.

Table I. Timetable of infant developmental examinations from birth to 2 years of age

Apgar score and physical examination	Birth
Neonatal assessment	Twice a week from birth to 3 wk of age; all examinations performed by a single tester
Visual recognition memory	190, 200, and 210 days of postnatal age
Playroom motor and behavioral development	2 days a week, 10 min/day, from 3 wks to 9 mo of age
Object permanence	3 days a week from 2 wk to 4 mo of age
WGTA memory and learning tasks with measures of activity and distraction	5 days a week from 4 to 14 mo of age
Anthropometric examination and cephalometric x-ray studies	1, 6, 12, and 24 mo of age
Free-play activity levels	1, 6, and 12 mo of age
Growth and health	Monitored continuously

If this period of pregnancy is vulnerable to subtle ethanol-related behavioral teratogenesis and not amenable to repair by subsequent abstinence from ethanol, then prevention strategies need to be directed toward nonpregnant women rather than pregnant women.

We evaluated cognitive, behavioral, and structural teratogenesis associated with early weekly ethanol exposure, followed by later gestational abstinence. We wished to confirm the teratogenicity of weekly exposure to ethanol, 1.8 gm/kg, throughout gestation and to determine whether early gestational exposure to this dose, followed by later gestational abstinence, was as detrimental.

METHODS

Maternal dosing, pregnancy management, and pregnancy outcomes from this project were presented in a separate article.[3] Briefly, one group of pregnant, time-mated pigtailed macaques received a previously established teratogenic dose of ethanol,[1] 1.8 gm/kg, administered orally once a week throughout gestational weeks 1 through 24. The second group of dams received a sucrose solution that was isocaloric and isovolemic to the ethanol solution from weeks 1 through 24. The third group received the ethanol solution in weeks 1, 2, and 3, and then the sucrose solution in weeks 4 through 24. The final group received the ethanol solution in weeks 1 through 6 and then the sucrose solution weekly until the end of pregnancy. There were seven live-born infants in the control group and in the 3-week and 24-week groups, and five live-born infants in the 6-week group. A timetable of the infant examinations is presented in Table I and briefly described below. A more detailed description of infant rearing and examinations was presented previously by Clarren et al.[1]

At birth, 5- and 10-minute Apgar scores were obtained to monitor neonatal well-being. Infant neurologic ratings were also obtained for rooting, sucking, grasping, eye blinking, and righting reflexes. The infants were placed in incubators and cared for 24 hours a day by the infant primate research laboratory nursery staff. A complete physical examination was performed on the day after delivery.

Computerized medical records, including information on pedigree, daily health and clinical care, growth, housing, and hematologic and virologic studies, were maintained on each infant by the full-time veterinary staff. Growth was also followed by obtaining anthropometric measures and standardized frontal and lateral cephalometric radiographs and photographs at 1, 6, 12, and 24 months of age. Anthropometric measures included left foot and crown-rump length, body weight, and head length, width, and circumference. Within the first month of life each infant was scrutinized for major and minor anomalies by a dysmorphologist (S.K.C.).

Infant motor, cognitive, and behavioral development through 14 months of age was evaluated with a battery of developmental assessments: neonatal assessments, object permanence, Wisconsin General Testing Apparatus, visual recognition memory, playroom motor and behavioral development, and free-play activity level in a playroom. The frequency and duration of each examination is presented in Table I. A brief description of each assessment is provided below. All assessments were performed by trained examiners unaware of the exposure history of the infants. Assessments requiring subjective ranking of behavior, performance, or both were conducted by testers for whom interobserver and intraobserver reliability was high. All tests are part of a cognitive-behavioral assessment battery developed and administered at the infant primate research laboratory for more than 20 years. Most were adapted from the human developmental field. The psychometric integrity of the assessment battery has been confirmed in studies conducted during the years.

In general, all infants in the University of Washington Infant Primate Research Laboratory are reared in single cages with surrogate mothers. Although this is not the way monkeys in the wild are reared, "normal" behaviors and development have been established for animals reared in this fashion and can be reliably separated from abnormal behaviors and development.

The neonatal assessment was adapted from the Brazelton

Neonatal Behavioral Assessment Scale.[4,5] Aspects of early functioning that are measured include behavioral state, attention, arousal, and physical responsivity to environmental stimulation. The infants were examined by a single tester who had more than 10 years of experience administering the neonatal assessment. The infants' responses were rated by the examiner on a 3- to 6-point Likert scale (e.g., grasp: 0, none; 1, partial; 2, complete but weak; 3, complete and strong). The full examination required about 15 minutes. Outcomes were scored as the age when a prespecified "mature" response was observed (e.g., mature grasp would be level 3, complete and strong).

The Object Permanence Test Series was adapted from procedures used in human infancy research.[6] Object permanence refers to the extent to which an infant perceives objects as permanent entities (when they are removed from sight) and is considered by many to be the basis for future cognitive operations. As in the human being,[7,8] the onset of this ability is a recognized developmental milestone in the macaque monkey.[9,10] The monkey progresses through the same stages in the acquisition of object permanence as the human being.[11] Both human[12] and macaque infants[11] considered at risk for cognitive impairment lag in the development of object permanence. Outcome is scored as the total number of test days required to reach criterion on each subtest.

The playroom motor and behavioral observations were used to document motor and postural development and the onset of species-typical facial expressions.[13] At 15 days of age the infants were assigned to permanently established social groups that contained five to eight age-matched peers from the colony. The infants in each group were socialized daily in an observation playroom equipped with ramps, shelves, and a few toys. The ages at onset of 12 motor behaviors and 3 facial expressions were recorded during 10-minute observation periods that occurred twice weekly for each infant. Scores were recorded as age at onset of each behavior. Observation continued until all infants in the group reached 9 months of age.

A battery of tests administered with the WGTA provided insight into a range of learning and memory abilities.[14] In general, animals considered at high risk for poor cognitive development perform more poorly than do their normal counterparts on aspects of this battery.[15] Scores for each subtest were recorded in terms of the number of sessions to reach criterion, the number of incorrect responses, or the amount of time required "on task" to figure out the problem.

Throughout the WGTA test battery, behavioral measures were collected. A timer was used to record the time per trial that the infant spent attending and not attending to the stimuli in each of the 13 WGTA tasks. Attention toward the task was defined as eye contact or direct hand contact with the task stimuli. Attention duration provided a measure of how much on-task time an infant required in the performance of the task, whereas the amount of time spent not attending to the task served as a behavioral indicator of distraction. At the end of each test session, the tester rated the infant's overall level of attention and activity during testing on a 5-point ordinal scale. These behavior scores were not collected on the first six infants born into the study but were subsequently adopted.

Infant free-play activity levels were quantitatively assessed at 1, 6, and 12 months of age by recording the animal's activity while alone in an observation playroom that contained shelves at various levels, a ramp, a suspended rope, and two toys. Free-play behavior was recorded for 10 minutes on videotape twice (on 2 separate days within a 1-week period) at each age and coded with single-frame accuracy.[16,17] Infant activity was quantified by measuring the frequency and rate of change of 11 mutually exclusive locomotor and postural behaviors during the 10-minute free-play sessions.

Our test of visual recognition memory is an adaptation of the Fagan Test of Human Infant Intelligence,[11] which indexes attention, discrimination, and memory abilities. Outcome is measured as the proportion of total looking time directed at a novel rather than a familiar stimulus.[12] The development of visual recognition memory in the macaque monkey, as tested by this procedure, has been shown to be similar to that of the human being.[18] Moreover, in both the human being[19] and the macaque monkey,[20] this task has been shown to differentiate between groups of normal infants and those considered to be at risk for cognitive impairment; normal infants usually demonstrate a novelty response, and high-risk subjects either have decreased novelty preference or perform at chance levels.

One-way analysis of variance, the Kruskal-Wallis test, and the chi-square test were used, where appropriate, to detect statistically significant differences between the four ethanol exposure groups. Because of the number of statistical tests that were performed, a more appropriate, albeit conservative, cutoff point for statistical significance would be a p value = 0.002 (Bonferroni adjustment), to reduce the risk of drawing false-positive conclusions. Because of the small sample size (inherent in primate research), only robust differences between exposure groups were statistically detectable. To minimize the risk of drawing false-negative conclusions based solely on statistical evaluations and to capitalize on the broad spectrum of infant outcome measures collected in this study, we placed emphasis on graphically presenting the results of all major outcome variables for each infant relative to the mean performance of the control group. With the exception of the visual rec-

Figure. Summary of all infant assessments through 6 months of age. Individual deviations on developmental and growth measures are compared in infant macaques exposed weekly to ethanol in utero for 0, 3, 6, or 24 weeks. Extreme deviations from control means are indicated by the symbol ●, while definite but less extreme deviations are indicated by the symbol ◑. Definitions for deviations in each column are found in the Results section. *Absent circles* indicate data not collected. *Asterisks* denote animals from the previous study.[1] The numbers 1 through 12 in the column headings correspond to the following: *1*, neurologic disorders (seizures ●, strabismus ◑); *2*, congenital anomalies (major or fetal alcohol syndrome–like); *3*, microcephaly; *4*, object permanence; *5*, WGTA composite score (memory and learning skills); *6*, visual recognition memory; *7*, distractibility behavior score (ordinal rating during WGTA testing); *8*, activity behavior score (ordinal rating during WGTA testing); *9*, distractibility (time spent off-task during WGTA testing); *10*, activity level (frequency and velocity during free play); *11*, playroom motor development (climbing ramp); *12*, playroom motor development (walking). *ETOH*, Ethanol; *Neuro./Dysm.*, neurologic disorders/dysmorphism; *MPPEC*, maternal mean peak plasma ethanol concentration.

ognition measure, delays were detected in performance or on developmental assessments that were measured on a continuous scale by transforming each infant's raw score into a normally standardized *z* score. Delayed performance was defined as performance resulting in *z* scores ≥ 2 SD from the mean of the control group. This graphic approach was better able to reveal the pattern and extent of developmental impairment in each animal.

Table II. Infant outcomes associated with ethanol exposure

Infant outcome	Gestational ethanol exposure (wk) 0	3	6	24	F*	p	Which groups differ†
Activity							
Mean No. of behaviors/min	12.8 (n = 7)‡	17.8 (n = 6)	30.0 (n = 5)	11.7 (n = 6)	5.2	0.008	6 wk from 0 and 24 wk
Mean frequency of high-energy behaviors§ during 10 min	35.4 (n = 7)	74.5 (n = 6)	130.8 (n = 5)	33.5 (n = 6)	4.4	0.016	6 wk from 0 and 24 wk
Mean activity behavior rating during WGTA testing	2.6 (n = 5)	1.8 (n = 5)	3.4 (n = 4)	2.8 (n = 5)	4.0	0.027	6 wk from 3 wk
Motor development							
Mean age (days) at onset of coordinated walking skill	54.0 (n = 12)	47.8 (n = 6)	58.6 (n = 5)	77.3 (n = 9)	4.6‖	0.041	Linear trend, no two groups differed significantly
Cognitive development							
Mean WGTA composite¶ cognitive score	19 (n = 10)	28 (n = 6)	36 (n = 5)	49 (n = 11)	5.7‖	0.024	Linear trend, no two groups differed significantly
Mean object-permanence composite¶ score	20 (n = 12)	17 (n = 6)	08 (n = 5)	61 (n = 11)	5.2	0.005	24 wk from 0, 3, and 6 wk

*F statistic, one-way ANOVA (‖ weighted linear term).
†Identified by using Student-Newman-Keuls test for multiple comparisons ($p < 0.05$).
‡Sample size variation reflects the inclusion of control animals and 24-week exposure animals from a previous study[1] when data were available.
§High-energy behaviors include swing, run, play, leap, hang, and climb.
¶Higher composite scores reflect poorer performance.

Table III. Mean percentage of looking time to novel stimuli, and mean frequency of fixations and mean duration per fixation to familiar and novel stimuli by ethanol-exposed and unexposed groups

Exposure to 1.8 gm/kg ethanol (wk)	n	Time spent looking at novel stimuli (%)	Frequency of fixations		Duration per fixation (sec)	
			Familiar	Novel	Familiar	Novel
0	12	57.0* ± 7.7	5.0 ± 3.4	4.9 ± 2.6	1.2 ± 0.7	1.4 ± 0.5
3	7	62.6† ± 6.8	4.2 ± 1.3	5.1 ± 1.8	0.8 ± 0.4	1.2 ± 0.7
6	5	52.3 ± 11.4	4.0 ± 1.9	5.1 ± 1.8	1.4 ± 0.6	1.2 ± 0.5
24	10	54.6 ± 12.0	4.9 ± 2.8	4.7 ± 2.4	1.2 ± 0.7	1.4 ± 0.8

Values are mean ± SD.
*Differed from a chance level of 50%, $t(11) = 3.15$, $p < 0.01$ (one-sample t test, two tailed).
†Differed from a chance level of 50%, $t(6) = 4.91$, $p < 0.01$ (one-sample t test, two tailed).

RESULTS

Postnatal growth. All infants had normal weight gain within the first 6 months of life relative to colony-generated norms adjusted for the gender and the number of generations from feral ancestry of each animal. Growth during the first 6 postnatal months in head length, width, and circumference, and in body length and weight, were comparable between the ethanol-exposed and the unexposed animals.

Postnatal health. Postnatal health as measured by the number of treatment days during the first 6 months of life was comparable across all groups of infants. At 39 days of age, one infant in the 3-week cohort (infant 47) had bacterial cultures positive for *Cryptosporidium* and *Campylobacter coli* and died 2 days later. Diarrheal illnesses have been common among colony infants and occurred periodically in every one of the control and ethanol-exposed infants in this study. With the exception of animal 47, all responded favorably to treatment.

The Figure summarizes the results of the infant developmental assessments through 6 months of age as described

in the paragraphs below. The trained examiners in both studies were rotated among all animals to reduce potential tester bias.

Neurologic outcome and congenital anomalies. The frequency of neurologic and congenital anomalies within each exposure cohort are summarized in the Figure. There were no major or minor dysmorphic features among the 12 control animals. One control animal had two brief grand mal seizures at 119 days of postnatal age, a phenomenon that occurs randomly in 1% of colony animals.[1] Of the 24 ethanol-exposed animals, 3 had fetal alcohol syndrome–like facial dysmorphic features. Animal 49 had a flattened, elongated midface. Animal 25 had a flattened philtrum and maxilla, and dental anomalies. One female fetus (animal 59), exposed weekly from gestational age 12 through 131 days, had holoprosencephaly and exencephaly diagnosed at day 133 of gestation. This fetus had the anticipated facial features associated with holoprosencephaly, including premaxillary agenesis and median cleft lip, and has been separately described.[21] No live-born infants had microcephaly or other major malformations of the heart, skeleton, or other organ systems.

Neonatal assessments. The ages when mature responses were attained for the tested motor and behavioral responses (grasp, clasp, self-righting, rooting, snouting, sucking, auditory startle, resistance to passive movement, visual and auditory orientation, visual follow, emotional state, and consolability) were comparable across all exposure cohorts. The mean age to reach the mature response for each behavior ranged from 2 to 4 days in the control subjects. The study had 80% power to detect mean differences as small as 4 days between any two groups at $\alpha = 0.05$ (two sided).

Cognitive development (object permanence and WGTA assessments). One infant in the control group and four infants in the 24-week cohort had significant delay in the 10 object permanence tasks (Figure). The 24-week cohort as a whole required significantly more sessions per task to reach criterion than did the control group and the 3- and 6-week cohorts (ANOVA: $F = 5.2$, $p = 0.005$) (Table II). Infant macaques at risk for cognitive impairment are typically most challenged by the tasks that require them to retrieve objects completely hidden from view.[11] In contrast, the ethanol-exposed infants were most challenged by the tasks that required them to retrieve objects that were in clear view or only partially hidden.

Two infants in the 3-week cohort, two infants in the 6-week cohort, and six infants in the 24-week cohort had significant delay ($\geq$2 SD from the mean composite score of the control cohort) in the memory and learning skills in the WGTA assessment (ANOVA linear trend: $F = 5.7$, $p = 0.02$) (Table II). No one task presented an exceptional challenge to the ethanol-exposed infants. The most striking contrast between the 24-week group and the control group was the time required to accomplish the tasks. The 24-week infants required two or three times more on-task time to discover how to perform the tasks, and on the Hamilton Search measure they had to search through twice as many boxes, compared with the average control infant, to locate the correct box.

Visual recognition memory. The results of the visual recognition memory assessment are presented in Table III. Both the control and 3-week exposure groups had a preference for the novel stimuli, as observed in normal human and macaque infants.[19, 22] In contrast, the 6- and 24-week exposure groups did not demonstrate a preference for either the familiar or novel stimulus.

Behavior during WGTA testing and free play. The ethanol-exposed animals who had higher activity levels, distractibility levels, or both during testing and free-play activity, in comparison with the control group, can be found in columns 7 through 10 in the Figure, and in Table II. The most striking contrast among the exposure groups was the level of activity during the unstructured free-play sessions in the playroom (Figure). The mean frequency and rate of change of free-play locomotor and postural behaviors among the five infants in the 6-week exposure group were twofold to threefold greater than the activity levels observed among the control group and the 3- and 24-week exposure groups (Table II).

Motor development. The onset of locomotor skills such as grasp release, walking, jumping, and climbing were monitored during free-play sessions in an observation playroom. The ethanol-exposed infants, particularly the 24-week exposure group, showed delay in onset ($\geq$2 SD from the mean age at onset for the control group) of two early-acquired skills—coordinated walking and the ability to climb a ramp (Figure; Table II). Additionally, one infant in the 6-week cohort (infant 49) was independently identified by three observers (unaware of the exposure history of the infant) to have a marked lack of motor coordination during the free-play sessions. The infant moved at a rapid pace, often stumbling and falling as a result of what appeared to be poor judgment of her motor capabilities. Her leaps were overambitious and misguided, and she frequently tripped over her own feet when moving across the floor. Although she was delayed at the start in her ability to climb the most easily accessible object, she rapidly attained criteria on the higher-placed shelves, perhaps because of her frequent and unabated attempts to reach them. She was also uncommonly friendly and trusting toward strangers, which is considered maladaptive in this species. She would cling to a stranger with a rough but playful manner and would resist any attempts to be released. This lack of motor coordination and the clinging personality persisted through 3 years of age.

Timing and level of ethanol exposure. We attempted to relate the severity of brain damage to the specific level and

timing of exposure of each animal. Although the mother animals were given the same dose of ethanol for body weight delivered under identical circumstances, their mean peak plasma ethanol levels varied from 176 to 266 mg/dl. Dosing was always initiated on the same day of the week, resulting in seven different dosing schedules relative to the day of conception. No clear patterns were detected relating the initiation, timing, or level of exposure with the type of abnormal outcome observed among animals or the overall severity of impairment observed in each animal. The power to detect patterns, however, was limited because of the few animals that had each dosing pattern. Abortions occurred across all dosing patterns and appeared unrelated to the day of initial exposure.

DISCUSSION

A unique advantage of our functional nonhuman primate model for studying ethanol teratogenesis is its ability to isolate the effects of ethanol from other environmental factors that inevitably plague human research in this area. Our model can be seen as an investigative bridge between studies of small laboratory animals and of human beings. We previously reported that an intoxicating dose of ethanol (achieving maternal mean peak plasma ethanol concentrations >140 mg/dl), delivered only once a week throughout gestation (24 weeks), consistently resulted in behavioral teratogenesis and sporadically resulted in physical teratogenesis.[1] We observed that cognitive abnormalities were more severe and consistent in animals exposed to ethanol during weeks 1 to 24 of gestation whose MPPECs were between 140 and 249 mg/dl than in animals exposed only during weeks 6 to 24 of gestation whose MPPECs were between 260 and 540 mg/dl, thus suggesting an early gestational period for ethanol-induced brain teratogenesis. Additionally, our work confirmed the suspicion in human studies that ethanol-related cognitive and behavioral abnormalities can occur without accompanying physical anomalies and that each affected subject may have a unique cluster of cognitive, behavioral, neurochemical, and/or neuroanatomic aberrations.[1, 23]

These results are important for prevention programs. Ethanol was found to induce fetal brain damage from a common binge pattern of drinking that is not necessarily "alcoholic" and is common in teenagers and young adults[24] who are at higher risk for unplanned pregnancy. The teratogenic threshold occurred at an intoxicating dose of ethanol (1.8 gm ethanol per kilogram of body weight: PPEC >189 mg/dl), which could be achieved by a 55 kg person consuming approximately a six-pack of beer or its equivalent. This teratogenic threshold is similar to one observed in rats.[25]

In our study we confirmed the teratogenicity of this ethanol dose and, in addition, we found that animals exposed to ethanol for only the first 6 weeks of gestation, a period that is roughly equivalent to 7½ weeks in a human being,[26] were indistinguishable, in terms of the frequency of abnormal outcomes identified by the assessment battery, from the animals exposed throughout gestation. The pattern of abnormal outcomes, however, appeared to differ between the two groups. The most striking contrast was the magnitude and consistency of hyperactivity observed among the 6-week exposure cohort during unstructured, free-play activity, a behavioral aberration that was seemingly absent in the 24-week exposure cohort. Hyperactivity and distractibility levels during testing appeared comparable between the two groups, albeit higher than in the control group. The most severely impaired live-born animal received only 6 weeks of ethanol exposure. This animal had significant developmental delay (≥2 SD from the control mean) on seven of the nine assessments and had behavioral and structural anomalies consistent with the diagnosis of fetal alcohol syndrome in human beings.

The frequency of abnormal outcomes in the 3-week exposure group, a period that is roughly equivalent to 3 weeks of gestation in human beings,[26] did not significantly exceed that of the control group, the limited power to detect clinically significant differences (because of the small sample size) precludes the drawing of a conclusion of no effect at this time. However, one animal did show impairment on four separate measures, which suggests the possibility of behavioral teratogenesis even in this gestational period.

It hardly seems appropriate to recommend that women continue to drink alcohol in pregnancy. Unfortunately, the results of our study suggest that weekly exposure to ethanol in the first 6 weeks of gestation is sufficient to produce behavioral and cognitive aberrations, and that the 6-week and 24-week cohorts appear to be at equal risk for damage. There is little evidence in our study that early gestational damage can be repaired by subsequent abstinence, but continued exposure appears to alter the pattern of brain injury. Information currently available suggests that women who stop drinking during gestation have healthier babies—that is to say, larger infants with fewer neonatal problems. We know of no study in human beings that can be compared with the present study.

If our study can be extrapolated to human beings, several implications can be drawn. First, the animals had normal physical examination findings, and most had grossly normal behaviors. Similarly affected human infants therefore would not be identified as abnormal by early physical examination, nor would any single type of early infant assessment have identified many as abnormal. Clinical studies that declare infants normal after in utero ethanol exposure on the basis of an early physical examination or a single developmental test should be considered suspect. Second, mothers who binge-drink, especially in early pregnancy, may not be ad-

dicted to ethanol and may not discuss an alcohol problem with their physicians. It may take rigor on the parts of obstetricians, perinatologists, and others to elicit this important piece of infant-at-risk history. Finally, most studies of human teratogenesis resulting from ethanol exposure report the average alcohol consumption rates during long gestational periods (i.e., first half of pregnancy, second half of pregnancy, or each trimester). The result could be two important methodologic errors. First, the weekly binge dose of ethanol used here would correlate with an average daily exposure of one to one and one-half drinks per day in an average female adult. Recent studies of rats by Bonthius and West[25] suggest that peak exposure, not mean or total exposure, is most important in predicting teratogenic impact. With an average exposure of one to one and one-half drinks per day, some studies have found a teratogenic effect and others have not. These differences might be related to differences in the numbers and types of binge exposures mixed together with lower but more steady exposures. The blending of different exposure periods may dilute early and apparently extremely teratogenic gestational periods.

Extrapolation of these data to other exposure patterns in human pregnancy, for counseling purposes, creates difficult problems. Further controlled studies are needed to establish the consequences of weekly alcohol exposure, twice-a-week exposure, and other exposure patterns. Even without these studies in hand, it is reasonable to assume that many patterns of early gestational exposure to alcohol are likely to cause permanent damage to the offspring.

It would certainly always be wise for women who drink regularly and in large volume to decrease or eliminate alcohol consumption during pregnancy, but our findings do not suggest that abstinence during later pregnancy can prevent or ameliorate early gestational damage from ethanol. The prevention of fetal brain damage from alcohol must rest with the prevention of alcoholism and high-risk alcohol use before pregnancy.

Immune Function in Offspring of Nonhuman Primates (*Macaca nemestrina*) Exposed Weekly to 1.8 g/kg Ethanol during Pregnancy: Preliminary Observations

Angelika Grossmann, Susan J. Astley, H. Denny Liggitt, Sterling K. Clarren, Faith Shiota, Bryan Kennedy, Margaret E. Thouless, and Lillian Maggio-Price

A preliminary investigation of immune host response was conducted in a group of fetal alcohol-exposed nonhuman primates (*Macaca nemestrina*) who were part of a broader ongoing study of ethanol teratogenicity. The mothers of the offspring received weekly oral doses of ethanol (1.8 g/kg) for the first 3 or 6 or the entire 24 weeks of gestation. A control group received sucrose solution weekly throughout pregnancy. Four of the 18 ethanol-exposed animals (22%) died or were euthanized after infectious disease or failure to thrive during the first year of life; none of the seven control animals died. This imbalance in survival prompted the present review of immune function in the remaining offspring. Parameters assessed included: (1) white blood cell count (WBC), (2) peripheral blood leucocyte subsets ($CD4^+$, $CD8^+$, $CD20^+$, and $CD11c^+$), (3) T-cell proliferation after activation with phytohemagglutinin (PHA), staphylococcus enterotoxin B (SEB), and tetanus toxoid (TT), (4) phagocytic activity of monocytes, and (5) serum immunoglobulin levels and serum antibody titers after TT vaccination. Mean T-cell proliferation to TT was significantly decreased ($p = 0.01$) in all ethanol-exposed animals relative to controls, with near-significant decreases ($p = 0.06$) in response to SEB in the ethanol-exposed animals. Lymphocyte proliferation in response to PHA was not altered. Ethanol-exposed animals had significantly lower TT titers than controls after initial vaccination and booster. WBC, leukocyte subsets, serum immunoglobulins, and monocyte phagocytic activity were not significantly different from control values. These preliminary observations suggest that T-cell proliferation and antigen-specific memory responses may be altered in offspring exposed to weekly doses of ethanol in utero and warrant further evaluation for confirmation.

Key Words: Immunity, Prenatal Ethanol Exposure, Immunosuppression, Nonhuman Primate Model, Fetal Alcohol Syndrome.

SINCE THE DESCRIPTION of fetal alcohol syndrome (FAS) in 1973,[1] there has been increasing evidence from human reports and animals studies linking prenatal alcohol exposure and immune deficits.[2] Johnson reported 13 FAS patients with recurrent infections; immunological evaluation showed decreased lymphocyte numbers, decreased in vitro proliferation, and decreased serum immunoglobulins.[3] Steinhausen et al.[4] also reported that FAS children are more susceptible to serious illnesses during their first 2 years of life. Abnormal thymus development and immune deficiency have been associated with in utero alcohol exposure in humans.[5] Since human reports of FAS have imprecise exposure patterns and incomplete medical histories, it is necessary to use animal models with precise ethanol exposures to study the teratogenic effects of ethanol on particular organ systems. Rodent studies have demonstrated that in utero alcohol exposure produces abnormalities in the offspring's developing immune system that persist in adult animals. These have been reviewed by Gottesfeld and Abel[6] and include thymus hypocellularity and proliferation,[7-9] decreased T-cell responses to mitogens,[10,11] inability of T-cells to use interleukin-2,[12] and long-lasting suppression of delayed type hypersensitivity.[13] However, most rodent studies have examined continuous, not binge, alcohol exposure. The advantage of this nonhuman primate study is that it addresses binge ethanol exposure, a common drinking pattern, during variable periods of gestation in an animal model closely related to man.

In the present preliminary investigation, several immunologic and hematologic parameters were evaluated in 17 nonhuman primates (*Macaca nemestrina*) who were part of an ongoing study of ethanol teratogenicity associated with weekly ethanol exposure.[14,15] In the original study, the mothers of 26 offspring received an oral dose of 1.8 g/kg of ethanol weekly for the first 0, 3, 6, or 24 weeks (full gestation) of pregnancy. Precise ethanol exposure information and complete medical histories were available for each animal.

The first indication that ethanol-exposed offspring might be immunocompromised was the 22% mortality due to infectious disease seen in the ethanol exposure groups (two females and two males in the 3- and 24-week ethanol exposure groups) compared to 0% in the control group. We, therefore, investigated whether the surviving ethanol-exposed animals had any alterations in certain hematologic and immunologic parameters. The primary objective of this investigation was to identify associations between fetal ethanol exposure and immune function through exploratory analyses to generate hypotheses for future studies.

METHODS

Animals

In the original study,[14] female pigtailed macaques (*M. nemestrina*) were time-mated at the University of Washington Regional Primate

From the University of Washington, Seattle, Washington.

Received for publication July 16, 1992; accepted January 5, 1993

Center's breeding facility. Upon confirmation of ovulation, the dams were randomly assigned to one of four exposure groups in blocked fashion to achieve an offspring age balance across the groups. They began weekly receipt of either ethanol (1.8 g/kg) or sucrose solution (isocaloric and isovolemic to the ethanol dose) within the first week of pregnancy. The ethanol and sucrose solutions were administered orally via a soft nasogastric tube.

The four maternal exposure groups included: controls, sucrose solution once per week throughout the 24-week pregnancy; 3-week group, ethanol solution once per week for the first 3 weeks of pregnancy, followed by weekly sucrose solution for the remaining 21 weeks; 6-week group, ethanol solution once per week for the first 6 weeks of gestation, followed by weekly sucrose solution for the remaining 18 weeks; and 24-week group, ethanol solution once per week throughout the 24-week gestation.

The mean maternal peak plasma ethanol concentration was 223 ± 28 mg/dl, a level that could be achieved by a 55-kg person consuming approximately a 6-pack of beer or its equivalent. All offspring were raised under identical environmental conditions.[15]

There were a total of 26 offspring in the original study,[14,15] five of which died or were euthanized before the start of the current immunologic study. We evaluated 21 animals (14 females and 7 males) between 1 and 3 years of age over a 1-year time period: seven animals in the control group, five animals in the 3-week group, five animals in the 6-week group, and four animals in the 24-week group. Four of the 21 animals were viremic for simian D-type retrovirus 2-Washington (SRV-2/Wa; two controls and two 3-week animals) and are not included in this report. All five offspring from control animals were females. There remained one male and two females in the 3-week group, two males and three females in the 6-week group, and one male and three females in the 24-week group. Some of the females were sexually mature. Animals were screened three times for SRV virus, and antibody titers during this 1-year study were all positive for SRV Ab measured by enzyme-linked immunosorbent assay (ELISA) and negative for SRV virus.

Collection of Peripheral Blood and Cell Isolation

After ketamine hydrochloride anesthesia (10 mg/kg), 10 to 15 ml of blood were drawn from the femoral vein into heparinized tubes. Peripheral blood mononuclear cells were obtained by centrifugation of whole heparinized blood over 95% Ficoll-Paque (Pharmacia, Piscataway, NJ) and washed twice in RPMI-1640 and 3% fetal calf serum.[16]

Cell Surface Staining with Monoclonal Antibodies

For measurement of leukocyte subsets, 0.5×10^6 cells were simultaneously stained for 20 min at room temperature with phycoerythrin (PE)-conjugated anti-CD4 [Leu 3a, Becton Dickinson (B-D) Mountain View, CA] and fluorescein isothiocyanate (FITC)-conjugated anti-CD8 (Leu 2a, BD). B-cells were stained with PE-conjugated anti-CD20 (Leu 16, B-D), and macrophages were stained with FITC-conjugated anti-CD11c (Leu M5, B-D). Stained cells were washed, fixed in 1% paraformaldehyde and stored in the dark until analysis within 24 hr. Analysis was performed using an Ortho Cytofluorograph 50 H with model 2150 computer (Ortho Diagnostic Systems, Westwood, MA), as previously described.[17]

Lymphocyte Proliferation

Lymphocyte proliferation was evaluated once or twice after stimulation with phytohemagglutinin (PHA), staphylococcus enterotoxin B (SEB), and tetanus toxoid (TT). For each analysis, blood was obtained from all animals on the morning of the same day. Peripheral blood mononuclear cells were isolated as described above. Cells were cultured in triplicate for 3 days (PHA, SEB) or 6 days (TT) in round-bottom 96-well microtiter plates in 200 μl of growth medium at 1×10^5 cells/well (PHA, SEB) or 2×10^5 cells/well (TT). Lymphocytes were stimulated with PHA (2.5 μg/ml), SEB (100 ng/ml), and TT (25–250 ng/ml). The growth medium was RPMI-1640 supplemented with 10% fetal bovine serum, 100 units/ml of penicillin, 100 μg/ml of streptomycin, and mercaptoethanol (5×10^{-5} M). During the last 12 hr, [^{3}H]thymidine was added at 0.5 μCi/well. Cells were then harvested onto glass fiber filters with a cell harvester and counted in a β-scintillation counter for 1 min, and radioactivity was reported as counts per minute. Lymphocytes incubated with medium alone showed variable and often high background counts; background counts were subtracted from counts per min of stimulated cells. For TT stimulation, the dose resulting in the maximal response was used.

Quantitation of Serum Immunoglobulins (Igs)

Serum immunoglobulin levels (milligrams per liter) were measured once on all animals before tetanus immunization using commercially available radial immunodiffusion assays (Binding Site, Birmingham, United Kingdom). Total serum IgG, IgA and IgM were determined in duplicate, and the mean titer was determined.

Tetanus Immunization and Antibody Titer

The animals were immunized four times (once monthly for 3 months) with 1 ml of TT, given intramuscularly (Lederle, Pearl River, NY), and revaccinated 253 days after the initial vaccination. Tetanus antibody titers (units per milliliter) were determined by ELISA, as previously described,[18] in the laboratory of Dr. David Nelson (National Cancer Institute, Bethesda, MD) before vaccination, 21 and 161 days after the last vaccination, and 28 days after the booster on day 253.

Phagocytic Activity

Phagocytic activity was measured once in all animals. This assay used 24-well plates containing round glass coverslips as adherent surfaces. Mononuclear cells were isolated from blood and seeded into individual wells of slide chambers to ensure surface adherence of 300 to 500 monocytes. Adherent cells in replicate chambers were then exposed to phagocytic particles by the method of Liggitt et al.[19] Two hundred randomly selected cells were counted from each chamber, and the percentages of cells containing zero, one to four, five to seven, or more than eight internalized particles were determined.

SRV Isolation and Detection of Antibody to SRV

All of the offspring were screened for SRV viremia and antibody status three times over the 1-year study. SRV was isolated from lymphocytes by coculturing them with Raji cells.[20] Antibodies to SRV were detected by ELISA[21] using a sodium deoxycholate-disrupted gradient-purified virus antigen.

Statistics

The primary goal of the analysis was to determine if associations could be found between the duration of fetal alcohol exposure and altered immune function in the study group of 17 exposed and unexposed nonhuman primates. Multiple statistical comparisons were conducted in exploratory fashion to generate testable hypotheses for future studies. Performing multiple statistical comparisons increases the probability of identifying false positive associations (type I errors); thus, the p values have been reported for the reader's interest, but should not be strictly interpreted. It should also be noted that because of the small sample size (inherent in primate research), only robust differences between exposure groups were statistically detectable. For the reader's interest, power estimations have been provided, where appropriate, to facilitate interpretation of the negative findings reported in this study.

One-way ANOVA with Scheffes' test for multiple comparisons and the Kruskal-Wallis test were used where appropriate, to evaluate mean

differences among the four exposure groups. The t and Mann-Whitney tests were used, where appropriate, to compare mean differences between the ethanol-exposed group as a whole with the control group.

A balanced ratio of males and females were born to each of the ethanol-exposed groups. The control group, however, was entirely female. The association between gender and exposure was weak and not significant (controls, 100% female; ethanol-exposed, 67% female; $\chi^2 = 0.7$, $p = 0.40$), but the power to detect confounding by gender was too small with the limited sample size; therefore, all analyses were repeated among females only and reported when the results differed from the results of analyses of males and females combined.

RESULTS

Susceptibility to Disease

Four of the 18 ethanol-exposed infants [3-week (one female and one male animal) and 24-week (one female and one male) exposed groups] died or were euthanized due to disease complications or failure to thrive compared with none of seven control animals. Etiologic agents isolated from four animals with diarrhea included *Shigella*, *Cryptosporidia*, and *Campylobacter*.

Lymphocyte Proliferation after Activation with SEB, TT, or PHA

Lymphocyte proliferation differed between the ethanol-exposed animals and the control animals depending upon the T-cell activator used. The mean lymphocyte proliferation in the ethanol-exposed groups after activation with TT was lower (882 ± 1,487 cpm) than that among the control group (2,102 ± 1,500 cpm, Mann-Whitney U = 4.0, $p = 0.01$, Fig. 1B). The contrast was increased when the comparison was restricted to females (mean proliferation to TT = 671 ± 505 cpm), but did not reach statistical significance because of the reduced sample size (Mann-Whitney U = 7.0, $p = 0.09$). Mean lymphocyte proliferation after stimulation with SEB was also lower among the ethanol-exposed groups (13,732 ± 7,011 cpm) relative to the control value (19,147 ± 12,380 cpm), but the difference did not reach statistical significance (Mann-Whitney U = 9.0, $p = 0.06$, Fig. 1A). Mean lymphocyte proliferation after activation with PHA was comparable across all exposure groups (Fig. 1C). The contrasts between exposure groups were not appreciably altered when the analyses for the SEB and PHA experiments were restricted to females. Differences in lymphocyte proliferation were not attributable to differences in the numbers of T-cells placed in culture, since T-lymphocyte fractions were comparable in the ethanol-exposed and unexposed animals (Table 1).

Antibody Titers to TT

Tetanus antibody titers increased after initial vaccination and booster in the control, 6-week, and 24-week exposure groups (Fig. 2). The mean antibody titer was significantly lower in the ethanol-exposed group (2,928 ± 1,357 U/ml) than that in the controls (5,589 ± 2,101 U/ml) after vaccination ($t = 3.1$, $p = 0.007$) and after the booster (ethanol exposed = 37,681 ± 27,110 U/ml versus control = 65,248 ± 11,041 U/ml, $t = 2.2$, $p = 0.04$). The 3-week exposure group showed a consistent and marked lack of antibody response to both the initial vaccination and the booster. The mean tetanus antibody titer after the tetanus booster was significantly lower in the 3-week group (8,635 ± 6,413 U/ml) than in the controls (65,248 ± 11,041 U/ml; one-way ANOVA: $F = 7.0$, $p = 0.005$; Scheffe test: $p < 0.05$). When the ANOVA analyses were restricted to females, the antibody response in the 3-week exposure group was significantly lower after vaccination (979 ± 562 U/ml; one-way ANOVA: $F = 4.0$, $p = 0.05$; Scheffe test: $p < 0.05$) and after booster (5,208 ± 3,434 U/ml; one-way ANOVA: $F = 6.0$, $p = 0.02$; Scheffe test: $p < 0.05$).

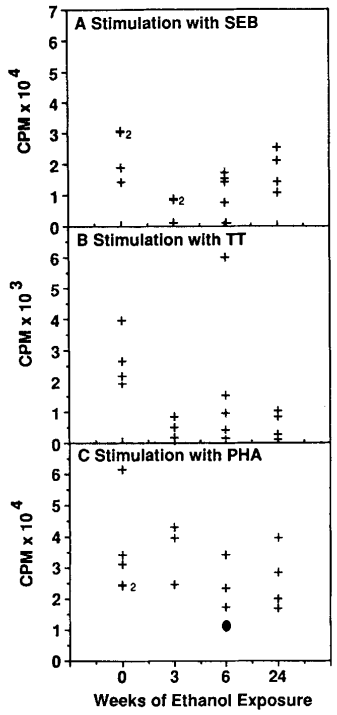

Fig. 1. Peripheral blood lymphocyte proliferation in offspring of *M. nemestrina* exposed to weekly oral doses of 1.8 g/kg of ethanol for the first 3 or 6 or the entire 24 weeks of pregnancy after stimulation with SEB (A), TT (B), and PHA (C) and in controls.

Immunoglobulin Levels

Mean IgG levels were consistently higher in the ethanol-exposed groups than in the controls, but this was not statistically significant (Table 2). The true difference between the mean IgG levels would have had to be greater than 9000 mg/liter for the study to have sufficient power

Table 1. Comparison of Hematocrit, WBC, and Leucocyte Subsets of Offspring of *M. nemestrina* Exposed to Weekly Oral Doses of 1.8 g/kg of Ethanol for the First 3 or 6 or the Entire 24 Weeks of Pregnancy and Controls

Ethanol exposure	n	Hematocrit (%)		WBC × 10^3/ml		T-Lymphocytes %CD4+		T-Lymphocytes %CD8+		B-Lymphocytes % CD20+		Monocytes % CD11c+	
		Mean	SD	Mean	SD	Mean	SD	Mean	SD	Mean	SD	Mean	SD
Controls	5	36.1	2.2	9.8	1.7	24.0	3.7	47.4	5.1	10.4	2.6	8.6	1.2
3-week exposed	3	35.5	1.8	10.8	2.9	49.0	6.0	29.0	7.0	7.3	2.9	5.6	3.1
6-week exposed	5	36.3	1.6	10.7	1.4	37.2	6.2	38.0	14.0	6.3	1.3	10.5	9.8
24-week exposed	4	35.3	2.3	10.2	3.7	34.0	14.7	22.7	8.0	13.5	10.1	9.5	5.4

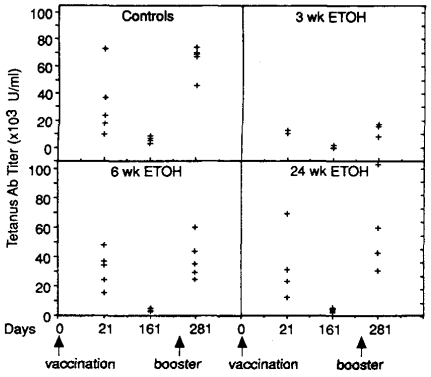

Fig. 2. Tetanus antibody titers (ELISA) in offspring of *M. nemestrina* exposed to weekly oral doses of 1.8 g/kg of ethanol (ETOH) for the first 3 or 6 or the entire 24 weeks of pregnancy and in controls. Tetanus antibody titers were measured before vaccination, 21 and 161 days after vaccination, and 28 days after booster (281 days after the initial vaccination). No animal had an appreciable tetanus titer before vaccination.

Table 2. Immunoglobulin Levels (Milligrams per Liter) in Offspring of *M. nemestrina* Exposed to Weekly Oral Doses of 1.8 g/kg of Ethanol for the First 3 or 6 or the Entire 24 Weeks of Pregnancy and Controls

	Ethanol-exposed			Controls		
	Mean	SD	n	Mean	SD	n
IgG	13,905	4,396	10	11,648	2,971	5
IgA	4,937	2,024	10	4,652	1,460	5
IgM	1,695	602	10	1,580	1,399	4

(80%) to detect it. Mean IgM and IgA levels were also consistently higher in the ethanol-exposed group than in the controls, but the magnitude of difference was not statistically significant. The contrasts between the ethanol-exposed and unexposed groups were not appreciably altered when the analyses were restricted to females.

Hematocrit, White Blood Cell Count (WBC), Leukocyte Subsets, and Monocyte Phagocytic Function

Hematocrits, WBC, and the percentages of T-lymphocytes, B-lymphocytes, and monocytes were comparable in the ethanol-exposed and unexposed animals (Table 1). Monocyte phagocytic function was also comparable in the ethanol-exposed and unexposed groups (data not shown). The above results were not appreciably altered when the analyses were restricted to females.

DISCUSSION

These studies were part of a larger behavioral and neural development study[14,15] and were initiated when the animals were 1–3 years old, after it was noted that there was a 22% mortality in the ethanol-exposed animals (4 of 18) compared to 0% in the control animals (0 of 7). It is important to note that the original study was not designed to evaluate immunologic parameters; the power to draw conclusions from negative associations is very low. It is not the function of this study to draw firm conclusions from these preliminary results, but, rather, to generate hypotheses and report outcome variability, which, in turn, will provide direction and facilitate the design of future studies. It is also important to note that the contrasts observed between the ethanol-exposed and unexposed animals are likely to be underestimated because the study was initiated after the most vulnerable and possibly immunocompromised animals in the ethanol-exposed groups died.

The four animals that died before the initiation of this study succumbed to infectious diarrheal disease. Diarrheal disease is common in laboratory monkeys[22] and *Shigella*, *Campylobacter*, and *Cryptosporidium*[23,24] are isolated in diarrheal episodes in the Infant Primate Laboratory. The majority of animals with infectious diarrheas respond to symptomatic therapy;[22] however, four of the ethanol-exposed offspring developed diarrhea that was refractory to treatment.

The fact that the control group, by chance, was entirely female raised concerns about the potential confounding effect that gender may have on our search for associations between ethanol exposure and immune outcome measures in this study. To address this concern, all analyses were repeated among females only and reported when the results differed from those of analyses of the males and females combined. The only comparisons that differed substantially when restricted to females were lymphocyte

proliferation after activation with TT and antibody response to TT vaccination. In both cases, the difference between the ethanol-exposed and unexposed groups increased. The sample size was too small to infer that males and females respond differently to fetal alcohol exposure. More importantly, these results strongly support the need to control for gender as a potential covariate in the design of future studies.

Although only a small group of animals was available, it is noteworthy that we found significantly decreased lymphocyte proliferation in the ethanol-exposed animals (compared to controls) after stimulation with TT and near-significant abnormalities in T-lymphocyte proliferation after stimulation with SEB. T-cells activated with SEB, a superantigen, showed less proliferation in all of the ethanol-exposed groups, especially in the 3-week exposed animals (Fig. 1A), suggesting abnormalities in T-lymphocytes with T-cell antigen receptor V_β expression.[25,26]

Immunization with tetanus toxoid allowed evaluation of recall responses. This is a sensitive assay of cellular immunity.[27,28] Ethanol-exposed animals had significantly reduced proliferation in response to tetanus antigen compared to that in the control group. The 3-week exposure group was affected the most severely. These findings may be related to abnormalities in antigen presentation, $CD4^+$ T-cell function, or $CD4^+$ help provided to antibody-producing B-cells. Since T-cell responses to lectin activators (such as PHA) are also dependent on adequate antigen presentation, which was not altered in the 3-week exposure group, a defect in antigen presentation is less likely. Decreased T-cell proliferation has been reported in children with FAS[29] and in rodents[8-11] with prenatal ethanol exposure. Antigen-specific memory responses have not been examined in rodent studies with prenatal ethanol exposure.

Children with FAS have decreased percentages of B-lymphocytes in the peripheral blood compared to controls.[29] In this study, 3- and 6-week exposed animals had lower percentages of B-lymphocytes. The magnitude of the decrease between children with FAS and controls was similar to the decrease in 3- and 6-week exposed animals, but these changes were not statistically significant. Nine of 13 children with FAS had decreased serum immunoglobulins.[29] We did not find decreased serum immunoglobulin levels (Table 2).

The mechanisms responsible for altered T-cell function with fetal ethanol exposure will require future studies with particular emphasis on thymic development. Thymic hypocellularity and alterations in thymocyte subsets and proliferation have been associated with in utero alcohol exposure in rodents.[7,8,30,31]

There was considerable variability in the lymphocyte proliferation assay. It is unclear why *M. nemestrina* have such a high variability, but other investigators working with *M. fascicularis*, *P. papio*, and *M. mulatta*[32-34] have also noted a high variability in immune function assays. Since lymphocyte proliferation assays in our laboratory have low variability in inbred pathogen-free mice, the variability is most likely intrinsic to outbred nonhuman primates. Some of the variability may be related to differences in menstrual cycles, which are variable and difficult to detect in young macaques (personal communication, J. Bielitzki).

Most studies evaluating immune function with prenatal ethanol exposure have used rats or mice. This is the first study to evaluate several aspects of host response in a nonhuman primate model, which more closely approximates the placentation and lymphoid system development of man. Our findings are preliminary and need confirmation with further prospectively designed studies.

ACKNOWLEDGMENTS

We thank Dr. D. Bowden for the review of this manuscript, Dr. David Nelson at the National Cancer Institute for performing the tetanus antibody titers, and Miss Kathy Eiffert for her assistance in handling animals.

ASTLEY, S. J., E. WEINBERGER, D. W. W. SHAW, T. L. RICHARDS AND S. K. CLARREN. *Magnetic resonance imaging and spectroscopy in fetal ethanol exposed Macaca nemestrina.* NEUROTOXICOL TERATOL **17**(5) 523–530, 1995.—Magnetic resonance imaging (MRI) and proton magnetic resonance spectroscopy (^{1}H-MRS) offer noninvasive ways to observe structural and biochemical changes which might serve as valuable diagnostic markers for detecting brain damage from prenatal ethanol teratogenesis. Cranial MR imaging and spectroscopy were performed on 20 nonhuman primates (*Macaca nemestrina*) with known prenatal ethanol exposures and well-documented cognitive and behavioral levels of performance. The choline : creatine ratio detected by ^{1}H-MRS in the brain increased significantly with increasing duration of in utero ethanol exposure. These signal alterations occurred in the absence of gross structural brain anomalies (detectable by MRI) and were significantly correlated with alcohol-related cognitive and behavioral dysfunction. These observations are consistent with reports of elevated choline : creatine ratios associated with various neurologic insults and disease states. The association observed between brain choline : creatine ratios and in utero ethanol exposure suggest a role for ^{1}H-MRS in elucidating mechanisms of ethanol teratogenicity.

Fetal alcohol syndrome (FAS) Magnetic Resonance Imaging (MRI) Magnetic Resonance Spectroscopy (MRS)
Cholinergic Acetylcholine

A PREVIOUS report has demonstrated that ethanol teratogenicity in nonhuman primates (*Macaca nemestrina*) can result from just once per week binge drinking in only the first 6 to 8 weeks of gestation (5). This exposure can produce cognitive and behavioral abnormalities with or without associated abnormalities in growth or facial form. Magnetic resonance imaging (MRI) and proton spectroscopy (^{1}H-MRS) offer noninvasive ways to observe structural and biochemical changes that might serve as valuable diagnostic markers for detecting brain damage from prenatal ethanol teratogenesis. Cranial MR imaging and spectroscopy were performed on a group of nonhuman primates with known prenatal ethanol exposures and well-documented cognitive and behavioral levels of performance (5,6) to test the usefulness of this technology in this disorder.

METHOD

Study Population, Maternal Dosing, and Infant Developmental Assessment

Cranial MRI and ^{1}H-MRS were performed on the offspring of 20 nonhuman primates (*Macaca nemestrina*) who were prenatally exposed to ethanol or sucrose (control) solution. The mothers of the offspring were time-mated over a period of 1.9 years and randomly assigned to one of four exposure groups. The dams in Group 1 received 1.8 g/kg ethanol once a week for the entire 24 weeks of pregnancy. Group 2 received a sucrose solution that was isocaloric and isovolemic to the ethanol solution once a week for the entire 24 weeks of pregnancy. Group three received the ethanol solution once a week for Weeks 1 through 3 and the sucrose solution

[1] Requests for reprints should be addressed to Susan J. Astley, Ph.D., Division of Congenital Defects, Children's Hospital and Medical Center, CH-47, 4800 Sand Point Way N.E., Seattle, WA 98105.

once a week for Weeks 4 through 24. Group 4 received the ethanol solution once a week for Weeks 1 through 6 and the sucrose solution once a week for Weeks 7 through 24. The ethanol and sucrose solutions were administered orally via a soft nasogastric tube. Dosing was always initiated on the same day of the week, resulting in seven different weekly dosing schedules relative to the day of conception [i.e., gestational days (GDs) 1, 8, 15...; GDs 2, 9, 16...; through GDs 7, 14, 21...]. The distribution of the seven dosing schedules was comparable across the four exposure groups.

MRI and ^{1}H-MRS were conducted in the fall of 1993 when the offspring were between 2.4 and 4.1 years of age (the human equivalent of early to late adolescence). These 20 offspring are the survivors of a larger group of offspring (n = 27) assessed in the original ethanol teratogenicity study (5). They include six offspring in the control group, five in the 3-week ethanol group, five in the 6-week ethanol group, and four in the 24-week ethanol group. A summary of the developmental outcomes, through 6 months of age, for each offspring are presented by animal study number in Fig. 1 in Clarren et al. (5). The offspring included in this MRI/S study include animal numbers 34 through 60, excluding animal numbers 39, 42, 47, 53, 54, 57, and 59. Care and handling of all animals was in accordance with institutional guidelines.

Maternal peak plasma ethanol concentrations were monitored on all dams within 1 week postpartum. The mean peak plasma ethanol concentration among the 14 ethanol exposed animals was 227 ± 33 mg/dl, a level that could be achieved by a 55 kg person consuming approximately 6 to 8 beers or its equivalent. Peak plasma ethanol concentrations were monitored in the postpartum period to minimize handling during pregnancy. Pre- and postpartum plasma ethanol concentrations were confirmed to be comparable (6). Maternal dosing, pregnancy management, and pregnancy outcomes are presented in detail in Clarren & Astley (6).

Infant motor, cognitive, behavioral, and physical development was documented from birth through 24 months of age with a comprehensive battery of assessments which were developed and have been administered at the Infant Primate Research Laboratory for over 20 years (5). Briefly, 5- and 10-min Apgar scores were obtained and a complete physical examination was conducted at birth. Early motor and behavioral reflex responses were monitored from birth through 3 weeks of age using an adaptation of the Brazelton Neonatal Behavioral Assessment Scale (2). Attention, discrimination, and memory abilities were monitored between 2 and 4 weeks of age with an adaptation of the Fagan Test of Human Infant Intelligence (14). Motor and behavioral development during social interaction with age-matched peers in a playroom was recorded twice weekly from three weeks to nine months of age. Object permanence conceptualization, the ability to perceive objects as permanent entities when removed from site, was monitored twice weekly from 3 weeks to 4 months of age using the Object Permanence Test Series. Learning and memory skills were tested daily from 4 to 14 months of age using the Wisconsin General Testing Apparatus (WGTA) (18). Measures of activity and distraction were recorded during all WGTA test sessions. Free-play activity level in an observation playroom was recorded and coded on videotape at 1, 6, and 12 months of age. Infant growth and craniofacial development was documented through anthropometric examination and collection of standardized cephalometric X-rays and photographs at 1, 6, 12, and 24 months of age. Detailed descriptions of infant rearing, assessment, and developmental outcomes through the first 6 months of life can be found in Clarren et al. (5,7).

In this MRI/S study, an unweighted composite score reflecting each animal's developmental impairment through 6 months of age was derived by dividing the number of assessments an animal failed by the number of assessments used to summarize each animals' development in Fig. 1 presented in Clarren et al. (5). Failure for each assessment was defined as

FIG. 1. Coronal and sagittal T1-weighted magnetic resonance images (400–550/12, repetition/echo times in ms), defining the region of interest for magnetic resonance spectroscopy. The center of the 3.4 cc volume of interest was selected on a coronal image selected from a sagittal localizer to include thalamus, parts of the internal capsule and basal ganglia, and adjacent white matter.

(a) performance > 2 SDs below the mean performance of the control animals or (b) presence of a neurologic disorder/congenital anomaly.

MRI and ^{1}H-MRS

MRI and ^{1}H-MRS were carried out on a General Electric Signa whole body MR Scanner operating at 1.5 Telsa, using version 4.6 software and hardware. The animals were sedated with an intramuscular injection of ketamine/xylazine (10 mg/kg), placed in prone position, and aligned comparably (Frankfort Horizontal plane at 90°; to the horizontal axis of the scanner) in a knee coil with the aid of a custom designed stereotaxic head holder. A knee coil was used to accommodate the small size of the animals' heads. Although blood gas or oximetry data was not collected, respiration was visually monitored and postioning in the Frankfort Horizontal alignment facilited maintanence of a free airway. MRI and ^{1}H-MRS were obtained sequentially utilizing the same hardware. The entire procedure (alignment, imaging, and spectroscopy) required approximately 60 min of sedation time.

The MRI study was performed first and included T1-weighted sequences in the sagittal and coronal planes, and both T1 and T2-weighted images in the axial plane. Sequence parameters for T1-weighted images were repetition time (TR) 400–550 ms and echo time (TE) 12 ms. Parameters for T2-weighted images were TR 2500 ms and TE 23 and 80 ms. A 16-cm field of view was utilized with slice thickness of 3 or 4 mm.

MR coronal images were used to define a 3.4 cc brain region of interest for spectroscopy (Fig. 1). Volume-localized spectra were achieved using the point resolved spectroscopy (PRESS) pulse sequence (27). This pulse sequence uses 90°–180°–180° radio frequency pulses and has three water suppression radio frequency pulses with gradient spoilers. Magnetic field homogeneity was adjusted with the *X*, *Y*, and *Z* gradients using the localized voxel immediately before spectral data acquisition. The acquisition parameters were: TR 2000 ms; TE 136 ms; voxel size 3.4 cc; sweep width of 1000 Hz; spectral frequency 63.8 MHz; number of acquisition points 1024; number of averages 100.

The above parameters result in acquisition of spectra with three principle resonances: choline-containing compounds (Cho), creatine-containing compounds (Cr), and N-acetyl aspartate (NAA) (Fig. 2A). The *N*-methyl groups of choline containing compounds resonate at 3.2 ppm in the MR spectra, Cr resonates at 3.0 ppm and the *N*-methyl group of NAA resonates at 2.0 ppm. Cho is a precursor for the neurotransmitter acetylcholine and for phosphatidylcholine and sphingomyelin, two common phospholipids in neuronal and glial membranes (25). NAA is relatively abundant in neural tissue and is believed to be involved in regulation of neuronal protein synthesis, myelin production, and the metabolism of several neurotransmitters such as aspartate and N-acetyl-aspartyl-glutamate (1). Both creatine and creatine phosphate contribute to the single creatine peak. Creatine serves as a reserve for high-energy phosphates in the cytosol of muscle and neurons and buffers cellular ATP/ADP reservoirs. The integrated areas of the ab-

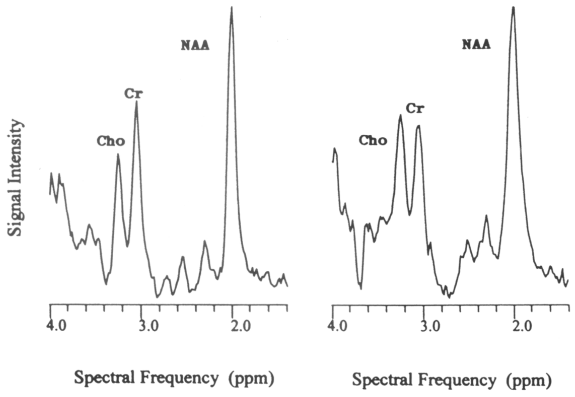

FIG. 2. A. Magnetic resonance spectrum, 2000/136 (repetition/echo time in msec), with the water signal suppressed, of a 3.4 cc brain tissue volume from a control animal (#37) and a 24-week ethanol exposed animal (#56). The Cho/Cr ratio (0.66) for the control animal is reflective of the group mean. The Cho/Cr ratio for the ethanol-exposed animal (0.95) was the highest observed ratio. choline (Cho), creatine (Cr), N-acetyl-aspartate (NAA). B. Baseline corrected spectra for the Cho, Cr, and NAA regions of the proton magnetic resonance spectra for the two animals presented in A. The solid line is the actual spectral data and the shaded line is the fit. The baseline was determined at constant ppm regions near the resonances for all the spectra and then fit to a linear equation. The baseline was subtracted from the spectrum before fitting was performed. Fitting was performed using a superposition of two resonances in the Gaussian equation for the Cho/Cr region and a single resonance Gaussian equation for the NAA region of the spectrum. The resonance areas were determined from the height and width resulting from the fit. choline (Cho), creatine (Cr), N-acetyl-aspartate (NAA).

sorption-mode resonances (peak areas) for Cho, Cr, and NAA were computed using Lorenzian/Gaussian peak-fitting software after automated baseline subtraction (Fig. 2B). Best fit was achieved using a 100% Gaussian distribution. Proton spectra were quantified by dividing the peak area of the metabolite of interest by the peak area of another metabolite in the spectrum providing relative rather than absolute measures of metabolite concentration. Because past studies have demonstrated that the creatine peak is relatively stable with various diseases, it is often used as a control value, with some limitations, to compare with changes seen in NAA and Cho (3).

Analysis

The MR images were reviewed for the presence of gross morphologic anomalies by two radiologists (EW, DWS) and a dysmorphologist (SKC), masked to the exposure history of the animals. Computer-aided volumetric analyses were not conducted. One-way analysis of variance (ANOVA) and Student-Newman-Keuls test for multiple comparisons were used to determine if significant differences in mean ^{1}H-MRS metabolite ratios and mean infant developmental impairment composite scores could be detected between the four ethanol exposure cohorts. Regression analysis was used to evaluate the relationship between ^{1}H-MRS metabolite ratios, gestational day of ethanol exposure, and composite scores of infant developmental impairment through 6 months of age.

RESULTS

Review of the MR images revealed no gross morphologic abnormalities of CNS structures among any of the animals. No gross differences in morphology or size of cerebral hemispheres, corpus callosum, brainstem, or cerebellum were visually detectable between the animals.

MRS revealed a statistically significant increase in the Cho : Cr ratio with increasing duration of in utero ethanol exposure (one-way ANOVA weighted linear trend: $F(3, 16) = 10.2, p = 0.006$ (Table 1, Fig. 3a). The 24-week ethanol cohort had a significantly higher mean Cho : Cr metabolite ratio relative to the control and 3-week ethanol cohorts (Student-Newman-Keuls multiple comparison test: $p < 0.05$). These results closely parallel the significant linear association observed between the infant developmental impairment scores and duration of ethanol exposure in which both the 6- and 24-week ethanol exposed cohorts differed significantly from the control group (one-way ANOVA weighted linear trend: $F(3, 16) = 6.8, p = 0.02$; Student-Newman-Keuls multiple comparison test: $p < 0.05$) (Fig. 3b). Although the increase in the Cho : Cr ratio could be due to an increase in Cho and/or a decrease in Cr, analyses of the ratios NAA : Cr and NAA : Cho strongly suggest that it is the Cho component that is changing with increasing duration of ethanol exposure, not the Cr.

No statistically significant associations were observed between the NAA : Cr and Cho : NAA metabolite ratios and duration of in utero ethanol exposure. Although the power to detect statistically significant associations was limited by the small number of animals in each group, the negative statistical results were supported by the lack of any pattern of association observed in the scatter plots (not illustrated).

Metabolite ratios did not vary with gender, age at the time of the MR evaluation, total dose of ketamine : xylazine/kg body weight, or gestational age at first dose of ethanol.

A scatter plot of the Cho : Cr ratios and the developmental impairment composite scores revealed a significant curvilinear relationship with 45% of the variance in the impairment score being explained by the Cho : Cr ratio ($r^2 = 0.45$; $F = 6.9$, $p = 0.006$). The curvilinear nature of the plot was dominated by the outcome of a single animal (animal #49) in the 6-week exposure cohort (identified by an asterisk in Fig. 4). This animal was the most developmentally delayed animal in the study and was the only animal with a Cho : Cr ratio greater than 2 SDs below the control mean. If the outlier is excluded from the analysis, the developmental impairment score increases linearly with increasing Cho : Cr ratio with 34% of the variance in the developmental outcome score being explained by the Cho : Cr ratio ($r^2 = 0.34$, $F = 8.6$, $p = 0.009$).

DISCUSSION

Results demonstrated brain Cho : Cr ratios detected by ^{1}H-MRS increased with increasing duration of in utero ethanol

TABLE 1

SUMMARY OF DESCRIPTIVE CHARACTERISTICS AND OUTCOMES ACROSS THE FOUR ETHANOL EXPOSURE COHORTS

Characteristics	Duration of Once-Per-Week Maternal Ethanol Exposure During Pregnancy			
	0 weeks	3 weeks	6 weeks	24 weeks
	(n = 6)	(n = 5)	(n = 5)	(n = 4)
Metabolite ratios, mean (SE)				
Cho : Cr*	0.66 (0.03)	0.67 (0.05)	0.72 (0.06)	0.85 (0.04)
NAA : Cr	2.01 (0.24)	1.63 (0.06)	1.95 (0.19)	2.07 (0.39)
Cho : NAA	0.34 (0.02)	0.41 (0.04)	0.37 (0.02)	0.44 (0.05)
Infant Developmental Outcome				
Scores†, mean (SE)	0.03 (0.02)	0.15 (0.05)	0.31 (0.09)	0.27 (0.04)
Female (n)	6	2	3	3
Age in years at time of MRI/^{1}H-MRS, mean (SE)	3.6 (0.2)	3.2 (0.2)	3.8 (0.1)	3.1 (0.3)
Age in days at first treatment dose, mean (SE)	— —	6.6 (1.1)	8.8 (1.2)	9.5 (1.3)
Ketamine : xylazine dose (mg/kg) mean (SE)	0.25 (0.05)	0.22 (0.03)	0.19 (0.01)	0.20 (0.03)

*One-way ANOVA weighted linear trend: $F(3, 16) = 10.2$, $p = 0.006$. Student-Newman-Keuls multiple comparison test: 24-week cohort differs from the control and 3-week cohort, $p < 0.05$. † One-way ANOVA weighted linear trend: $F(3, 16) = 5.8$, $p = 0.02$. Student-Newman-Keuls multiple comparison test: 6- and 24-week cohorts differ from the control group, $p < 0.05$. SE = Standard Error.

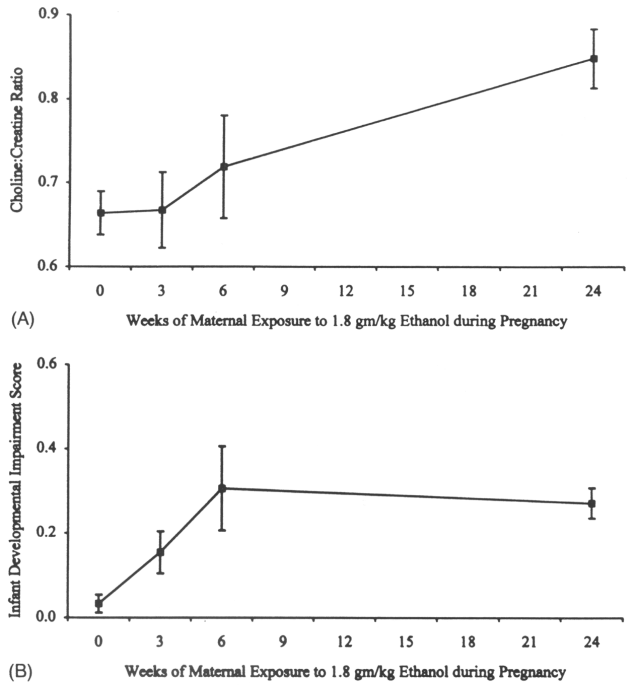

FIG. 3. A. Mean (±SE) brain choline : creatine ratios for the control, 3-week, 6-week, and 24-week ethanol exposure cohorts. The mean Cho : Cr metabolite ratio increased linearly with increasing duration of ethanol exposure (Oneway ANOVA weighted linear trend: $F(3, 16) = 10.2$, $p = 0.006$). B. Mean (±SE) infant developmental impairment score for the control, 3-week, 6-week, and 24-week ethanol exposure cohorts. The mean infant developmental impairment score increased linearly with increasing duration of ethanol exposure (one-way ANOVA weighted linear trend: $F(3, 16) = 6.8$, $p = 0.02$).

exposure, $F(3, 16) = 10.2$; $p = 0.006$, in this nonhuman primate model of fetal alcohol syndrome (FAS). These alterations occur in the absence of gross morphological abnormalities among live born animals (detectable by MR imaging). The Cho : Cr ratios were also observed to increase with increased cognitive and behavioral dysfunction in these animals ($r^2 = 0.45$; $F = 6.9$, $p = 0.006$). The observed increase in the Cho : Cr ratio is consistent with reports of elevated Cho : Cr ratios associated with various neurological insults and disease states (e.g., brain ischemia, brain tumors, multiple sclerosis, and Alzheimer's disease) (4,21,26,31,23). The absence of gross morphological abnormalities is consistent with observations in our previous study of ethanol teratogenicity in nonhuman primates (8). Morphological abnormalities such as agenesis of the corpus callosum have been reported in a few FAS case-series (9,19,22) but the prevalence appears to be quite low.

The Role of Choline and Detection by ^{1}H-MRS

Choline is a precursor for two important molecules, phosphatidylcholine (PtdCho) and acetylcholine (AcCho). Cho is present in membranes of all cells, where it constitutes the polar subunit of PtdCho, sphingomyelin, and plasmalogens. Within cholinergic neurons, Cho is also the precursor for the synthesis of AcCho (16). The rate of AcCho synthesis is regulated by the concentration of substrate Cho in cholinergic neurons. Choline acetyltransferase (CAT) catalyzes the synthesis of AcCho in the reaction: Cho + acetyl coenzyme A → AcCho + coenzyme A. AcCho is a neurotransmitter that is critical for many aspects of memory, cognition, and mood (13).

There remains uncertainty in the field of MR spectroscopy as to which of the choline containing compounds contribute to the 3.2 ppm peak. The total concentration of the major water soluble choline containing compounds including choline, glycerophosphocholine, phosphorylcholine, CDP-choline, AcCho, and choline-plasmalogen total to less than 1.6 mM (25). Conversely, lipid-soluble sphingomyelin and PtdCho occur in concentrations that are over 20 mM, but the proton spectrum of "normal" brain has little (if any) lipid signal because the phospholipids in cell membranes have limited mobility (37,15). It is believed that the choline peak seen in ^{1}H-MRS reflects all choline stores but is most likely dominated by sig-

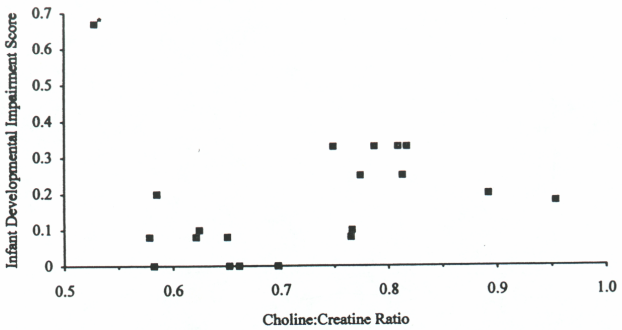

FIG. 4. Scatterplot of the the brain Cho/Cr ratios detected by ^{1}H-MRS and the developmental impairment composite scores. There is a significant curvilinear relationship with 45% of the variance in the impairment score being explained by the Cho : Cr ratio ($r^2 = 0.45$; $F = 6.9$, $p = 0.006$). The curvilinear nature of the plot was dominated by the outcome of a single animal in the 6-week exposure cohort (identified by an asterisk), which may be suggestive of a threshold effect. If the outlier is excluded from the analysis, the developmental impairment score increases linearly with increasing Cho : Cr ratio with 34% of the variance in the developmental outcome score being explained by the Cho : Cr ratio ($r^2 = 0.34$, $F = 8.6$, $p = 0.009$). choline (Cho) creatine (Cr).

nal from lipids being mobilized for membrane synthesis (e.g., brain tumor growth) or breakdown (e.g., demyelination observed in multiple sclerosis).

Cholinergic-based research in Alzheimer's Disease (AD) provides supportive evidence that the choline peak seen in ^{1}H-MRS may indeed be reflective of membrane destabilization. In AD, cortical AcCho and CAT levels are significantly reduced relative to age-matched controls (11,38). As noted, the rate of AcCho synthesis is regulated by the concentration of substrate Ch in cholinergic neurons. The decline of cortical AcCho in AD is attributed to the selective loss of cholinergic neurons, particularly from the cholinergic pathway projecting from deep nuclei located in the septum near the diagonal band of Broca to the hippocampus and from the nearby basal nucleus of Meynert to the cerebral cortex (10) (Fig. 5). Wurtman et al. (39) hypothesized that Cho deprived cholinergic neurons catabolize their own membranes ("autocannabalism") to free-up Cho for AcCho synthesis. Wurtman et al. suggest that this dual use of Cho for membrane and neurotransmitter synthesis could make AcCho producing cells particularly vulnerable to alterations in Cho levels. In a recent ^{1}H-MRS study, Meyeroff et al. (23) observed significantly higher Cho/Cr signals in patients with AD relative to elderly controls. Cho/Cr was 37% higher ($p = 0.0002$) in the mesial gray matter of the centrum semiovale and 23% higher ($p = 0.05$) in adjacent lateral voxels located in a predominantly white matter region of the posterior cortex. The authors note the consistency of their observations with reports in the AD literature document-

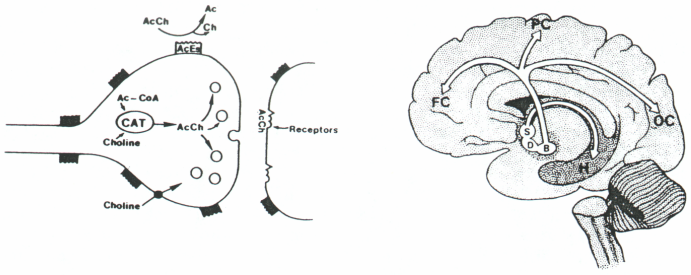

FIG. 5. Cholinergic pathways innervating cortex. The cholinergic neuronal cell bodies of the basal forebrain located in the nucleus basilis of Meynert (B), the diagonal band of Broca (D), and the medial septal nucleus (S) send axons that innervate the entire cortex including the frontal (FC), parietal (PC), and occipital (OC) cortex, as well as the hippocampal formation (H). (Reprinted with permission by Coyle et al., 1983).

ing membrane degradation effects due to increased phospholipid turnover (28,29) and defective membrane lipid compositions associated with membrane bilayer destabilization (17). As Meyerhoff et al. state, these observations are unified by Wurtman's "autocannabalism" theory on the pathogenesis of AD.

Depletion of Cholinergic Nuclei in a Mouse Model of FAS

Although limited work has been focused on the cholinergic system in FAS research, a recent study in mice has confirmed that in utero ethanol exposure can cause severe depletion of cholinergic nuclei (32). In that study, C57B1/6J mice were given two doses of ethanol (2.9 g/kg maternal body weight per dose, 500–600 mg/dl maternal peak blood alcohol concentration) on GD 7. In the mildly affected brains of GD 18 fetuses, fewer cells were immunoreactive for CAT in the medial septal nucleus and the vertical and horizontal nucleus of the diagonal band of Broca. In the severely affected brains, cells immunoreactive to CAT were totally absent. The severely affected mice had craniofacial anomalies consistent with those observed in humans with FAS. Schambra reports that without the projections of cholinergic neurons of the medial septal nucleus and the vertical nucleus of the diagonal band of Broca to the hippocampus, memory deficits as well as difficulty in inhibiting unwanted behaviors can be expected, as is reported to occur in FAS humans.

Although Schambra (32) and Sulik (34,35) have identified GD 7 in the mouse (Stage 9 of embryonic development, gastrulation) as a critical stage when acute exposure to ethanol can result in medial forebrain anomalies and FAS-like facial dysmorphia, the outcomes observed in this non human primate study cannot be isolated to a single stage of development because ethanol was administered weekly. There is one event, however, that was observed in this study that not only suggests that timing of exposure may be an important factor related to outcome but also provides a link between the outcomes observed in Schambra's study and the outcomes observed in this study. Schambra (32) and Sulik (35,35) report a continuum of ethanol induced teratogenic damage with holoprosencephaly representing the severe end of the spectrum. Sulik (36) goes on to speculate that severe cases of FAS represent the mild end of the holoprosencephaly spectrum. In this group of non human primates, one ethanol exposed animal was born with holoprosencephaly (33), an event that has never before been reported in the non human primate literature. Only one other animal (animal #56) in this MRI/S study had a weekly dosing pattern that was identical in timing (GDs 12, 21, 26 . . .), level, and duration to the holoprosencephalic animal. That animal had the highest Cho : Cr ratio of the group, a ratio that was 4.8 SDs higher than the control mean. Stage 9 of embryonic development in man (30) and macaque is estimated to occur at 20 ± 1 days postovulation.

Area Localized for ^{1}H-MRS

The majority of cortical cholinergic innervation is derived from nerve cells in the basal forebrain (20). The primary source of cortical cholinergic innervation in the rat originate from neurons in the ventral and medial aspects of the *globus pallidus*, extend into the hypothalamus and range rostrally to include the diagonal band of Broca and the medial septal nucleus (12). These areas correspond to the areas of cholinergic nuclei depletion observed in the FAS mouse model following in utero ethanol exposure (32). Comparative neuroanatomic studies indicate that the major part of this cholinergic system in primates is located in the nucleus basilis of Meynert (22) (Fig. 5), an area that was incorporated in the 3.4 cc voxel localized for ^{1}H-MRS in this primate study.

Based on the mechanism of cholinergic membrane vulnerability postulated by Wurtman et al. (39) one could speculate that the increased Cho : Cr ^{1}H-MRS signal ratios observed in this study may be associated with membrane breakdown. If AcCho is deficient, as might be expected based on the type of cognitive/behavioral impairment which is characteristic of patients with FAS (and is confirmed to be present in these nonhuman primates), breakdown of cholinergic neuron membranes could serve as a compensatory measure to free up Cho for AcCho synthesis. As demonstrated by Tunggal et al. (37), choline from catabolism of membrane phospholipids might considerably contribute to the AcCho neurotransmitter pool of the CNS. If cholinergic membranes were breaking down, one would expect to observe elevated Cho : Cr ^{1}H-MRS signals.

Interestingly, the only animal that deviated from the pattern of increased Cho : Cr signal with increased cognitive impairment was animal #49, the animal with the most profound cognitive and behavioral impairment and the only live born animal with minor facial dysmorphia. One could speculate that this animal may have sustained a level of damage that was beyond that of the other animals, perhaps severe enough to result in depletion of cholinergic nuclei. In such case, compensatory measures such as membrane breakdown would be less successful at achieving adequate AcCho levels and would result in a lower Cho : Cr MRS signal, as was observed. Ongoing neuroanatomical and neurochemical studies may shed light on the apparent uniqueness of this individual animal.

In conclusion, the association observed between brain Cho : Cr ratios and in utero ethanol exposure suggest a role for ^{1}H-MRS in elucidating mechanisms of ethanol teratogenicity. There may further be diagnostic benefits derived from the metabolic information available from ^{1}H-MRS in evaluation of FAS. These findings add further weight to the developing body of knowledge that purport that behavioral abnormalities can be attributable to prenatal exposure to ethanol in utero without evidence of microcephaly or structural aberration at the resolution level of CT or MR imaging. To our knowledge, this is the first reported association between in utero ethanol exposure and cranial Cho : Cr ratios detected by ^{1}H-MRS. Although further study is required to confirm this association, the dose-response nature of the association and documented cholinergic vulnerability in other animal models of FAS lend credence to this observed association.

ACKNOWLEDGEMENTS

We thank Douglas M. Bowden and the staff at the University of Washington Regional Primate Research Center (RPRC), the Infant Primate Research Laboratory, and the Child Development and Mental Retardation Center for their support of this study and the RPRC Bioengineering Division their help in the design and construction of the MRI stereotaxic head-holder. We also thank the staff of the University of Washington MRI Diagnostic Laboratory for the use of their facilities and expertise in conducting this study.

This research was supported in part by grants from General Electric (No. R32672.17) and the USPHS (AA05616).

A Fetal Alcohol Syndrome Screening Tool

Susan J. Astley and Sterling K. Clarren

The purpose of this study was to derive a multivariate, quantitative case definition of the fetal alcohol syndrome (FAS) facial phenotype from a dysmorphologist-derived gold standard and use it to develop an effective screening tool for identification of children at risk for FAS. The facial and physical features of a racially mixed group of children (0.2–10.0 years of age), evaluated by a single dysmorphologist in the University of Washington FAS Clinic, were used to determine which feature or set of features best differentiated between children with and without a diagnosis of FAS. The study population was divided into two groups balanced on gender, age at examination, race, diagnosis, and date of examination. Group 1 was used to identify the most differentiating feature(s), and group 2 was used to validate the differentiating capability of the feature(s). Group 1 included 97 children (20 with FAS and 77 without FAS). Group 2 included 97 children (19 with FAS and 78 without FAS). Discriminant analysis identified smooth philtrum, thin upper lip, and short palpebral fissures as the cluster of features that best differentiated children with and without FAS based on the discriminant function [D = 1.7953086 + 0.8116083 (thin upper lip) + 2.6411562 (smooth philtrum) − 3.4073780 (% predicted right palpebral fissure length)]. Patients with a D-score ≥ 1.5 were classified as at-risk for FAS (screen positive). Using this cut-off value for the D-score, children in group 1 were classified with 100% sensitivity (20 of 20 true positives) and 90.0% specificity (70 of 77 true negatives). The children in group 2 were classified with 100% sensitivity (19 of 19 true positives) and 87.3% specificity (68 of 78 true negatives). Across all 194 patients, sensitivity was 100% [95% confidence interval (97–100)] and specificity was 89% [95% confidence interval (85 to 93)]. Seventy-one percent (n = 12) of the 17 false-positives had a true classification of possible fetal alcohol effects. Sensitivity and specificity were unaffected by race, gender, and age through 10 years. This screening tool is effective at differentiating children with and without FAS as diagnosed by a single dysmorphologist (S.K.C.) at the University of Washington FAS Clinic. Assessment of diagnostic interrater agreement between trained dysmorphologists and testing in other clinic populations will be needed to assess the tool's external validity.

Key Words: Fetal Alcohol Syndrome, Screening.

FETAL ALCOHOL syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. FAS is characterized by cognitive/behavioral dysfunction, a unique cluster of minor facial anomalies, and is often accompanied by growth deficiency. FAS is the leading known cause of mental retardation in the Western World,[1] with an estimated incidence of 1–3 per 1000 live births.[2] Not all individuals exposed to alcohol during gestation have FAS. Individuals who have been exposed to alcohol in utero and present with cognitive/behavioral disabilities, but do not have the characteristic FAS facial appearance, are often classified as having possible fetal alcohol effects (PFAEs). Unlike FAS, PFAE is not a recognized medical diagnosis, for in the absence of the FAS facial phenotype, the cognitive/behavioral dysfunction cannot be definitively linked to the prenatal alcohol exposure in any one individual.[3] The cognitive/behavioral disabilities associated with PFAE are as severe as those associated with FAS. The incidence of PFAE is unknown, but is speculated to exceed that of FAS.

Individuals with FAS endure life-long disabilities. These disabilities are often compounded by secondary disabilities, such as low self-esteem, depression, aggression, school failure, and juvenile detention when the syndrome goes undiagnosed. These secondary disabilities come at a high cost to the individual, their family, and society, and can be reduced by early diagnosis and receipt of appropriate intervention.

Failure to diagnose FAS stems in large part from the difficulty inherent in making the diagnosis. Although confirmation of central nervous system dysfunction and growth deficiency are relatively straightforward clinical procedures, diagnosis of the FAS facial phenotype is less straightforward. An accurate diagnosis of the facial phenotype is best achieved by a trained dysmorphologist. Dysmorphologists typically use a "gestalt" approach to diagnosing FAS. The gestalt (or general clinical impression) approach focuses on the whole rather than the parts. It is qualitative rather than quantitative in nature. Use of a gestalt approach to pattern recognition is not unique to dysmorphologists. Anyone who has recognized an individual as having Down's syndrome is using a gestalt method. The phenotypic expression of Down's syndrome is sufficiently distinct that one need not measure the facial features to render an accurate phenotypic diagnosis. The gestalt method is a well-accepted standard of syndrome diagnosis that can be conducted with sufficient accuracy and reproducibility when performed by trained professionals.[4] The gestalt method becomes less accurate and reproducible when conducted by untrained individuals trying to diagnose a birth defect syndrome like FAS. Lack of diagnostic accuracy not only affects the individual patient, but also curtails public health screening and surveillance efforts aimed at tracking the incidence/prevalence of FAS; tracking that is paramount to service provision and primary prevention.[5]

The definition of a gold standard is "a method, procedure, or measurement that is widely accepted as being the best available. Often used to compare with new methods."[6] Although there is no officially recognized gold standard for the diagnosis of FAS, the gestalt method of diagnosis performed by a trained dysmorphologist was selected to serve as the gold standard for this study. The purpose of this study was to derive a case definition of the FAS facial phenotype from this gold standard and use it to develop an effective screening tool for identification of children at risk for FAS in the University of Washington FAS Clinic.

METHODS

Overview

This study was conducted at the Centers for Disease Control-sponsored FAS Clinic at the Center of Human Development and Disabilities at the University of Washington (Seattle, WA). The FAS Clinic serves a large, racially mixed patient population, all of whom are diagnosed by a single dysmorphologist (S.K.C.) with recognized expertise in FAS. The prevalence of FAS in the patient population is 20%. All patients from birth to 10.0 years of age, evaluated in the Clinic between January 1993 (the month the Clinic opened) and January 1995, were eligible for entry into the study (n = 194). The age range was restricted to maximize the accuracy of the FAS diagnosis, because the face often becomes less specifically anomolous after puberty. The 194 patients were randomly divided into two groups (n = 97 per group) balanced on age at examination, gender, race, diagnosis, and date of examination. A discriminant analysis was used to identify the facial/physical feature(s) that best differentiated the patients with and without FAS in group 1. The multivariate discriminant equation generated by the discriminant analysis served as both the FAS phenotypic case definition and the method (or screening tool) by which risk of FAS was assessed among patients in group 2. Application of the screening tool to group 2 served as an opportunity to test (or validate) the tool's performance among the University of Washington FAS Clinic patients.

Referral Population

The University of Washington FAS Clinic sees patients of all ages from all over the State of Washington. The geographic and racial distribution of the Clinic's patient population approximates the State's population. Referred patients typically have cognitive/behavioral dysfunction and a known or suspected history of in utero alcohol exposure. A small subset of the patients are referred solely on the basis of a history of in utero alcohol exposure. This subset tends to be infants awaiting foster/adoptive care.

Diagnosis

All patients were diagnosed by a trained dysmorphologist (S.K.C.) using a "gestalt" method of diagnosis (described herein). Patients were classified into 1 of 4 categories defined as follows:

FAS: Reported in utero alcohol exposure, CNS dysfunction, distinct presentation of the FAS facial phenotype, with or without documented growth deficiency.

AFAS (atypical fetal alcohol syndrome): Reported in utero alcohol exposure, CNS dysfunction, mild presentation of the FAS facial phenotype, with or without documented growth deficiency.

PFAE: Reported in utero alcohol exposure, CNS dysfunction, absence of the FAS facial phenotype, with or without documented growth deficiency.

Other: In utero alcohol exposure reported or suspected, but no diagnosis of FAS, AFAS, or PFAE was made because of the absence of both FAS-like facial anomalies and CNS dysfunction.

These classifications served as the "gold standard" (or true) classifications from which to compare the predicted classifications generated by the screening tool.

Measures

All patients evaluated in the FAS Clinic receive a comprehensive evaluation by a team of professionals, including a pediatrician/dysmorphologist (S.K.C.), a developmental pediatrician, a geneticist, a clinical psychologist, an educational psychologist, an educational liaison, a communication specialist, an occupational therapist, a social worker, and a public health nurse. Each patient receives a complete physical and dysmorphic examination. The physical and facial measures recorded and entered into this analysis are listed and defined in Table 1. The phenotypic

Table 1. Physical and Facial Measures Collected at the Time of Clinical Evaluation

Measure	Description
Eyes and eyebrows	
Palpebral fissure length	Distance between outer and inner canthi for right and left eyes (cm)
Inner canthal distance	Distance between right and left inner canthi (cm)
Clown eyebrows	High-arched eyebrows; (definitely, somewhat, or not present)
Ptosis	Drooping of the eyelid(s); (definitely, somewhat, or not present)
Epicanthal folds	Lateral extension of the skin of the nasal bridge down over the inner canthus; (definitely, somewhat, or not present)
Midface	
Nose length	Distance from inner canthus to the subnasion (cm)
Midface height	Distance from inner canthus to the lower border of the upper lip (cm)
Flat nasal bridge	(Definitely, somewhat, or not present)
Hypoplastic midface	Flat midface; (definitely, somewhat, or not present) (Fig. 2)
Mouth	
Smooth philtrum	Vertical ridges between the upper lip and the subnasion; (definitely, somewhat, or not present) (Fig. 1)
Thin upper lip	(Definitely, somewhat, or not present) (Fig. 1)
Abnormal palate	(Definitely, somewhat, or not present)
Palmar creases	
Hockey stick creases	(Present, absent)
Body measures	
Height	Height percentile for age and gender
Weight	Weight percentile for age and gender
OFC	% predicted occipital frontal circumference (OFC) for age and gender

Definitely smooth philtrum and definitely thin upper lip

Likert scale 2

Somewhat smooth philtrum and somewhat thin upper lip

Likert scale 1

Well defined philtrum and full upper lip

Likert scale 0

expression of several facial features are ranked on a 3-point Likert scale (definitely present, somewhat present, and not present). Pictorial examples of each of these rankings for thin upper lip, smooth philtrum, and hypoplastic midface are presented in Figs. 1 and 2. Right and left palpebral fissure lengths were measured for all patients and were found to be identical in 85% of the patients and within 0.1 cm of one another in 97% of the patients. Therefore, the right palpebral fissure length was arbitrarily selected for entry into the analysis. Several of the measures were transformed to age and/or sex-standardized measures as follows. Right palpebral fissure length, inner canthal distance, and occipital frontal circumference were converted to percent predicted measures for age and/or gender using formulas derived from plots of normal values published in Hall et al.[7] The formuli used to compute percent predicted palpebral fissure length for age were:

Predicted mean palpebral fissure length (mm)

$$= 19.154 + 3.2385\,(\text{age}) - 0.6242\,(\text{age}^2) + 0.0689\,(\text{age}^3) - 0.0037\,(\text{age}^4) + 0.000076\,(\text{age}^5)$$

where age is measured in years and is between 0 and 16 years.

Percent predicted right palpebral fissure length (PFL)

$$= \text{observed right PFL/predicted mean PFL}.$$

Height (cm) and weight (kg) were converted to height and weight centiles adjusted for age and gender using EPI-INFO, public-domain software distributed by the Centers for Disease Control and Prevention.[8] Norms for nose length and midface height were not available; therefore, the nose/midface ratio was used rather than the absolute measure of each feature.

Discriminant Analysis and Computation of Sensitivity and Specificity

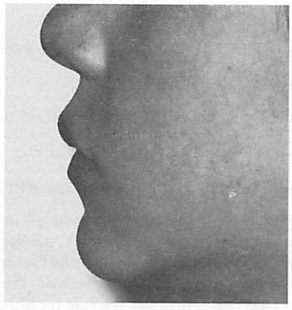
Discriminant analysis with step-wise variable selection (Wilk's lambda; F to enter = 3.84, F to remove = 2.71) was used to identify the physical features that best differentiated patients with and without FAS/AFAS. Prior probability of FAS/AFAS was computed from the prevalence in the study sample. The unstandardized canonical discriminant function coefficients were computed to derive the formula for calculation of each patient's discriminant score (or D-score). The D-score was used to classify whether or not a patient was at risk for FAS/AFAS. The D-score distributions for the patients with and without FAS/AFAS in group 1 were plotted to identify the D-score cut-off value that resulted in the highest sensitivity and specificity with priority given to maximizing the sensitivity. Sensitivity is the proportion of patients with FAS/AFAS who are correctly screened positive for FAS/AFAS. Specificity is the proportion of patients without FAS/AFAS who are correctly screened negative for FAS/AFAS.

D-scores for patients in group 2 were computed using the discriminant equation derived from group 1. Patients with D-scores ≥ 1.5 were classified as at-risk for FAS/AFAS (screen positive). Patients with D-scores < 1.5 were classified as not at risk for FAS/AFAS (screen negative). The sensitivity and specificity of the discriminant function (or screening tool's) performance were computed for group 2 as previously described.

RESULTS

The total population of 194 patients, 0.2–10.0 years of age, was divided into two groups ($n = 97$ per group) and successfully balanced on age at examination, gender, race, diagnosis, and date of examination (Table 2). Selected physical and facial characteristics of all patients are presented by diagnostic category (FAS, AFAS, PFAE, and Other) in Table 3. As would be expected, the presence of many of the individual physical and facial characteristics decrease as one progresses from the diagnostic classification of FAS, AFAS, PFAE, to Other. No two children with FAS had an identical pattern of facial features. The variation of phenotypic expression across the 27 children with FAS is displayed in Fig. 3.

In group 1, step-wise discriminant analysis selected hypoplastic midface, smooth philtrum, and thin upper lip as the three characteristics that best differentiated the patients with and without FAS/AFAS (sensitivity = 100%, specificity = 89.4%). Palpebral fissure length and hypoplastic midface were observed to be correlated (Spearman rank correlation coefficient = -0.37, $p < 0.000$) (Fig. 4). In an effort to identify features that could be most accurately recorded and were least influenced by race, palpebral fissure length was substituted for hypoplastic midface in the model without any loss of discrim-



Definitely Hypoplastic Midface

Likert Scale = 0

Fig. 2. Illustration of the 3-point Likert scale used to rank hypoplastic midface.

inating power. Because a flattened midfacial profile is a "normal" characteristic in some races (including Asian and American Indian), inclusion of this feature would limit the positive predictive value of the tool. Discrimination was best when smooth philtrum and thin upper lip were dichotomized as 0 = not present, 1 = somewhat/definitely present. The discriminant equation for computation of the D-score was:

$$D = 1.7953086 + 0.8116083\ (\text{thin upper lip}) + 2.6411562\ (\text{smooth philtrum}) - 3.4073780\ (\%\ \text{predicted right palpebral fissure length}).$$

This discriminant equation served as the quantitative, multivariate, phenotypic case definition for FAS/AFAS. A D-score cut-off value of ≥1.5 = at-risk for FAS/AFAS resulted in the maximum sensitivity (100%; 20 of 20 correctly classified as having FAS/AFAS) and specificity (90.9%; 70 of 77 correctly classified as not having FAS/AFAS) for patients in group 1. The discriminant equation classified the FAS/AFAS risk of group 2 patients with 100% sensitivity (19 of 19 correctly classified as FAS/AFAS) and 87.2% specificity (68 of 78 patients correctly classified as not having FAS/AFAS).

Across groups 1 and 2 combined, the discriminant formula classified the patients' FAS/AFAS risk status with 100% sensitivity (39 of 39 true positives) and 89% specificity (138 of 155 true negatives). The 95% confidence intervals for the estimate of sensitivity was 97–100%. The 95% confidence interval for the estimate of specificity was 85–93%. The distribution of D-scores for all 194 patients with and without FAS/AFAS is illustrated in Fig. 5. Seventeen of the 197 patients (9%) were classified as false-positives. Twelve of the 17 false-positive classifications (71%) had a true classification of PFAE. Selected characteristics of these 17 patients are presented in Table 4. Misclassification was not associated with race, gender, or age. Race, gender, and age had little influence on the sensitivity and specificity, as illustrated in Table 5. Three of the 194 patients had other syndrome diagnoses: Marfan syndrome, William's syndrome, and Schprintzen's syndrome. None of these patients received a diagnosis of FAS/AFAS in the FAS Clinic, and all three were correctly screened as not having FAS/AFAS.

DISCUSSION

This study has demonstrated that children with and without FAS, as diagnosed by a single dysmorphologist (S.K.C.) at the University of Washington FAS Clinic, can be consistently differentiated based on the combined level of expression of three facial features: palpebral fissure length, philtrum smoothness, and upper lip thinness. The clinical population included males and females, 0.2 and 10 years of age, from several racial backgrounds, including Caucasian, African, American, American Indian, Alaskan Native, Asian, Hispanic, and Mexican American. The screening tool performed with a high level of accuracy, with minimal influence by gender, race, and age up to 10 years. The patient population was purposely restricted to individuals ≤10.0 years of age, because it is well documented that the FAS facial features often change with the onset of adolescence.[9–12]

The development of this FAS screening tool represents a potential turning point in our ability to reliably and effectively screen children at risk for FAS. Emphasis was placed on identifying discriminating facial features for several reasons. First, they can be readily measured by individuals other than fully trained dysmorphologists/clinical geneticists. Second, unlike CNS dysfunction and growth deficiency, the facial phenotype is the only aspect of the syndrome that is specific to FAS, thereby serving as an ideal screening factor. Third, the facial features captured in this screening tool can be readily assessed from facial photographs, opening up the possibility of conducting population-based screening and/or surveillance with relative ease and efficiency. A recently completed pilot study (n = 20) assessing the feasibility of developing an FAS screening tool using facial features captured from photographs resulted in 100% sensitivity and specificity (Astley and Clarren, unpublished data).

This study represents the first step in the development of this tool. The next step is to test its performance in other clinical and population-based samples. Application in a variety of populations will serve to further validate its sensitivity and specificity, as well as document it's predictive value positive (PV+) and negative (PV−) in the field. The PV+ is the probability that a person with a positive FAS screening result does indeed have FAS. The PV− is the probability that a person with a negative FAS screening result does not have FAS. PV+ and PV− are dependent on the sensitivity and specificity of the screening tool, as well as the prevalence of FAS in the population being screened.

The performance of this screening tool is dependent on the accuracy and precision with which morphometric data is collected and to that end, standardized methods of data collec-

tion must be established[13] and intra- and interrater reliability will need to be documented. The gold standard selected for use in this study was the clinical judgment of a single dysmorphologist (S.K.C.). Because a formal assessment of diagnostic agreement between trained dysmorphologists has never been conducted, the results of this study reflect the clinical judgment of this dysmorphologist.[14]

One of the purposes of this study was to derive a case definition of the FAS facial phenotype using the gestalt method of diagnosis as the gold standard. The FAS facial phenotype is characterized by a cluster of minor facial anomalies that include small palpebral fissures, a flat midface, a smooth philtrum, and a thin upper lip.[15] But how small do the palpebral fissures have to be? How thin must the upper lip be? How is thinness measured? What combination of features must be present to establish a phenotypic diagnosis? Must all features be present? Are four of five sufficient? These are questions continually being asked by clinicians and researchers faced with diagnosing or classifying individual patients. Because the gestalt method of diagnosis does not rely on direct measurement of these features, answers to these questions have never been available. Without answers to these questions, establishment of an FAS phenotypic case definition has remained elusive. By quantitatively recording the phenotypic expression of facial features in our patient population, discriminant analysis was able to derive a multivariate, quantitative case definition that, for the first time, provides answers to these questions. Establishment of a case definition will provide a consistency of diagnosis across clinical and research

CI, confidence interval.

arenas that currently does not exist. This study does not proclaim to have established *the* FAS phenotypic case definition. The case definition must be reached by consensus across clinical and research teams. This study simply presents a methodologic approach that could be used to derive a phenotypic case definition.

A case definition and photographic screening tool for the facial phenotype of fetal alcohol syndrome.

Susan J. Astley, PhD. And Sterling K. Clarren, MD

from the Department of Epidemiology, School of Public Health and Community Medicine, and the Department of Pediatrics, School of Medicine, University of Washington, Seattle

Objectives: **The purpose of this study was to demonstrate that a quantitative, multivariate case definition of the fetal alcohol syndrome (FAS)3 facial phenotype could be derived from photographs of individuals with FAS and to demonstrate how this case definition and photographic approach could be used to develop efficient, accurate and precise screening tools, diagnostic aids and possibly surveillance tools.**

Study Design**: Frontal facial photographs of 42 subjects (0 to 27 years of age) with FAS were matched to 84 subjects without FAS. The study population was randomly divided in half. Group 1 was used to identify the facial features that best differentiated individuals with and without FAS. Group 2 was used for cross validation.**

Results**: In Group 1, stepwise discriminant analysis identified three facial features (reduced palpebral fissure length / inner canthal distance ratio, smooth philtrum, and thin upper lip) as the cluster of features that differentiated individuals with and without FAS in Groups 1 and 2 with 100% accuracy. Sensitivity and specificity were unaffected by race, gender, and age.**

Conclusions**: The phenotypic case definition derived from photographs accurately distinguished between individuals with and without FAS demonstrating the potential of this approach for developing screening, diagnostic, and surveillance tools. Further evaluation of the validity and generalizability of this methodology will be needed. (J Pediatr 1996; 129:33-41)**

Fetal alcohol syndrome is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. FAS is characterized by cognitive/behavioral dysfunction, a unique cluster of minor facial anomalies, and pre- and/or postnatal growth deficiency[1]. FAS is the leading known cause of mental retardation in the Western World[2] with an estimated incidence of 1 to 3 per 1,000 live births[3]. Individuals with FAS endure lifelong physical, intellectual, cognitive and behavioral disabilities. These disabilities are often compounded by secondary emotional and behavioral disabilities such as low self esteem, depression, school failure, and criminality when the syndrome fails to be diagnosed. These secondary disabilities come at a high cost to the individual, their family, and society and can be reduced by early diagnosis and receipt of appropriate intervention[4,5].

See commentary, p. 3

D-score	Discriminant Score
FAS	Fetal alcohol syndrome

Efforts to prevent FAS and its associated secondary disabilities are currently stymied by the lack of efficient and effective surveillance, screening, and diagnostic tools.

Development of these tools have, in turn, been stymied by the lack of an effective FAS case definition[6]. An ideal case definition for screening and surveillance of FAS would focus on the minimum cluster of features unique to FAS which are amenable to accurate, precise, and efficient measurement. The FAS facial phenotype is characterized by a cluster of minor facial anomalies which include small palpebral fissures, smooth philtrum, and thin upper lip[1]. Criteria have never been established regarding how small, how smooth, or how thin these features must be nor have criteria been established as to how many of these features must be present.

The goals of this study were to demonstrate (1) that an objective, quantitative, multivariate case definition of the FAS facial phenotype could be derived from facial photographs and (2) that this methodologic approach could be used to develop highly efficient, accurate, and precise screening tools, surveillance tools, and diagnostic aids for FAS.

METHODS

Overview. Frontal facial photographs of 42 subjects with FAS (birth to 27 years of age) were pair matched on age, race and gender to the frontal facial photographs of two randomly selected subjects without FAS (n = 84). The 126 patients were randomly divided into two groups (n = 63 per group) balanced on age, gender, and race. Stepwise discriminant analysis was used to identify the facial feature(s) that best differentiated the subjects with and without FAS in Group 1. The multivariate discriminant equation generated from the discriminant analysis in Group 1 served as both the FAS phenotypic case-definition and the method (or screening tool) by which risk of FAS was assessed among patients in Group 2. Application of the screening tool to Group 2 served as an opportunity to test the tool's validity.

Study Population and Photographic Quality. Photographs of FAS cases and controls were selected from among 1,110 frontal facial images of 740 clinical and research subjects stored in a computerized image database. This study was conducted with the approval of the University of Washington and Children's Hospital and Medical Center Human Subjects Divisions.

Computerized images of subjects with FAS have been collected over the years from syndrome diagnosis textbooks, the medical literature, colleagues, and patients examined by one of the authors at the CDC-sponsored University of Washington FAS Clinic. Each patient with FAS who was selected for this study were examined by clinicians with recognized expertise in the diagnosis of FAS and were felt, by the clinician, to have the facial phenotype of FAS at the time of the photograph. There were no age, race, or gender restrictions placed on selection of FAS cases. Each patient with FAS was matched on gender, race, and age at the time of the photograph (within two years), to two control subjects confirmed not to have a diagnosis of FAS. Control subjects may or may not have had documented prenatal alcohol exposure. The study controls were selected from a pool of 560 subjects which included patients seen at the University of Washington FAS Clinic and subjects who had participated in previous morphometric studies. Each pair of controls were randomly selected from among all controls meeting the matching criteria for each FAS case.

Photographs had to meet the following criteria for inclusion into the study: 1) camera aligned in the Frankfort Horizontal plane with minimal left-to-right rotation (i.e., both planes of rotation were within ± 5 degrees by visual inspection), 2) subject had a relaxed facial expression with eyes fully open and lips gently closed, and 3) image had adequate exposure and focus to allow accurate measurement of facial features.

Computer images and facial measures. All photographs were captured at 640 by 480 pixel resolution on a 256 unit gray scale using OPTIMAS (Optimas Corp., Edmonds, Wash.) image acquisition and enhancement software. The images were saved in tag-image-file (TIF) format. To reduce measurement bias, the FAS case/control status of each photograph was masked by cropping two separate images from each original TIF image: 1) a computer image that included just the eyes and 2) a computer image that included just the philtrum and mouth. All facial measurements were collected from these cropped images.

The facial measures recorded from each subject are listed and defined in Table 1. Emphasis was placed on measuring features previously identified as being specific to FAS[7] and features which could be reliably measured from photographs. Right and left palpebral fissure lengths and inner canthal distance were measured using the distance measurement tool in the OPTIMAS software. The photographs did not contain internal measures of scale, therefore a reduced palpebral fissure length / inner canthal distance ratio was used as a proxy measure for small palpebral fissure length. Direct measures obtained from patients diagnosed with FAS at the University of Washington FAS Clinic have confirmed the presence of short palpebral fissure lengths relative to normal inner canthal distances[7],supporting the validity of the proxy measure. The phenotypic expression of philtrum smoothness and upper lip thinness were recorded on 5-point Likert scales (Fig. 1). Upper lip thinness was also recorded on a continuous scale using an objective measure of shape called circularity (or perimeter^2 / area). The circularity of a circle is 4*Pi (about 12.57) which is theoretically the smallest value that this measure can have. As an object tends towards the shape of a line (or thinness), the circularity tends towards infinity. Philtrum contour was also measured objectively by recording pixel luminosity on a 256 continuous gray scale. With the OPTIMAS software, a line was drawn horizontally across

The Journal of Pediatrics
Volume 129, *Number* 1

the philtrum, centered between the upper lip and subnasion, with a length equal to the distance from the left to right corners of the mouth and a width 20% of the vertical distance between the upper lip and subnasion. The length of the line was divided into 100 units of equal size. Pixel luminosity was averaged over each of the 100 units and plotted to portray the gray scale variation (or shadows and highlights cast by the philtral ridges) across the philtrum (Fig. 2). The darkest luminosity in the philtrum furrow was subtracted from the brightest luminosity at a philtrum ridge to generate a measure of philtrum smoothness. The more deeply furrowed the philtrum, the greater the contrast in the luminosity of the ridge relative to the furrow. Upper lip thinness and philtrum smoothness were recorded on both Likert ordinal scales and objective continuous scales to assess the reliability and utility of each. The Likert scale has the advantage of being technologically simple, meaning the feature can be scored by hand in the event a computer is unavailable. The disadvantage is lower accuracy and precision. In direct contrast, the continuous measures of circularity and luminosity have the advantage of total objectivity, resulting in high accuracy and precision, but require access to appropriate software for derivation.

Discriminant analysis. Stepwise discriminant analysis (maximizing the Wilk lambda) was used to identify the facial feature(s) that best differentiated patients with and without FAS in group 1. Prior probability of FAS was set equal to the prevalence in the study sample (33%). The unstandardized canonical discriminant function coefficients were computed to derive the discriminant equation for calculation of each subject's discriminant score or D-score. The D-score was used to *predict* each subject's diagnostic classification (FAS, not FAS). The D-score distribution for the subjects with and without FAS in group 1 were plotted to identify the D-score cutoff value that resulted in the most accurate diagnostic prediction (i.e., had the highest level of sensitivity and specificity). Sensitivity is the proportion of patients with FAS who are correctly screened as having FAS. Specificity is the proportion of patients without FAS who are correctly screened as *not* having FAS. Sensitivity and specificity were computed by comparing each subject's true clinical diagnosis to their predicted diagnosis derived from the discriminant equation.

For cross validation, the discriminant equation and D-score cutoff value derived from group 1 were applied to group 2. Sensitivity and specificity for group 2 were computed by comparing each subject's true diagnosis with their predicted diagnosis.

RESULTS

The total population of 42 subjects with FAS and 84 controls were successfully balanced on gender, race, and age at the time the photograph was taken (Table II).

Table I. Facial measures recorded from the computerized frontal facial photographs

Facial feature	Description (units of measurement)
Eye region	
Palpebral fissure lengths	Distance between outer and inner canthi of right and left eyes (centimeters of computer monitor screen)
Inner canthal distance	Distance between right and left inner canthi (centimeters of computer monitor screen)
Mouth region	
Philtrum smoothness	Area between upper lip and subnasion, with focus on presence of midline vertical furrow bordered by two vertical ridges (Fig.1)
	5-Point Likert ordinal scale (1 deeply furrowed, 2 somewhat furrowed, 3 mid range, 4 somewhat smooth, 5 very smooth)
	Pixel luminosity: contrast between philtrum's ridges and furrow—the lower the contrast, the smoother the philtrum (0 to 255 continuous gray scale: 0 = white, 255 = black)
Upper lip thinness	Upper lip demarcated by its vermilion border (Fig.1)
	5-Point Likert ordinal scale (1 very thick, 2 somewhat thick, 3 mid-range, 4 somewhat thin, 5 very thin)
	Circularity – the larger the circularity, the thinner the upper lip (perimeter^2/area)

The age distribution of the study population was as follows: birth to two months (n = 1), 3 to 12 months (n = 4), 1 to 5 years (n = 43), 6 to 10 years (n = 46), 11 to 15 years (n = 22), 16 to 20 years (n = 6), 20+ years (n = 4). No two subjects with FAS had an identical pattern of facial features. The variation of phenotypic expression across the 42 subjects with FAS relative to the 84 control subjects is displayed in Fig. 3.

Discriminating facial features and the influence of measurement scale. Stepwise discriminant analysis selected all three facial features (palpebral fissure length / inner canthal distance ratio, philtrum smoothness measured on a Likert scale, and upper lip thinness measured on the continuous scale of circularity) as the cluster of features that best differentiated the patients with and without FAS. When the ordinal and continuous scales used to measure philtrum smoothness and upper lip thinness were interchanged in the discriminant equation, sensitivity and

	Philtrum/Upper Lip	Philtrum Likert Score	Upper Lip Likert Score	Philtrum Luminosity	Upper Lip Circularity
A		5	5	0	178.6
B		4	4	2	72.0
C		3	3	4	55.1
D		2	2	7	50.0
E		1	1	15	44.5

Fig. 1. Pictorial examples of the 5-point Likert ordinal scales used to rank upper lip thinness and philtrum smoothness. The corresponding continuous measures of upper lip circularity (perimeter^2/area of vermilion border) and philtrum luminosity (contrast in pixel luminosity between the philtral ridge and furrow with luminosity measured on a 256 unit gray scale) are also presented.

specificity were minimally influenced. The discriminant classification and cross validation results are presented below for each measurement scale.

Philtrum and upper lip measured on a Likert scale. When palpebral fissure length / inner canthal distance ratio, philtrum smoothness measured on a Likert scale, and upper lip thinness measured on a Likert scale were entered into the discriminant equation derived from group 1, a D-score greater than 0.7 differentiated the subjects with and without FAS with 100% sensitivity and specificity.

Table II. Demographic profile of subjects with and without FAS

Characteristic	Control group (n=84)	FAS group (n=42)
Age (yr)		
Mean (SD)	7.9(4.7)	6.5(5.2)
Minimum-maximum	1.5-26.7	0.0-24.2
Gender		
Girls: n(%)	28(33)	14(33)
Race: n(%)		
White	64(77)	32(77)
Black	4(5)	2(5)
American Indian	10(12)	5(12)
Alaskan Native	2(2)	1(2)
Asian	2(2)	1(2)
Hispanic	2(2)	1(2)
Other syndromes: n(%)		
Williams syndrome	1(1)	0(0)
Dubowitz syndrome	1(1)	0(0)
Aarskog syndrome	1(1)	0(0)
Marfan syndrome	1(1)	0(0)

When this discriminant equation and D-score cutoff value were applied to group 2 for cross validation, subjects from group 2 were also differentiated with 100% sensitivity and specificity.

The discriminant equation (equation 1) derived across all 126 subjects, was as follows: D-score=0.7408-- 5.7337 (palpebral fissure length / inner canthal distance ratio) + 1.1677 (philtrum Likert score) + 0.1587 (upper lip Likert score). A D-score greater than 0.8 was the cutoff value for classifying a subject as having FAS on the basis of screening (sensitivity = 100%, specificity = 100%, overall accuracy = 100%). Discriminant equation 1 explained 100% of the total variance (chi-square value [3, 126] = 224, p = .0000).

Philtrum and upper lip measured on continuous scales. When palpebral fissure length / inner canthal distance ratio, philtrum smoothness measured on the continuous scale of luminosity, and upper lip thinness measured on the continuous scale of circularity were entered into the discriminant equation derived from group 1, a D-score less than -0.5 differentiated the subjects with and without FAS with 95% sensitivity and 100% specificity. When this discriminant equation and D-score cutoff value were applied to group 2 for cross validation, subjects from group 2 were differentiated with 100 % sensitivity and 93 % specificity.

The discriminant equation (equation 2) derived across all 126 subjects was as follows:D-score = -6.4719 + 8.6104 (palpebral fissure length / inner canthal distance ratio) + 0.0767 (philtrum luminosity) - 0.0145 (upper lip circularity). A D-score less than -0.5 = cutoff value for classifying a subject as having FAS on the basis of screening (sensitivity = 99%, specificity = 95%, overall accuracy = 98%).

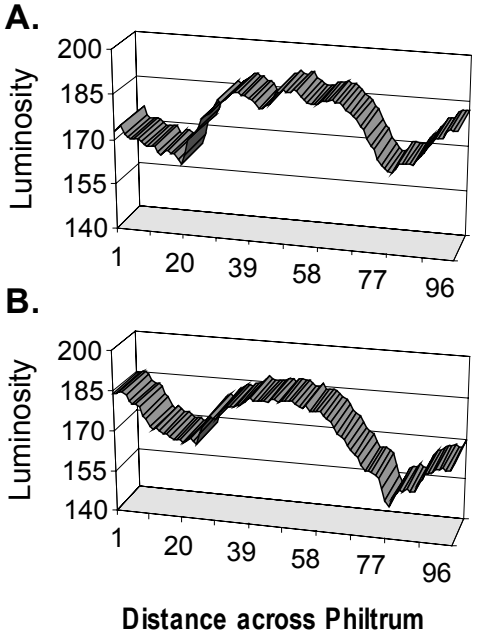

Fig. 2. Plot of pixel luminosity on a 256 unit gray scale along a line drawn horizontally across the philtrum from the left corner of the mouth (x axis = 1) to the right corner of the mouth (x axis = 100). A luminosity of 0 = black and a luminosity of 255 = white. **A**. Example of a deeply furrowed philtrum (Likert scale = 1). **B**. Example of a very smooth philtrum (Likert scale = 5).

Discriminant equation 2 explained 100% of the total variance (chi-square value [3,126] = 130, p = .0000).

Philtrum measured on a Likert scale, upper lip measured on a continuous scale. When palpebral fissure length / inner canthal distance ratio, philtrum smoothness measured on a Likert scale, and upper lip thinness measured on continuous scale of circularity were entered into the discriminant equation derived from group 1, a D-score greater than 0.7 differentiated the subjects with and without FAS with 100% sensitivity and specificity. When this discriminant equation and D-score cutoff value were applied to group 2 for cross validation, subjects from group 2 were also differentiated with 100% sensitivity and specificity.

The discriminant equation (equation 3) derived across all 126 subjects was as follows: D-score =1.1075 - 6.0082 (palpebral fissure length / inner canthal distance ratio)+ 1.1448 (philtrum Likert score) + 0.0066 (upper lip circularity). A D-score greater than 0.7 = cutoff value

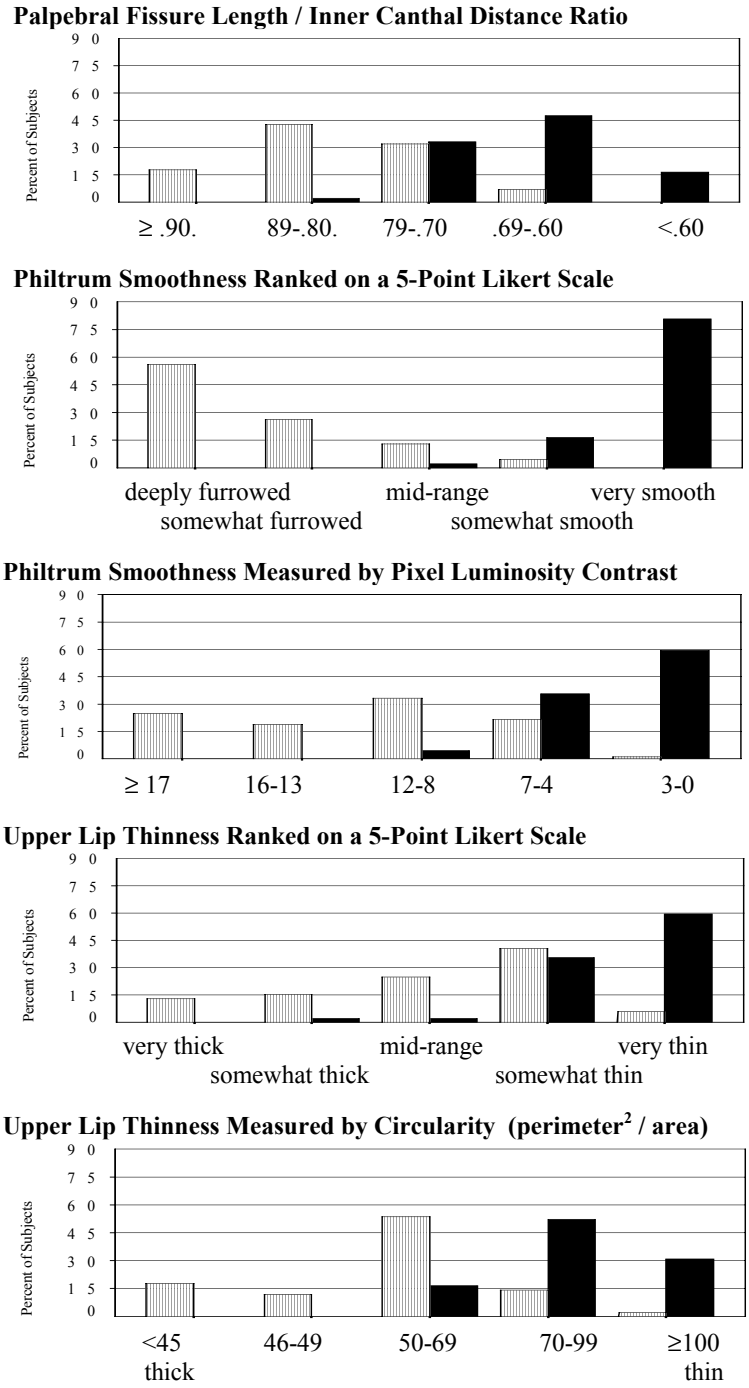

Fig. 3. Variation in expression of facial features among the 42 subjects with (black bars) FAS and 84 subjects without (*gray bars*) FAS. The circularity measure of upper lip thinness reflects the perimeter^2/area of the vermilion border. Philtrum luminosity contrast reflects the contrast in pixel luminosity between the philtrum's ridge and furrow, with luminosity recorded on a 256 unit gray scale.

The Journal of Pediatrics *Astley and Clarren* **39**
Volume 129, *Number* 1

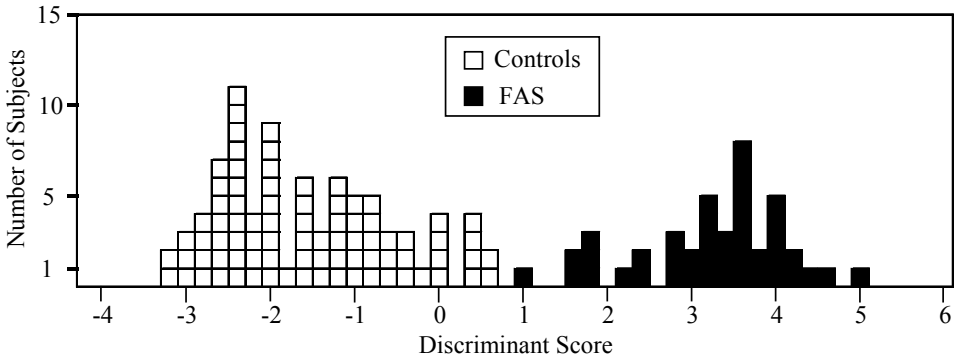

Fig. 4. Distribution of discriminant (*D*) scores among the patients with and without FAS based on the following discriminant equation: D-score = 1.1075 - 6.0082 (palpebral fissure length/inner canthal distance ratio)+ 1.1448 (philtrum Likert score) + 0.0066 (upper lip circularity). (The discriminant equation was derived across all 126 subjects.)

classifying a subject as FAS on the basis of screening (sensitivity = 100%, specificity = 100%, overall accuracy = 100%).

Equation 3 reflects the most objective, sensitive, and specific discriminant function explaining 100% of the total variance (χ^2 [3,126] = 226, p = .0000). The distribution of D-scores for all 126 subjects with and without FAS, derived from equation 3, is presented in Fig. 4.

Sensitivity and specificity across all six discriminant equations were unaffected by race, gender, and age in this study population.

Of the 84 control subjects, four had other syndrome diagnoses: Marfan syndrome, Williams syndrome, Dubowitz syndrome and Aarskog syndrome. All discriminant equations correctly screened the four subjects as not having FAS.

DISCUSSION

This study has demonstrated that a phenotypic case definition of FAS can be derived from frontal facial photographs of individuals with FAS. It has also illustrated how this case-definition and methodologic approach can be used to develop an accurate and precise screening tool and diagnostic aid. The discriminating cluster of facial features identified from the photographs are identical to the facial features identified by direct facial measurement in a previous study[7], thus supporting the validity of this photographic approach. Sensitivity and specificity were unaltered by race, gender, and age in both this and the previous study populations[7], supporting the potential generalizability of this methodology. Further studies, however, will be necessary to more definitively evaluate phenotypic variation that may occur across races.

It was particularly encouraging that the computer was able to identify a common phenotypic pattern in patients whom FAS was diagnosed by more than one clinician, not only illustrating that a phenotypic consensus can be reached, but also illustrating a method by which to establish such a consensus. This is not to say that phenotypic classification does not vary across the clinical and research communities. One need only review the literature[8] and published photographs to see how broadly the original[1, 10] and revised[10] descriptions of the FAS facial phenotype are interpreted, resulting in misclassification of research subjects and misdiagnosis of clinical patients. It is not that clinicians and researchers cannot consistently identify the facial phenotype; they simply do not have sufficiently specific guidelines for achieving such consistency.

To further test the ability of the function to differentiate between FAS and other syndromes with similar facial phenotypes, facial measures were obtained from the photographs of 10 additional control subjects published in syndrome diagnostic textbooks with the following syndromes: fetal hydantoin syndrome, Dubowitz syndrome, Noonan syndrome, Turner syndrome, Bloom syndrome, Aarskog syndrome and Opitz syndrome. Ages ranged from 1 to 20 years, with a distribution comparable to the 126 subjects with and without FAS. All but the individual with fetal hydantoin syndrome were classified correctly as not having the facial phenotype of FAS. This suggests that this screening tool will effectively separate the dysmorphic features of FAS from normal and also from many, but not necessarily all, other syndromes.

A key factor in the success of this study was the quality of the photographic images. It is important to note that all photographs were taken by nonprofessional photographers using handheld cameras. Obtaining a quality photograph does not require sophisticated equipment or expertise. One need only focus on three elements: proper alignment[11], proper exposure, and a relaxed facial expression, all of which can be easily attained by shooting a test roll of film with a properly aligned photograph in hand as a guide.

Table III. Contrasts in facial features and discriminant scores between the study groups with and without FAS.

Predictor and Outcome Variables	Control group (n = 84)	FAS group (n = 42)	Test statistic	p

* Contrast in pixel luminosity between philtral ridge and furrow measured on a 256 unit gray scale.
† Perimeter^2 / area.
‡ Based on Discriminant Equation 1: D = 0.7408 - 5.7337 (palpebral fissure length/inner canthal distance ratio) + 1.1677 (philtrum Likert score) + 0.1587 (upper lip Likert score) derived across all 126 subjects.
§ Based on Discriminant Equation 2: D = -6.4719 + 8.6104 (palpebral fissure length/inner canthal distance ratio) + 0.0767 (philtrum luminosity) - 0.0145 (upper lip circularity) derived across all 126 subjects.
□ Based on Discriminant Equation 3: D = 1.1075 - 6.0082 (palpebral fissure length/inner canthal distance ratio) + 1.1448 (philtrum Likert score) + 0.0066 (upper lip circularity) derived across all 126 subjects.

Recording facial measurements indirectly from a photograph rather than directly from the face has several advantages. By capturing a photographic or computer image, all three key facial features can be recorded on objective, continuous scales with the aid of computer software. This approach maximizes measurement accuracy and precision. If computer-derived continuous measures can be developed which validly capture the information obtained by the Likert scales, the process of phenotypic classification could be computer automated. The results of this study support the feasibility of such an endeavor. The continuous measure of circularity used to measure lip thinness was highly correlated with the Likert ranking (Spearman rank correlation coefficient 0.84: p = 0.000) and performed with equal sensitivity and specificity (100%). The continuous measure of luminosity used to measure philtrum smoothness was also highly correlated with the Likert ranking (Spearman rank correlation coefficient 0.74: p = 0.000). Although sensitivity and specificity dropped by 1% and 5%, respectively, modification of the luminosity measure could help regain the discriminating power. The increased accuracy, precision, and efficiency which could be achieved with this computerized photographic approach are all key to developing effective surveillance tools, screening tools, and diagnostic aids.

No two individuals with FAS have identical facial features; all, however, present with the overall gestalt. To define the gestalt, one must take a multivariate approach, not a univariate check list approach as illustrated in Fig. 3.

The discriminant analysis used in this study accomplished this by identifying both the minimum number of features and the magnitude of expression of each feature that most accurately differentiated individuals with and without the facial gestalt. The discriminate analysis identified short palpebral fissures, smooth philtrum, and thin upper lip as the minimum cluster of features needed to define the phenotype and differentiate individuals with highest accuracy. Further studies to confirm the validity and generalizability of these study results will be necessary. In the discriminant equation, the three facial features serve as the predictor variables, each with a beta coefficient reflecting their level of contribution to the overall gestalt appearance. The equation computes a discriminant score which, in essence, is a proxy measure of the gestalt appearance recorded on a continuous scale. To use this equation, one would measure the three facial features from a photograph, insert the values into the equation, compute the discriminant score, and classify the phenotype based on whether the individual's discriminant score fell above or below the cutoff value. This equation not only provides a method by which to differentiate individuals with and without the facial phenotype of FAS but also provides a standardized objective language in which clinical researchers can describe the magnitude of expression of the phenotype in their study populations for comparative purposes.

Surveillance generally uses methods distinguished by their practicality, uniformity, and frequently their rapidity, rather than by complete accuracy[12]. To date, effective methods for FAS surveillance do not exist[13]. Passive surveillance such as hospital-based birth defects registries[14] examine only the medical record, not the patient, and focus on an age group when FAS is known to be misdiagnosed and underreported[15]. Passive surveillance has resulted in marked underestimation of FAS prevalence. In contrast, active surveillance relies on direct collection of data from patients and, although more costly, results in more valid and reliable data and results in estimated rates of FAS that are an order of magnitude higher than those estimated from passive surveillance[13]. The results of this study demonstrate that computerized analysis of facial photographs has the potential for serving as a highly efficient, reproducible, and potentially highly accurate active surveillance tool. Photographic analysis has the following advantages: 1) photographic images are inexpensive, 2) they do not require professional expertise or sophisticated equipment to collect; 3) they can be stored and analyzed with complete anonymity by cropping the images; 4) data can be transferred over the Internet for centralized analysis maximizing consistency of interpretation; 5) use of a highly accurate and objective case definition would result in highly reproducible results over time which is paramount to tracking trends; and 6) population-based surveillance of more representative segments of the population could be achieved because a broad age range can be accurately assessed and surveillance need not be restricted to hospital or research institutions because of the ease with which data can be collected.

Primary prevention of secondary disabilities associated with FAS will require accurate and reliable screening tools and diagnostic aids. Unlike surveillance, screening and diagnosis target individuals for the purpose of early identification and intervention. An ideal screening tool is highly sensitive, specific, accurate, precise, reproducible and valid. This tool has demonstrated all of these qualities in this study population.

We express our thanks to Cliff Astley for his computer programming support, Erik McArthur for the computer capture of all photographic images and Ann P. Streissguth, Ph.D. and Hans-Ludwig Spohr, M.D. for their contribution of photographs to this study.

About FAS Facial Photographic Analysis Software

FAS Facial Photographic Analysis Software [Version 2.1.0]

Susan J. Astley Ph.D.
University of Washington
Seattle, Washington, 98195
astley@uw.edu

GRANT. The University of Washington grants to User, a limited, non-transferable, royalty-free, non-exclusive license to input pictures, display, and use tools within the software to measure elements as defined within the software, and view results from the software for internal purposes provided User complies with the terms of this License Agreement.

CONDITIONS OF USE. Permission is granted to execute the software on one or more computers, and create one back-up copy of the software for archival purposes. User may not copy, modify, translate, decompile, disassemble, or reverse engineer the software or any copy thereof. **USER MAY NOT COPY OR DISTRIBUTE ANY IMAGE THAT IS PART OF THIS SOFTWARE OR INSTRUCTION MANUAL.**

TERMINATION.
TERM of LICENSE. This License Agreement is effective until December 31, 2030.

You may terminate this license agreement at any time by providing UW with written notice of termination. UW may terminate this License Agreement if you do not comply with any terms or conditions of this License Agreement by providing you with written notice of your noncompliance, in which event you will have five business days to cure your noncompliance to the satisfaction of UW. If you fail to do so, the license agreement will terminate automatically at the end of those five days without any need for further notice from UW. UW may also terminate this agreement for any reason by giving you ninety days advance written notice of termination. Upon termination [whether by you or by UW] you shall destroy the software and documentation and erase any copies residing on computer equipment.

THIS SOFTWARE IS PROVIDED "AS IS" AND WITHOUT ANY WARRANTY EXPRESSED OR IMPLIED. UW EXPRESSLY DISCLAIMS ANY AND ALL WARRANTIES, WHETHER EXPRESS OR IMPLIED, PERTAINING TO THE MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE OF WORK OR ANY SUBJECT MATTER OTHERWISE PROVIDED TO USER UNDER THIS AGREEMENT. Users should evaluate the information obtained from software using their professional judgment. User acknowledges that software is for information and educational purposes only and is not a substitute for the professional judgment of User. If information from software will form a basis of a treatment decision, User should first confirm information from the software with other sources. **USER'S RELIANCE UPON SOFTWARE IS SOLELY AT USER'S OWN RISK.** The information contained in the Software is intended as a supplement to, and not a substitute for, the knowledge, expertise, skill and judgment of users.

This software may not run on your particular hardware/software configuration. The University of Washington and the Fetal Alcohol Syndrome Diagnostic & Prevention Network (FAS DPN) bear no responsibility for any direct, indirect, incidental, consequential, special, exemplary, punitive, or other damages arising out of or relating in any way to the use of this software. In addition the FAS DPN cannot provide user support for installing or using this software.

PART I. INTRODUCTION

What is Fetal alcohol syndrome (FAS)?

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The syndrome has been broadly characterized by pre- and/or postnatal growth deficiency, a characteristic set of minor facial anomalies, central nervous system (CNS) abnormalities (Jones and Smith, 1973; Clarren and Smith, 1978; Smith, 1979; Rosett, 1980; Sokol and Clarren, 1989; Stratton *et al*., 1996). Although these previous publications do provide guidance, they are not sufficiently specific to assure diagnostic accuracy and precision. In 1997, a new more rigorous and comprehensive, case-defined method for diagnosing the full spectrum of outcomes in individuals with prenatal alcohol exposure was created called the FASD 4-Digit Diagnostic Code (Astley & Clarren, 1997, 1999, 2000; Astley et al., 1999, Astley, 2004a). The 4-Digit Code is a validated set of guidelines intended for use by an interdisciplinary team in a FASD diagnostic clinic (Astley, 2011, 2013; Astley et. al. 2009).

The FASD 4-Digit Diagnostic Code

The four digits of the diagnostic code reflect the magnitude of expression of four key diagnostic features of FAS/D in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) CNS abnormalities, and (4) gestational alcohol exposure (Fig. 1). The 4-Digit Diagnostic Code is generated by first recording key clinical data on the standardized FASD Diagnostic Evaluation Form and following specific case-definitions to generate each digit.

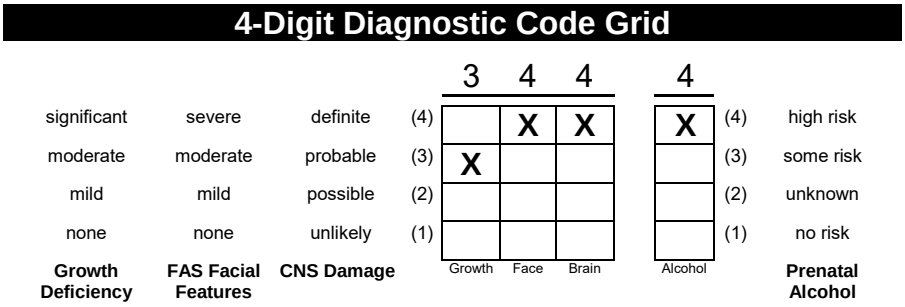

Fig. 1. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic" presence of the FAS feature. Each Likert rank is specifically case-defined. The 4-Digit Diagnostic Code can be used to diagnose individuals of all ages. The 4-Digit Diagnostic Code has been used effectively for diagnosis (Astley & Clarren, 2000), screening (Astley et. al., 2002) and surveillance (Astley, 2003) efforts in the Washington State FAS Diagnostic & Prevention Network of clinics since 1997 (Astley et al., 2014). The 2004 diagnostic guide entitled "*Diagnostic Guide for Fetal Alcohol Spectrum Disorders: The 4-Digit Diagnostic Code*" the *Lip-Philtrum Guides*, and the *FAS Facial Photographic Analysis Software* can be ordered from the website fasdpn.org.

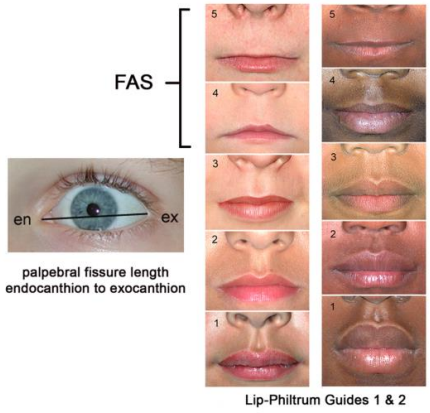
Facial Features of FAS

The most specific feature of FAS is the facial phenotype. The FAS facial phenotype is characterized by the presence of all three of the following minor anomalies at any single point in time:

1. **Palpebral fissure lengths** (PFL) two or more standard deviations below the mean.

2. A **smooth philtrum** defined as a Rank 4 or Rank 5 on the 5-point likert scale depicted on the FAS DPN Lip-Philtrum Guides (Astley & Clarren, 1999, 2000).

3. A **thin upper lip** (thin vermilion border) defined as a Rank 4 or Rank 5 on the 5-point Likert Scale depicted on the FAS DPN Lip-Philtrum Guides (Astley & Clarren, 1999, 2000).



This case-definition for the FAS facial phenotype was derived empirically by Astley and Clarren (1995, 1996), matches the original definition by Smith (1979), and is confirmed to be highly sensitive and specific to FAS and prenatal alcohol exposure (Astley & Clarren 1996, 2001; Astley et al., 2002; 2009; 2013).

Other facial anomalies may be present. The presence of other anomalies should be recorded, but should not be used in lieu of any of the three diagnostic features (small palpebral fissures, smooth philtrum, and thin upper lip) of the FAS facial phenotype.

FAS Facial Analysis Software

This software was developed for use by health care and medical research professionals. Computerized image analysis has been used effectively to measure and rank the magnitude of expression of the FAS facial phenotype on thousands of individuals evaluated in the FAS DPN clinics (Astley & Clarren, 2001; Astley et al., 2002, Astley, 2010. 2013). This software was developed to provide healthcare professionals with a user-friendly, inexpensive, objective method for analyzing facial photographs obtained in a clinical or research setting. Please read the License Agreement for further details.

PART II. GETTING STARTED

Professional qualifications for use of this software

This software is intended for use by healthcare and research professionals.

Computer System

This software is a Microsoft WINDOWS application. Please go to fasdpn.org for computer system specifications.

To Install the Facial Software, Version 2.0.0 (2012) or Version 2.1.0 (2016)

Please go to the fasdpn.org website for the most current installation instructions.

To Upgrade from Version 1.0.0 (2003) to Version 2.0.0 (2012) or Version 2.1.0 (2016)

Please go to the fasdpn.org website for the upgrade instructions.

Version 2.0.0 provides the following additional features:

1. Two additional PFL normal growth charts are included: Canadian and Scandinavian. These new charts are considered more accurate (Astley, 2011a) growth charts for Caucasian PFLs than the Hall (1989) PFL growth charts. See more details posted on the fasdpn.org website.

2. Version 1 required all photo analysis data be stored in a single database file that could only be named **data.fas.** This file was permanently positioned in the FAS software's data directory in the following path (**C:\Program Files\FAS\Data\data.fas**). Version 2 allows the User to assign any name to the database file (e.g., **data2012.fas**) and place it anywhere on their hard drive or server. By default the Version 2 database file is named **data2012.fas** and is placed in the following path (**C:\FAS\Data\data2012.fas**). The User can create multiple database files. They can browse to locate and select which database file they want their photo analysis data to be stored in.

Version 2.1.0 includes the new Lip-Philtrum Guides with frontal and ¾ view images.

A User can upgrade to Version 2.0.0 or 2.1.0 without losing the photo analysis data they have accumulated to date using Version 1.0.

Help

A copy of the License Agreement and a copy of this Instruction Manual can be found by clicking on the Help button in the top menu bar when the software is open. Please use your IT support personnel.

Fundamentals Regarding Version 2

1. The software installation program loads the software in a FAS folder off the C: drive **C:\FAS**

2. The data you generate from analyzing photographs is stored in a Microsoft Access database that comes with the software. This is why the software requires you to have Microsoft Office/Access installed.

3. When you install the software, the Access database is assigned the default name **data2012.fas** and is placed in the following path: **C:\FAS\Data\data2012.fas**

4. After you install the software, you can assign any name to this Access database as long as it ends in **.fas**. You can also store the Access database anywhere on your computer. And you can create more than one Access database to store your photo analysis data.

5. Your photo images are NOT stored in the software's Access database. Your photo images are stored wherever you decide to store them on your computer. When you open a photo into the software for analysis, the software stores the current location (or path) of the photo on your hard drive in the Access database. This allows the software to locate the photo if you choose to evaluate it again. If you move the photo on your hard drive after you have analyzed the photo, the software will not know where to find the photo. The Access database only stores the original location (path) of the photo. Keep this in mind as you organize your photos for analysis.

6. The facial software contains formulas to calculate palpebral fissure length (PFL) and inner canthal distance (ICD) z-scores. These formulas are generated from published growth charts. These formulas are stored in the same Access database as your photo analysis data. If you are installing Version 2 of the software, these formulas come with the default Access database (**data2012.fas**). If you have Access databases created with version 1.0, some of these formulas (Canadian and Scandinavian formulas) will be missing. This will not pose a problem. There are directions below for how to import these new formulas into your version 1.0 databases.

7. You can load this software on as many computers as you like.

8. We cannot provide software support. We recommend you involve your IT support personnel when installing this software.

To Open the Software

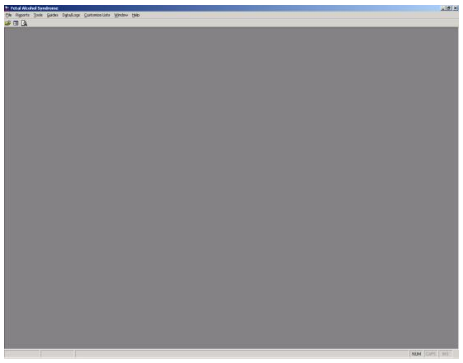


Fig. 2. This blank screen will appear when you open the software.

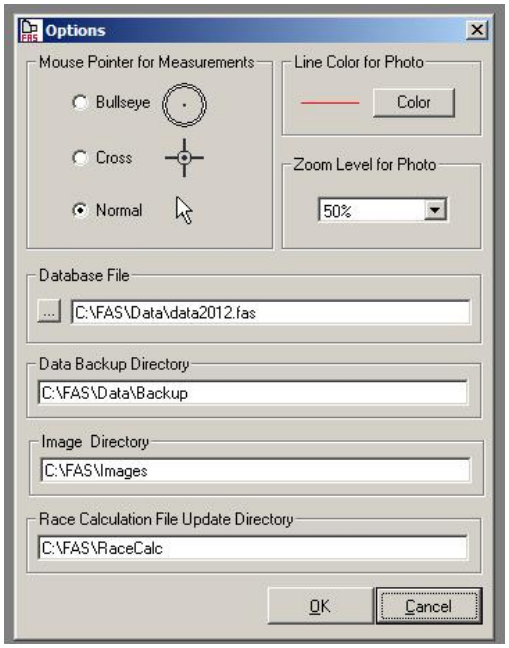

Fig. 3. The Options window allows you to select the directory where you want your backup files to be stored. It also allows you to designate which folder to go to first to look for new images to analyze.

1. Left mouse click on the Windows start button in the lower left corner of your monitor. Left mouse click on "Launch FAS.exe".

2. The software will open to the following blank screen (Fig. 2).

3. If you loaded Version 2.0 or 2.1 for the first time, the software will open, pointing to the default **data2012.fas database,** where your photo analysis data will be stored. This blank database comes with one "practice case: John Doe" permanently stored in it (for training purposes). When you start analyzing photos, your data will also be stored in this database.

4. If you want to store your data in a different database (perhaps a previous database with photo analysis data already in it that you created using Version 1.0), do the following:

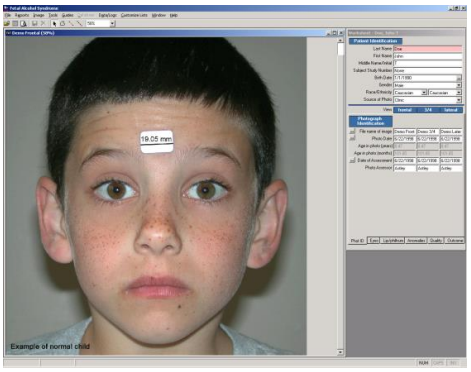
   a) Left mouse click Tools in the menu at the top (Fig. 2). Left mouse click on Options from the drop-down menu to open the Options screen (Fig. 3).

   b) Left mouse click on the browser button under "Database File" (Fig. 3). Navigate to the **.fas** database you want to store your photo analysis data in.

   c) Click OK. Restart the software.

   d) IMPORTANT: If you selected a **.fas** database created from Version 1.0, the new Canadian and Scandinavian PFL growth charts will be missing. See "**Importing New Racial Calculations for PFL Z-scores**" below.

To Open the "John Doe" Demonstration Case



John Doe Demonstration/Practice Case
John Doe has normal facial features.

Follow the instructions below to open the existing demonstration case called "John Doe".

This fictitious demonstration case provides an example of a completed analysis. It also serves as a Practice Case. Instructions for using the Practice Case are presented later in this Instruction Manual.

1. To open Select File/Open/Existing Subject File from the top menu bar.

2. Double-click on the file named John Doe.

3. Click on the OK button.

PART III. TAKING THE FACIAL PHOTOGRAPHS

How to take the 3 standardized facial photographs

Fig 4. Standardized Photo Set Guide. Example of a normally developed child.

Internal Measure of Scale: An internal measure of scale (adhesive paper sticker) is placed on the patient's forehead between their eyebrows (Fig. 4). It should not be placed high on the forehead or off center to the right or left. A small, adhesive paper sticker 1/2 inch to 3/4 inch in size serves well and can be purchased from an office supply store. Do not use "homemade' stickers. Use store-bought stickers that are machine cut for accuracy. Make sure the sticker is firmly attached (not curled up along the edges). Print the size of the sticker on the sticker.

Frontal, ¾ and Lateral Pictures: A frontal, a ¾ view, and a lateral photograph of the patient's face are obtained using a digital camera (Fig. 4). The ¾ view is taken to facilitate ranking philtrum smoothness by purposely driving a flash of light across the philtrum to see if a shadow is cast. Stand approximately 3 feet from the patient and zoom in with the camera lens so that the patient's head fills the entire frame. This provides the highest resolution image. Be careful not to distort the photo by holding the camera too close to the patient's face (see our website fasdpn.org for more details).

Facial Expression: The facial expression should be relaxed with no smile, lips gently closed, eyes wide open and no eyeglasses. A smile will make the lip appear thinner and the philtrum appear smoother than they truly are (Fig. 5).

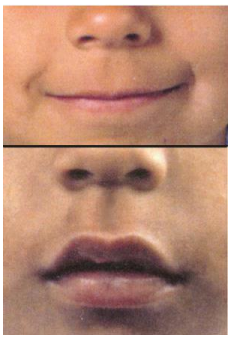


Fig. 5. This is the same child with and without a smile. When the child smiles, her lip appears thinner and her philtrum appears smoother than it truly is. Rankings based on the top photo would be inaccurate.

Rotation: The lens of the camera should be placed in-line with the patient's *Frankfort Horizontal Plane* as illustrated in Fig. 6A. To determine if the camera is in the patient's Frankfort Horizontal Plane when viewing the face through the camera, an imaginary line drawn between the upper border of the left tragus and right tragus should fall across the left and right lower bony orbital rims (Fig. 6B). There should also be no left-to-right rotation of the image; both ears should be equally visible in the frontal photo.

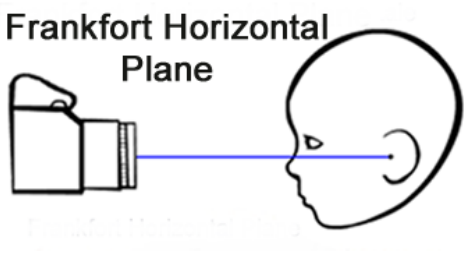

Fig. 6A. The center of the camera lens is placed in the patient's Frankfort Horizontal Plane (a line drawn from the external auditory canal through the lower border of the bony orbital rim (orbitale)).

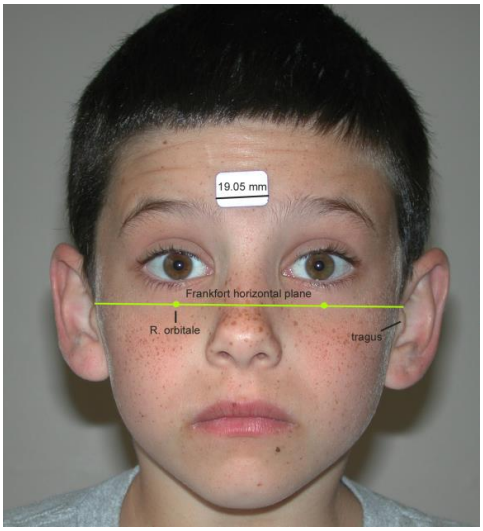

Fig. 6B. When viewing the patient through the camera, the camera is in the patient's Frankfort Horizontal Plane if a line drawn between the left and right auditory canals (or the upper border of the right tragus and left tragus) falls along the right and left orbitale landmarks.

Impact of Rotation on Measurement of Features *Upward –Rotation (head tipped back) w*ill make the upper lip appear thicker than it truly is. All other features will be unaffected. *Downward-Rotation*: will make the upper lip appear thinner than it truly is. All other features will be unaffected. *Right or Left Rotation* will cause the circularity measure for lip thinness to be smaller (thicker) than it truly is because the length of the lip will be foreshortened. The mean PFL and inner canthal distance will remain accurate even with marked left or right rotation as long as the endocanthion and exocanthion landmarks are clearly discernable. The reason mean PFL and inner canthal distance are largely unaffected by right-left rotation is because the internal measure of scale is also rotating by an equal degree.

Properly aligned facial photographs are obtained in the FAS DPN clinics with a hand-held camera and seated patient. Stereotaxic equipment and tripods are not necessary. Take multiple photos if necessary. Sometimes one photo will provide a good measure of the eyes while a second photo will provide a good measure of the lips.

Additional Training / Instructional Resources: More detailed pictorial and animated instruction for how to take standardized facial photographs can be obtained from the FAS DPN website and the research publications by Astley (2011a, 2015) posted on the website.

Camera / Image Resolution Specifications

Digital Camera

The recommended minimum specifications for a digital camera are:

- 3 Mega Pixel resolution or greater
- Flash
- Zoom feature that allows you to fill the camera frame with the facial image.

Image Resolution

In general, an ideal facial image has at least 1000 data points (or pixels) across the width of the face when the image is viewed at its original magnification (or 100% zoom).

Image Formats

This software imports the following image formats

- jpeg (.jpg)
- tiff (.tif)
- bitmap (.bmp)

PART IV. USING THE MEASUREMENT TOOLS, PICTORIAL GUIDES AND SCORING TABLES

Tools and Guides to Measure Facial Features

- Several tools and pictorial guides are provided to help you measure the facial features.
- Select the tools and guides from the TOOLS and GUIDES drop-down menus.
- An image must be open and 'active' before a TOOL can be selected. To activate a photo, click your mouse anywhere on the open photo and the top border of the photo will turn blue.
- Each TOOL and GUIDE is described below.

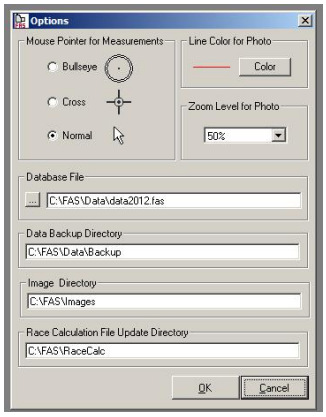
TOOLS include:

- Pointer for pointing to objects.
- Circularity Tool for outlining upper lip thinness.
- Single Distance Tool for measuring the size of the internal measure of scale (paper sticker).
- 3-Distances Tool for measuring the left and right palpebral fissure lengths and the inner canthal distance.
- Tool Options to select style of pointer, line color, etc.

GUIDES include:

- Picture Guides
  1. 2 Lip-Philtrum Guides (Caucasian and Black).
  2. FAS Face/Other Anomalies Guide provides a pictorial example of the FAS facial features and other commonly seen minor facial anomalies.
  3. Rotation Guides (Up/Down, Left, Right) document different degrees of rotation in frontal images.
  4. Landmark/Rotation Guide identifying key facial landmarks and proper image rotation.
  5. Standardized Photo Set Guide providing an example of the frontal, ¾ and lateral photos.
- Table Guide for deriving the ABC-Score for the face.
- Circularity Practice Guide for practicing outline upper lips to compute circularity.

Tool Options Guide



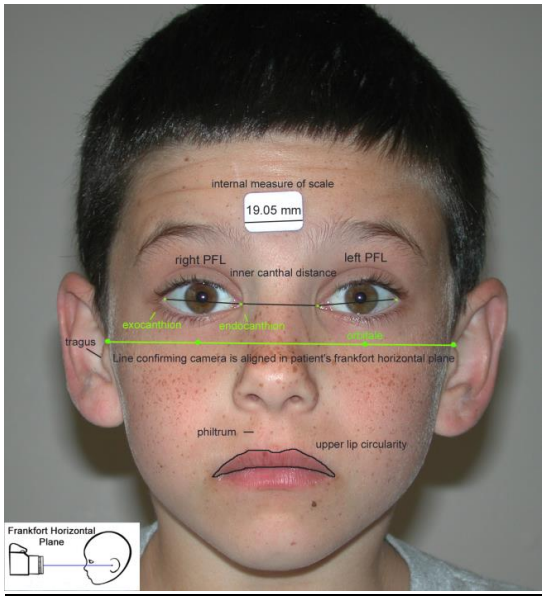
To Use: Select from the Guides drop-down menu from the top menu bar.

The User can select the following options:

- Mouse Pointer style for the Circularity, Single Distance and 3-Distance Tools.
- Line color.
- Default zoom level for the Photo.
- Database File that is currently active.
- Directory where backups will be stored.
- Directory where software will first go to when asked to open a new photo.
- Directory for PFL race formulas.

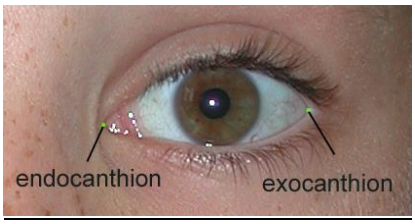
Identifying Key Facial Features

The Landmark/Rotation Guide



To view: Select from the Guides drop-down menu on the top menu bar.

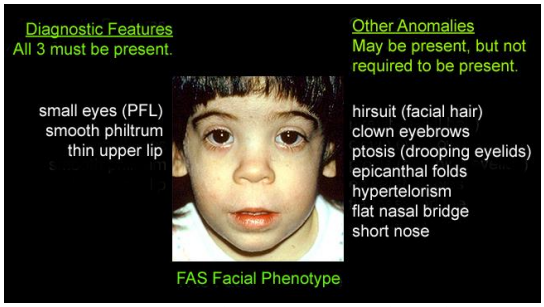
This Guide identifies key facial features (palpebral fissure length (PFL), philtrum, upper lip) and landmarks (endocanthion, exocanthion, orbitale, and tragus) used to measure the FAS facial phenotype. The child pictured has a normal facial phenotype. The Guide also provides a pictorial example of the Frankfort Horizontal Plane used to align the camera with the face. More detailed information about image rotation can be found elsewhere in this Instruction Guide.



Palpebral Fissure Length (PFL)

The palpebral fissure length (PFL) is defined as the distance from the endocanthion landmark to the exocanthion landmark.

The FAS Face and Other Anomalies Guide



Pictorial examples of Diagnostic FAS facial features and other facial anomalies

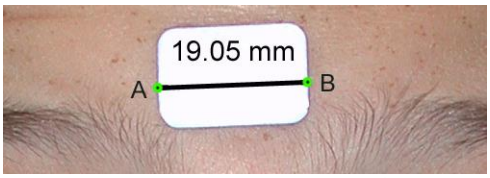
To view: Select from the Guides drop-down menu on the top menu bar.

This young girl presents with the three facial features (listed on the left) that are diagnostic of the FAS facial phenotype. She also presents with other minor facial anomalies (listed on the right) that may or may not be present in an individual exposed to prenatal alcohol exposure. If other anomalies are present, they should be documented, but they are not used to diagnose the FAS facial phenotype.

Measuring the Internal Measure of Scale

The Single-Distance Tool

Single-Distance Tool Icon



Measuring the horizontal length of the internal measure of scale (or paper sticker).

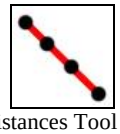
To use: Click the left mouse button on the image then click on the Single-Distance icon or select the tool from the TOOLS drop-down menu on the top menu bar.

This Tool measures the distance between two points. For example, to measure the length of the sticker on the forehead, click on the frontal photo, select the tool and highlight the "Length of Scale in Photo" cell in the Worksheet by clicking in it (the cell will turn pink). Now click and release the left mouse button on point A and click and release the left mouse button on point B. A straight line will be drawn on the photo as an overlay. The sticker length, in units of pixels, will automatically fill into the Worksheet cell.

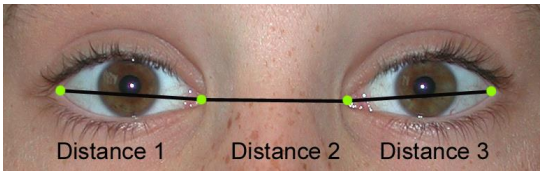
When measuring the internal measure of scale, its horizontal length should be measured, not it's vertical height.

Measuring PFLs and Inner Canthal Distance

The 3-Distances Tool



3-Distances Tool Icon



With the 3-Distances Tool, you can measure these 3 distances (the subject's Right PFL, Inner Canthal Distance and Left PFL) with the following 4 mouse-clicks on the subject's R. exocanthion, R. endocanthion, L. endocanthion and L. exocanthion.

To use: Click the left mouse button on the image, then click on the 3-Distances icon or select the tool from the TOOLS drop-down menu from the top menu bar.

For expediency and accuracy, this Tool measures three distances (R. PFL, Inner Canthal Distance and L. PFL) with just 4 mouse clicks. When the tool is selected, the Worksheet cell for R. PFL is automatically highlighted. Click and release the left mouse button on the patient's R. exocanthion, R. endocanthion, L endocanthion and L exocanthion, in that order. The length in units of pixels for each feature will be automatically displayed in the proper cells on the Worksheet. The true length in mm and z-score of each feature will also be automatically computed if the following cells are filled in: birth date, photo date, normal chart race, gender, real scale length and length of scale in photo.

Measuring Lip Thinness

The Circularity Tool

Circularity Icon

An example of the upper lip outlined to compute circularity. This is the most accurate method for measuring upper lip thinness.

To use: Click the left mouse button on the image, then click on the Circularity Icon or select from the TOOLS drop-down menu from the top menu bar.

This Tool measures the circularity (or thinness) of the upper lip in the frontal photo. Circularity = perimeter^2 /area. The thinner the upper lip, the greater the circularity. When the tool is activated, the user outlines the upper lip while holding the left mouse button down. The left mouse button is released when the outline is complete. Circularity is automatically computed, ranked and inserted into the proper cell of the worksheet. Circularity is a more accurate and objective method for computing lip thinness than simply selecting the picture on the Lip-Philtrum Guide below that best matches the lip in the patient's facial photograph.

The Lip-Philtrum Guides

Guide 1

Guide 2

Lip Rank	Lip Circularity	
	Pictured	Range
5	178	≥ 131.5
4	85	75.5 to 131.4
3	65	57.5 to 75.4
2	50	42.5 to 57.4
1	35	≤ 42.5

Table on backside of Lip-Philtrum Guide 1.

Lip Rank	Lip Circularity	
	Pictured	Range
5	80	≥ 62.1
4	57	52.1 to 62.0
3	39	30.1 to 52.0
2	29	27.5 to 30.0
1	25	≤ 27.5

Table of backside of Lip-Philtrum Guide 2.

To use: Two Guides are available. Guide 1 is used for Caucasians and all other races with lips similar to Caucasians. Guide 2 is used for Blacks and all other races with thicker lips like Blacks. Select a Guide from the GUIDES drop-down menu from the top menu bar. When displayed, place the mouse cursor on the guide and hold the left button down to move the Guide over the surface of the facial photograph.

These guides serve as pictorial 5-point Likert Scales for visually ranking upper lip thinness. The user selects the lip rank that best matches the lip thickness in the patient's facial photograph. The Rank of each lip is printed to the left of the each lip photo. The circularity of each lip pictured is printed in a Table on the backside of the Lip-Philtrum Guides. These Tables are reproduced here.

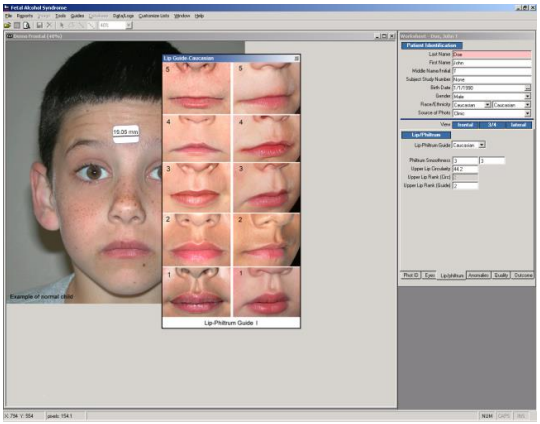
The range of circularity for each Rank is printed in a Lip Circularity Table on the backside of the Lip-Philtrum Guides. Note the ranges differ by race.

The most accurate measure of lip thinness is obtained using the circularity tool.

Measuring Philtrum Smoothness

The Lip-Philtrum Guides

Guides for ranking
lip thinness and philtrum smoothness.



The Lip-Philtrum Guides can be opened and moved around across the top of the facial image. If the Guide happens to disappear behind the facial image on the computer screen, simply click on "Window" in the top Menu bar and click on the name of the Guide to bring it back in view.

To use: Select from the GUIDES drop-down menu from the top menu bar. When displayed, place the mouse cursor on the guide and hold the left button down to move the Guide over the surface of the facial photograph.

The guides provide a pictorial 5-point Likert Scale for visually ranking philtrum smoothness. The user selects the philtrum that best matches the philtrum in the patient's facial photograph. The rank of the philtrum is printed on the left.

Note that there are two Lip-Philtrum Guides (1 and 2). The philtrum ranks are identical between the two Guides. In other words, the Rank 3 philtrum pictured in Guide 1 is the same depth as the Rank 3 philtrum pictured in Guide 2.

A Rank 5 philtrum is completely smooth. A Rank 4 philtrum is a barely visible indentation that typically must be viewed at an angle to detect. Go to our fasdpn.org website for additional photo examples of Rank 4 and 5 philtrums. A Rank 3 philtrum is the population mean. A Rank 1 philtrum is extremely deep with very prominent philtral ridges. A Rank 1 philtrum will be almost as rare in the population as a Rank 5 philtrum.

Lip thinness and philtrum smoothness are measured independently of one another. In other words, an individual can have a Rank 5 upper lip with a Rank 1 philtrum.

Guide for Scoring the FAS Facial Phenotype

The following Tables are used to derive the facial ABC-Score and the facial 4-Digit Code Rank (Astley, 2004; Astley & Clarren, 2000). These Tables serve as the case-definitions used to describe the full continuum of expression of the FAS facial features.

The user can view these tables by going to the Guides drop-down menu in the top menu bar. The user does not need to refer to these Tables to score the facial phenotype. The software automatically generates an ABC-Score and 4-Digit Diagnostic Code rank for the face when the user measures the palpebral fissure lengths, philtrum smoothness and upper lip thinness. These scores are presented at the end of the Worksheet under the OUTCOME tab.

Table 1A. Deriving the ABC-Score for the Face

The first step in deriving the 4-Digit Code rank for the facial phenotype is to derive the facial ABC-Score. For example, if a patient's palpebral fissure lengths were 2 or more standard deviations below the norm (≤ -2 SD) and their philtrum and upper lip received Likert scores of 2 and 3 respectively, the facial phenotype would receive an ABC-Score of **CAB**.

5-Point Likert Scale for Philtrum & Lip	Z-score for largest Palpebral Fissure Length	Circle the ABC-Scores for: Palpebral Fissure	Philtrum	Upper Lip
4 or 5	≤ -2 SD	**C**	C	C
3	>-2 SD and ≤ -1 SD	B	B	**B**
1 or 2	> -1 SD	A	**A**	A

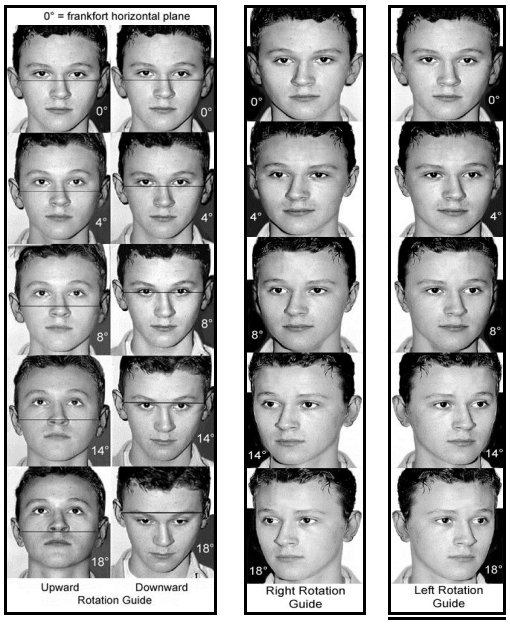
Table 1B. Deriving the 4-Digit Diagnostic Code Rank for the Face.

The final step is to convert the ABC-Score for Facial Phenotype to a 4-Digit Diagnostic Code Rank. A **CAB** score translates into a 4-Digit Diagnostic Code rank of **2.** This rank would serve as the second digit in the 4-Digit Diagnostic Code.

4-Digit Diagnostic Code Rank*	Level of Expression of FAS Facial Phenotype	Palpebral Fissure - Philtrum - Lip ABC-Score Combinations
4	Severe	CCC
3	Moderate	CCB, CBC, BCC
2	**Mild**	CCA, CAC, CBB, CBA, **CAB**, CAA BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	Absent	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

Measuring the Rotation of the Facial Image

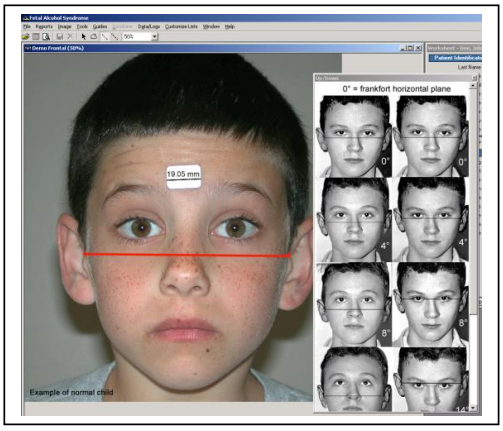
The Rotation Pictorial Guides



Up is (+)
Down is (-)

Right is (+)

Left is (-)



To view: Select from the GUIDES drop-down menu from the top menu bar. When displayed, place the mouse cursor on the guide and hold the left button down to move the Guide over the surface of the facial photograph.

These guides were obtained by placing the subject in a stereotaxic device to achieve accurate measures of rotation in degrees. The most accurate measures of facial features are made from a facial image that has no up, down, right or left rotation. These guides assist you in documenting the magnitude of rotation that may exist in the photograph.

Frontal Image: Ranking Up/Down Rotation

To rank the number of degrees the face in the frontal image is rotated up or down from the Frankfort Horizontal Plane, use the single-distance tool to draw a line from the top of the right tragus to the top of the left tragus in the patient's frontal photograph. See lower left image on this page and the Landmark/Rotation Guide pictured on next page. Compare the position of this line to the position of the lines drawn on the facial images in the Up/Down Rotation Guide. As the face is rotated up the line moves down toward the tip of the nose. As the face is rotated down the line moves up toward the eyebrows. Record your best estimate of the number of degrees of rotation up or down in the proper cell in the Worksheet. You may type in any degree of rotation from -45 to +45 in the cell. You are not restricted to the 5 levels of rotation presented in the Guide.

Frontal Image: Ranking Left/Right Rotation

Use these guides to assist you in judging the number of degrees the subject's head is rotated to their right (+) or their left (-). Record your best estimate of the number of degrees of rotation right or left in the proper cell in the Worksheet. You may type in any degree rotation from -45 to +45 in the cell. You are not restricted to the 5 levels of rotation presented in the Guide.

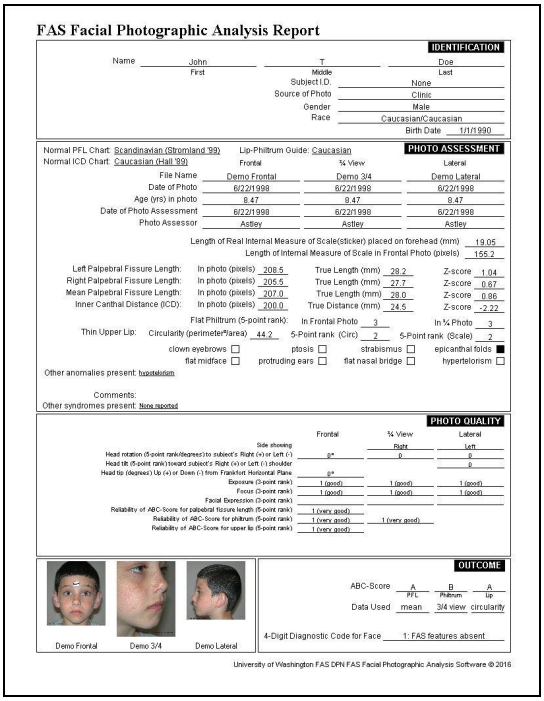
PART V. ANALYZING AN IMAGE

Example of a Complete Analysis and Outcome Report

Standardized Photo Set

This is a child with normal facial features.

An example of a complete analysis and outcome report on the Standardized Photo Set pictured to the left is available for your review. This example is of a child with normal facial features.



FAS Facial Photographic Analysis Report

Outcome Report

To Use: Select File/Open/Existing Subject File from the top menu bar. Double-click on the file named John Doe. Click on the OK button. The frontal, ¾ and lateral facial photos and completed Worksheet will appear for your review and practice. To view the Report, select Reports from the top menu bar. Check the box for the subject named John Doe. Press the Preview button. To print the Report, click on the Print icon on the Tool Bar.

All data in this Sample Case are write-protected so you cannot save any changes you make to the Worksheet or Report.

This Sample Case also serves as a practice case for you. See below for more detailed instructions on how to use this Sample Case as a Practice Case.

Opening an Image and Worksheet

To Open a New Photo

To Open a New Photo: Select File / Open / Photo from the top menu bar. Navigate through your hard drive to locate the image file you what to measure. Double-click on the image file. A blank Worksheet will automatically open when an image is opened. The Worksheet will not appear if an image is not open.

Typically, you will be analyzing a set of 3 photos (frontal, ¾, and lateral) for each patient. You will find it most efficient to open all three photos before beginning the analysis. You can toggle between the three opened photos by clicking on *Window* in the top menu bar and clicking on the image filename you want to view. More efficiently, once the file names of the 3 photos are entered into the Worksheet, you can click on the blue View banner in the Worksheet labeled Frontal, ¾ and Lateral, just below the Patient Identification section, to view each photo. You may also view all photos at one time by clicking on *Window* in the top menu bar and selecting *Tile Images.*

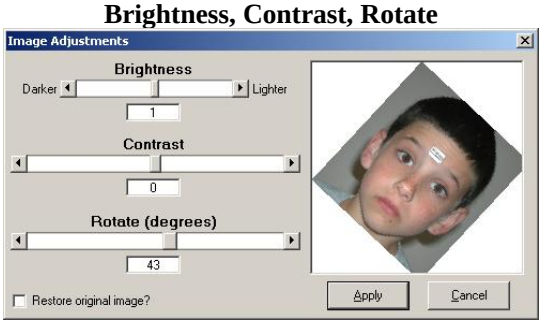
To Open an Existing Subject File

Sample photos of a normal child.

To *Open an Existing Subject File:* Select File / Open / Existing Subject File from the top menu bar. Double-click on the subject's name to highlight it. Then click the OK button. A Worksheet will automatically open with data saved from the previous saved analysis.

Enhancing the Image

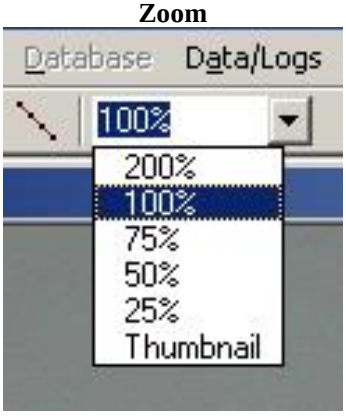
Brightness, Contrast, Rotate



To Use: First open an image. Then select Image / Image Adjustments from the top menu bar.

To adjust *Brightness, Contrast or Rotation* of the image, either slide the control bar from left to right, left-click on the arrows at either end of the slide or type in a positive or negative number in the box below the slide.

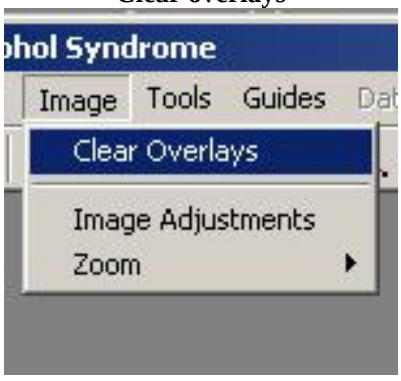
Zoom



To Use: First open an image. Then select Image / *Zoom* from the top menu bar to select a magnification % from the drop-down list or Select a magnification % directly from the drop-down list on the tool bar. You may also type in any incremental number (without a % sign) into the cell next to the down arrow to select intermediate magnification. For example, if you typed 35 in the cell, the image would be presented at 35% magnification. An hour-glass will appear as the magnified image is being generated.

If the image disappears when you enlarge it, you have enlarged it beyond what your video driver can handle. This may occur with very large photos. If this occurs, reduce the zoom incrementally until the image re-appears

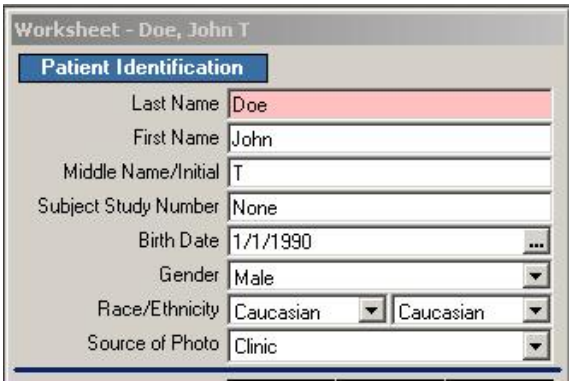
Clear overlays

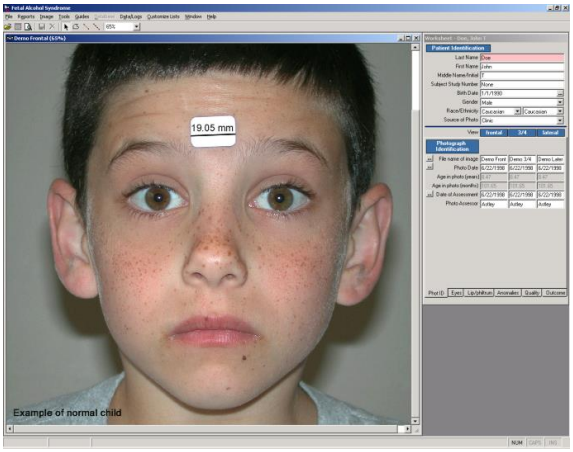


To Use: First open an image. Then select Image / *Clear Overlays fr*om the top menu bar. All distance and circularity measurements drawn on the image as temporary overlays will be removed.

Analyzing an Image
Recording Data on a Worksheet

Patient Identification Section of Worksheet





To view: To open a Worksheet, you must first open an image. The Patient Identification section of the Worksheet is always visible when a Worksheet is open. The cell highlighted in pink is the active cell waiting for data entry.

When an image is opened, the image will appear on the left side of the monitor and a blank Worksheet will open on the right side of the monitor.

The first section of the worksheet is labeled: Patient Identification.

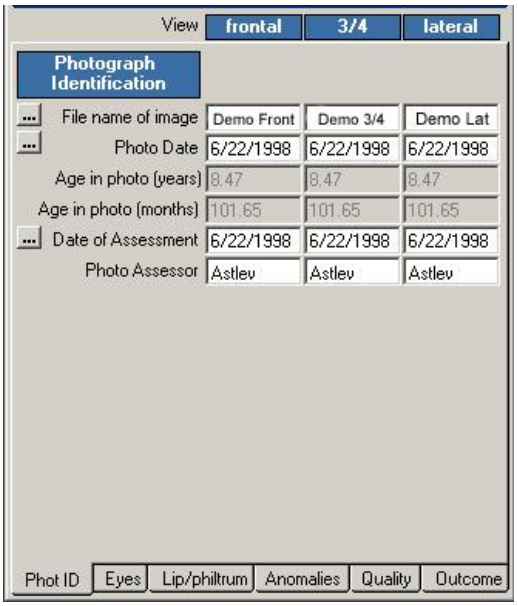
Complete the information by either typing directly into the cells or selecting drop-down menus with the down-arrow.

Dates: Dates can be selected from a calendar by pressing the button on the date line. Click on the calendars year to reveal additional arrows for increasing or decreasing the year. When the correct date is selected, close the calendar and the date will appear in the Worksheet cell. You can also just type the date in the cell. Important: ensure your computer's "Regional Date Setting" is set to English (United States) (mm/dd/yyyy format). See instructions on our website fasdpn.org

Race: Each patient is identified by two races (one for each parent). For example, if both parents are Caucasian, race would be coded Caucasian, Caucasian. If one parent is Caucasian and one is Black, race would be coded Caucasian, Black. Additional races can be added to the drop-down lists by selecting the Customized Lists button on the top menu bar.

Source of Photo: You may want to document the source of the photo (i.e., clinic, research, etc). You can customize the Source of Photo list by selecting the Customized Lists button on the top menu bar.

Photo Identification Section of Worksheet



Once the 'File Name of Image' is entered into the cells for the frontal , ¾ and lateral images, you can click on the BLUE frontal, ¾ and lateral View buttons shown above to view each of those images or toggle back and forth between them.

To View: Select the Photo ID tab at the bottom of the Worksheet.

Photo View: The information requested for the frontal, ¾ and lateral images are presented in the 1st, 2nd and 3rd columns respectively.

File name of image: This is the name you assigned to the electronic facial image. The name of the image file can be typed into the cell or automatically filled in by clicking the mouse in the data cell, (which makes the field active or pink), and then clicking on the opened image. The name of the image file will automatically enter into the active cell. An expedient way to open the three images and enter their filenames automatically into the File Name of Image cells is to 1) open the frontal image and click on the 'File Name of Image' cell for the frontal image. Next, open the ¾ image and click on the 'File Name of Image' cell for the ¾ image. Next, open the lateral image and click on the 'File Name of Image' cell for the lateral image.

Photo Date: This is the date the photo is taken. This date will be used to automatically compute the age of the patient in the photo from the patient's birth date. Your computer's 'Regional Date Setting' must be set to English (United States) for proper age computation (see fasdpn.org for details).

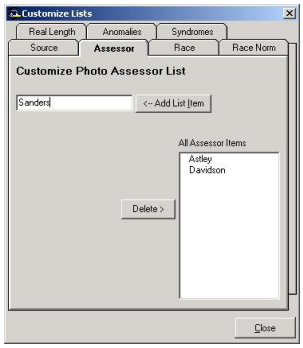
Age in Photo: Age in years and months are grayed out to indicate they will be automatically computed when the birth date and photo date are entered.

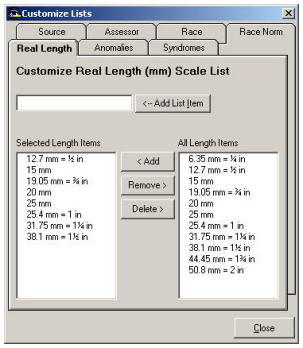
Date of Assessment: This is the date the photograph is being analyzed.

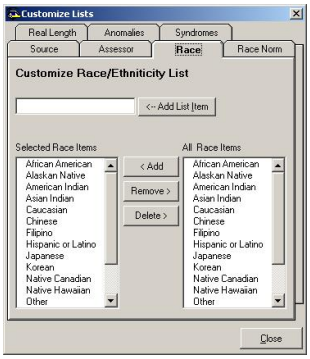
Photo Assessor: This is the name of the person analyzing the photo. This drop-down list can be customized by selecting Customized Lists from the top menu bar.

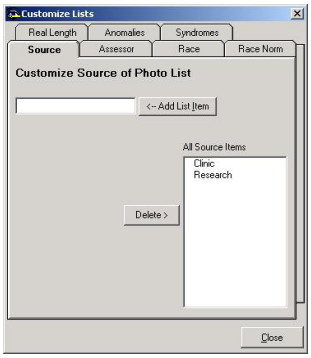
Quick Tip: If the photo date, date of assessment and photo assessor are the same for each image, enter this information for the frontal image, then just click on the Photo Date cell for the ¾ and lateral images and all information from Photo Date to Photo Assessor will automatically fill into the cells.

Customizing Lists









To View: Select "Customize List" from the top Menu Bar.

Each of the following lists can be updated to include additional entries.

Real Length of the internal measure of scale (sticker)
Anomalies
Syndromes
Source of image
Assessor of image
Race of subject
Race Norms for palpebral fissure lengths

To update a list,

1. Click on the appropriate Tab (Lets use Assessor as an example).

2. Type in the new entry in the cell next to "Add List Item". We typed in the name Sanderson.

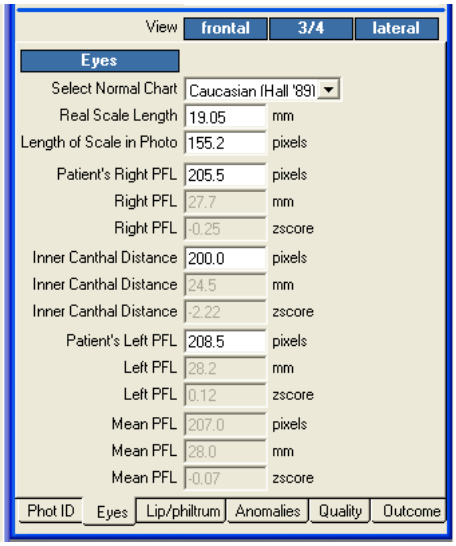
3. Click on the "Add List Item" button. This will add the name Sanderson to our list of assessors.

4. Click on the "Close" button.

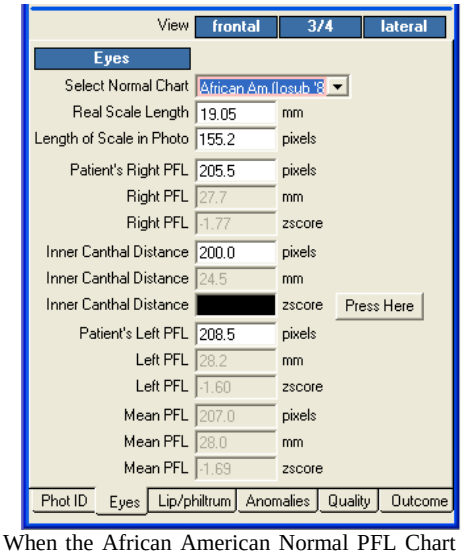
The Race Norms tab is currently inactive. Please refer to the section below entitled "**Importing New Racial Calculations for PFL Z-scores**" for instructions on how to import the new Canadian and Scandinavian PFL formulas. In future versions of this software, additional racial norms for palpebral fissure lengths may be added as norms are established. Currently, racial norms are available for Caucasian (Hall et al., 1989), Canadian (Clarren et al., 2010; Scandinavian (Stromland et al., 1999; and African American (Iosub et al., 1985) palpebral fissure lengths.

Selection of the proper PFL grow charts is very important. The Iosub charts should be used for African Americans. We recommend the Stromland charts for Caucasians. See our website fasdpn.org for more details on which PFL growth charts to use.

Eyes Section of Worksheet



When the Caucasian, Canadian, or Scandinavian Normal PFL Charts are selected, the z-score for Inner Canthal Distance (ICD) is computed using the Hall (1989) normal charts. Z-scores require birth date, photo date, and gender to be entered because all z-scores are age dependent and some are gender dependent.



When the African American Normal PFL Chart is selected, PFL z-scores require birth date, photo date, and gender to be entered. Inner Canthal Distance z-scores are not available for African Americans.

To View: Select the Eyes tab at the bottom of the Worksheet. All eye measurements are obtained from the frontal image.

Only data fields in white are to be filled-in by you. Click the mouse cursor in a white cell to enter data. It will turn pink to designate it is the active cell. Gray fields are computed automatically.

Normal Chart Race: Select the race that best matches the most predominant race of the patient. This selection determines which normal anthropometric chart is used to compute PFL z-scores. Four racial selections are available in Version 2: Caucasian (Hall et al, 1989); Canadian (Clarren et al., 2010), Scandinavian (Stromland et al., 1999), and African American (Iosub et al., 1985). Inner Canthal Distance normal charts are only available for Caucasian (Hall et al., 1989). See our website (fasdpn.org) for guidance on which PFL charts to use.

Real Scale Length: Select the real length of the internal measure of scale (sticker) placed on the patient's forehead. This list can be customized by selecting Customized List from the top menu bar.

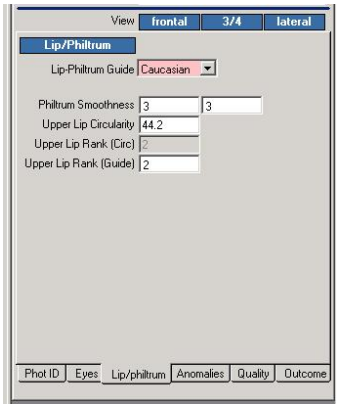
Length of Scale in Photo: This is the horizontal length of the sticker measured in units of pixels using the Single-Distance tool. First click on the image, then click on the Single-Distance Tool, then click on the Length of Scale in Photo cell (it will turn pink when selected), then measure the length of the sticker. See direction above under Single-Distance Tool.

The remaining three data fields are measured using the 3-Distances Tool.

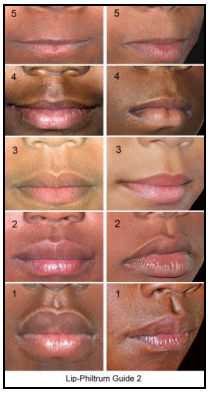
Patient's Right PFL: ___ (pixels)
Inner Canthal Distance: ___ (pixels)
Patient's Left PFL: ___ (pixels)

When this tool is selected, data will automatically enter into the R. PFL, Inner Canthal Distance and L. PFL cells in that order, thus they must be measured in that order. With the left mouse button, click on the patient's R. exocanthion, R. endocanthion, L. endocanthion and L. exocanthion in that order. The gray cells will compute automatically based on the birth date, photo date, gender and the race of the normal anthropometric chart selected.

Lip / Philtrum Section of Worksheet



Guide 1



Guide 2

To View: Select the Lip/Philtrum tab at the bottom of the Worksheet.

Photo View: The information requested for the frontal and ¾ images are presented in the 1st and 2nd columns respectively. You can conveniently view the frontal, ¾ and lateral images by clicking on the Blue frontal, ¾ and lateral View buttons.

Lip-Philtrum Guide (Race): Use the drop-down menu to select which Lip-Philtrum Guide is most appropriate to use based on the subject's race(s). Guide 1 is for Caucasians and races with lips like Caucasians. Guide 2 for Blacks and races with thicker lips similar to Blacks.

Philtrum Smoothness: Open a racially appropriate Lip-Philtrum Guide by clicking on GUIDES in the top menu bar. Use this Guide to select which rank on the 5-Point Scale best matches the philtrum smoothness in the patient's frontal and ¾ photos. Philtrum smoothness is most accurately measured from the ¾ view photo. Assign the same philtrum rank for the ¾ and frontal photos. You can move the Guide across the patient's photos by placing the mouse cursor on the Guide and holding the left mouse button down and dragging.

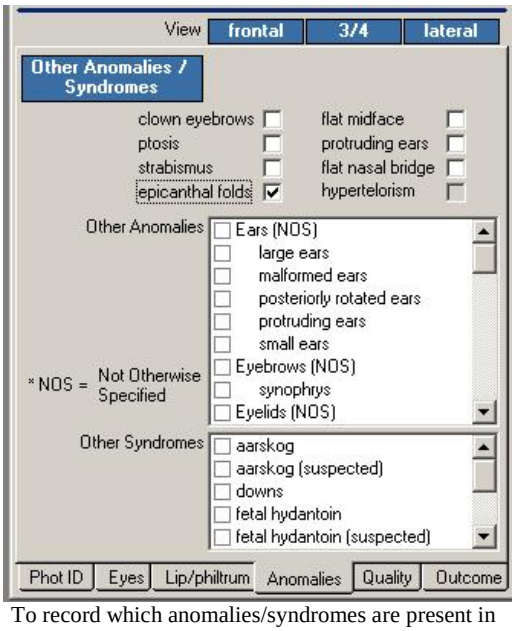
Upper Lip Circularity: Upper lip thinness is most accurately measured using the Circularity Tool. Open the Circularity Tool from the tool bar and measure lip circularity in the frontal photo as instructed above under the Lip Circularity Tool. The circularity of the lip will automatically enter into this field.

Lip thinness is ranked on a 5-Point scale. There are two ways to achieve this: 1) compute the rank automatically from the circularity or 2) judge the rank based on the best pictorial match on the Lip-Philtrum Guide. You will have the option of selecting which method you want to use for ultimately scoring the face under the Outcome Tab.

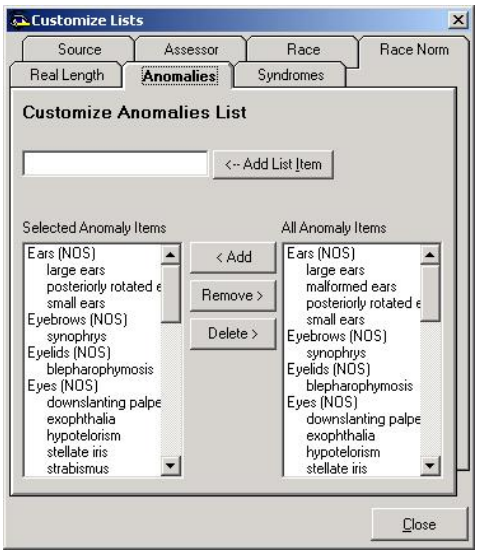
Upper Lip Rank (circularity): The Rank of the upper lip thinness will be automatically computed from the circularity measure and entered into this grayed-out cell. The Rank will be based on which racial Lip-Philtrum Guide you selected. Note, if you toggle between the two Guides, the Rank based on circularity will update to reflect which Guide is selected.

Upper Lip Rank (guide): Use the Lip-Philtrum Guide to select which picture on the 5-Point Scale best matches the lip thinness in the patient's photograph.

Other Anomalies / Syndromes Section of Worksheet



To record which anomalies/syndromes are present in an individual subject.



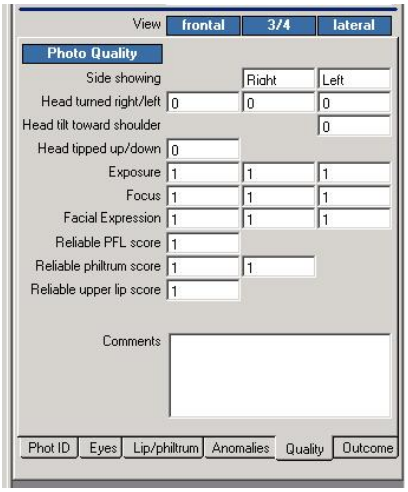
To add new anomalies or syndromes to the list presented under the Anomalies Tab in the Worksheet.

To Use: Select the Anomalies tab at the bottom of the Worksheet.

Anomalies: Place a ✓ in the box next to the anomaly(ies) that the patient has. This list can be customized to include additional anomalies. Go to Customized Lists on the top menu bar and select the Anomalies tab. The additional anomalies you add to the customized list will appear at the end of the Other Anomalies List in the Worksheet. Hypertelorism will automatically get checked if the z-score for the inner canthal distance is ≥ + 2.0. Hypotelorism will automatically get checked if the z-score for the inner canthal distance is ≤ -2.0.

Syndromes: Place a ✓ in the box next to any other syndromes that are known or suspected to be present. This list can be customized to include additional syndromes. Go to Customized Lists on the top menu bar and select the Syndromes Tab. The additional syndromes you add to the customized list will appear in alphabetical order in the Other Syndromes list on the Worksheet.

Photo Quality
Section of Worksheet



To View: Select the Quality tab at the bottom of the Worksheet.

Photo Quality
The quality of a photo will impact the accuracy of the facial measures. The quality of the photo should be taken into consideration when rendering a clinical decision. Photos of poor quality should not be used.

It is recommended that you take some practice photos of a person with widely varying quality (severe rotation, big smile, eyes not fully open, etc) and compare the measures you obtain from those photos with the measures you obtain from a high quality photo of the same individual. This will give you a good idea how much the quality of a photo can impact measurement accuracy.

Photo View: The information requested for the frontal, ¾ and lateral images are presented in the 1st, 2nd and 3rd columns respectively. Not every column requires information.

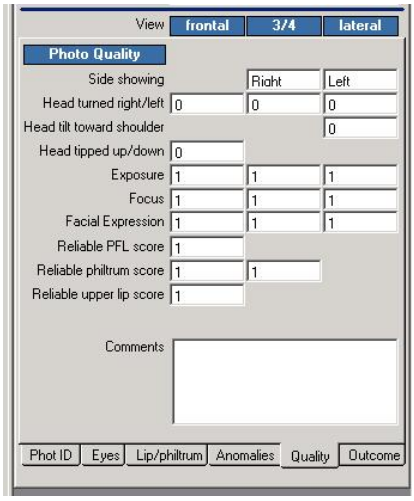
Side Showing: Record whether the right or left side of patient's face is showing in the ¾ and lateral photos.

Head Turned Right / Left in Frontal Image: Use the drop-down menu to record how many degrees the patient's face is rotated toward their right (+) or left (-) in the frontal photo. Use the Right and Left Rotation Pictorial Guides to assist you. You may type in any whole number degree rotation from –45 through +45.

Head Turned Right / Left in ¾ Image: Use the drop-down menu to record how much (on a 5-point scale) the patient's face is rotated toward their right (+) or left (-) in the 3/4 photo. There is no pictorial guide to assist you. Mild rotation implies the amount of rotation present will have only a small impact on the accuracy of the measures obtained from that image. Severe rotation implies the amount of rotation present will have a marked impact on the accuracy of the measures obtained from that image. A ¾ view photo that is rotated too far right or left could impact your ability to accurately measure the smoothness of the philtrum.

Photo Quality Section of Worksheet

(Continued)



Head Turned Right / Left in Lateral Image: Use the drop-down menu to record how much (on a 5-point scale) the patient's face is rotated toward their right (+) or left (-) in the lateral photo. There is no pictorial guide to assist you. Mild rotation implies the amount of rotation present will have only a small impact on the accuracy of the measures obtained from that image. Severe rotation implies the amount of rotation present will have a marked impact on the accuracy of the measures obtained from that image. The measure most likely to be impacted is flat midface. A lateral photograph of the left side of the face that is rotated toward the subject's left will make the midface appear flatter than it truly is. If the same photo was rotated to the subject's right, the midface would appear less flat than it truly is.

Head Tilt Toward Shoulder in Lateral Image: Use the drop-down menu to record how much (on a 5-point scale) the patient's head is tilted toward their left or right shoulder. There is no pictorial guide to assist you. Mild rotation implies the amount of rotation present will have only a small impact on the quality of the measures obtained from that image. Severe rotation implies the amount of rotation present will have a marked impact on the quality of the measures obtained from that image. The measure most likely to be impacted is flat midface.

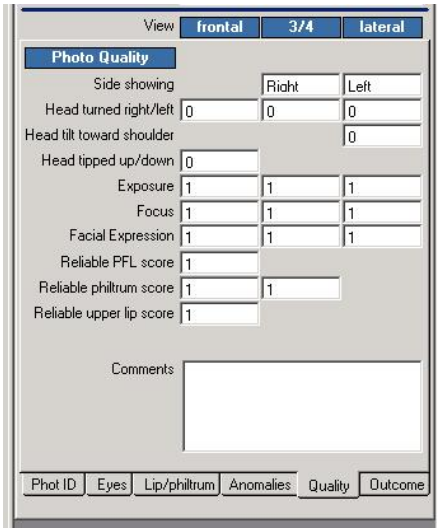
Head Tipped Up / Down in Frontal Image: Use the drop-down menu to record how many degrees the patient's face is tipped up or down in the frontal photo. Use the Up/Down Rotation Pictorial Guide to assist you. You may type in any degree of rotation from –45 through +45 using your best judgement.

Exposure: Use the drop-down menu to record on a 3-point scale if the photo has good exposure, is a bit light/dark or is too light/dark.

Focus: Use the drop-down menu to record, on a 3-point scale, if the photo has good focus, is a bit blurry or is too blurry.

Photo Quality Section of Worksheet

(Continued)

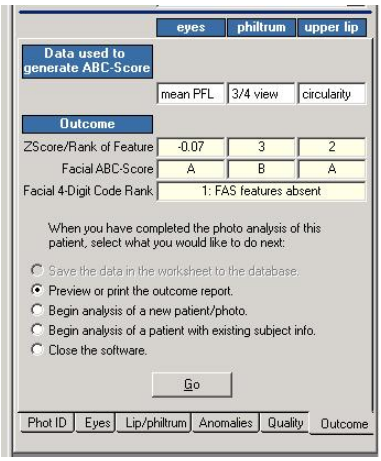


Facial Expression: Use the drop-down menu to record, on a 3-point scale, if the facial expression is relaxed, has a mild facial expression or a severe facial expression. Facial expressions (like a big smile or eyes that are not fully open) can impact measurement accuracy. The goal is to have a relaxed face.

Reliable PFL, Philtrum and Upper Lip Scores. Use the drop-down menus to record, on 5-point scales, if the quality of the photographs leads to reliable ABC and 4-Digit scores for each of these three diagnostic features.

Comments: Enter any comments you wish to have recorded in the database and Outcome Report.

Outcome Section of Worksheet



To Use: Select the Outcomes tab at the bottom of the Worksheet.

Outcome: This last section provides the final scores for the facial phenotype.

Data used to generate ABC-Score: You have the option of selecting which data you would like to use to generate the Facial ABC-Score and 4-Digit Rank. For example, click on the mean PFL cell and note that you can select R.PFL, L.PFL or mean PFL from a drop-down menu. Your selection should be based on which source of information provided you with the most accurate data.

Eyes: You have the option to select the mean PFL, right PFL or left PFL to generate the z-score. The mean PFL is recommended because it will adjust for any right-to-left rotation that may exist in the photo. On rare occasion, the quality of the photo or a true asymmetry in the size of the right and left PFL requires that just the right or left PFL be selected rather than the mean. If there is a true asymmetry in the size of the two PFLs, (> 2 mm's) AND there is NO right-to-left rotation in the frontal image, choose the largest and/or most normal PFL rather than using the mean of the two PFLs.

Philtrum: You have the option to use the philtrum rank from the frontal or the ¾ view photo. Often the ¾ view provides a more accurate measure.

Upper lip: You have the option to have the upper lip be ranked from the circularity measure or from the best matched picture on the Lip-Philtrum Guide. Circularity is often the more accurate measure.

Z-score/Rank of Feature: The z-score or rank of each feature will automatically fill into the cell based on which source of data you chose to use to generate the ABC-Score.

Facial ABC-Score: This score is automatically computed. A is normal, B is moderately abnormal, C is abnormal. (See Astley, 2004a)

Facial 4-Digit Rank: This score is automatically computed. Rank 1= FAS features absent; Rank 2 = FAS features mild; Rank 3 = FAS features moderate; Rank 4 = FAS features severe. (See Astley 2004a)

Practice Image Set "John Doe"

Standardized Photo Set

This case, John Doe, serves as a Practice Case.
This is an example of a normal child.
The Identification data inserted in the Report is fictitious

University of Washington FAS DPN FAS Facial Photographic Analysis Software © 2016

Practice Case Report for John Doe

To Use: Select File/Open/Existing Subject File from the top menu bar. Double-click on the file named John Doe. Click on the OK button. The frontal, ¾ and lateral facial photos and a completed Worksheet will appear for your review and practice. To view the Report, select Reports from the top menu bar. Check the box for the subject named John Doe. Press the Preview button. To print the Report, click on the Print icon on the Tool Bar.

The purpose of this practice case is to allow you to practice using the measurement tools to see if you can duplicate the outcomes of key measures like:

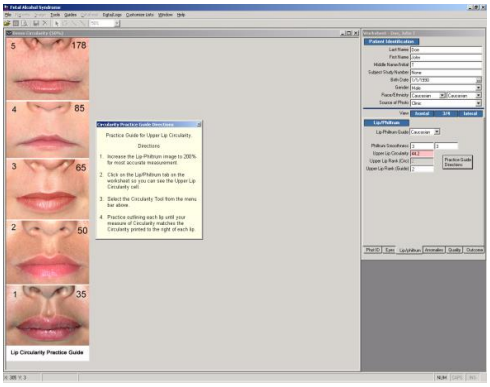
Left PFL = 208.5 pixels
Right PFL = 205.5 pixels
Inner Canthal Distance = 200.0 pixels
Internal Measure of Scale = 155.2 pixels
Lip circularity = 44.2
Philtrum smoothness = Rank 3

It is recommended you first print the report to use as a Guide, because once you start altering data in the Worksheet, your alterations will be reflected in the Report.

Even though you can alter the data in the Worksheet and Report, you will not be able to save the altered data. This will protect the Practice Case for future use and reference.

To refresh the Practice Case to its original data, go to the Outcome Tab on the Worksheet, select *Begin analysis of a patient with existing subject info* and click on GO. Double click on John Doe and press the OK button. A refreshed version of the Practice Case will appear on our screen.

Circularity Practice Guide



Circularity Practice Guide presented with the Directions visible and the Upper Lip Circularity cell highlighted pink.

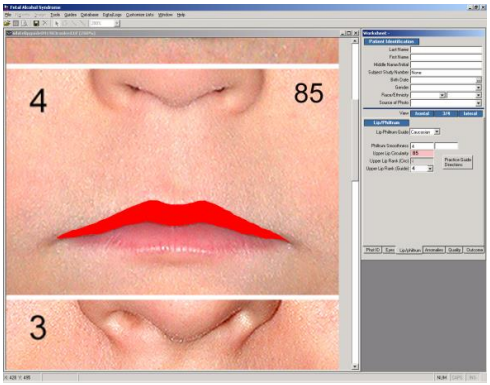


Image zoomed to 200% for measuring circularity.

To Use: Select Guides / Circularity Practice Guide from the top menu bar. The Lip-Philtrum Guide 1 will appear for you to practice outlining.

For Directions:

1. Click on the "Practice Guide Directions" button showing in the Lip/Philtrum window of the Worksheet.
2. Increase the Lip-Philtrum Guide to 200% for most accurate measurement.
3. Select the Circularity Tool from the top menu bar. Notice the Upper Lip Circularity cell is pink.
4. Practice outlining the red portion of the upper lip until your measure of circularity repeatedly matches the circularity printed to the right of each lip photo. Note that your outline should reach from the left to the right corners of the mouth.
5. Each time you select the Circularity tool to outline a lip; a window will appear alerting you that "There is already an upper lip circularity value. Do you want to overwrite it?" Say Yes.
6. To end the session, click on the Outcomes Tab at the bottom of the worksheet and click on "Begin analysis of new patient/photo".

Tips:

Note that more accurate, reproducible measures can be achieved when the image is increased in size (up to 200% zoom). The circularity of the lip does not change with magnification, but your ability to outline it accurately will. Try measuring the same lip at 50%, 100% and 200% zoom to see for yourself.

Adjust your mouse tracking specifications to achieve maximum hand-mouse control.

Test your ability to outline the same lip and get the same circularity each time. See our website (fasdpn.org) for an animated example of lips being outlined.

Consider outlining a subject's lip 2 or 3 times and taking the average across the multiple measures to obtain the most accurate measure of circularity.

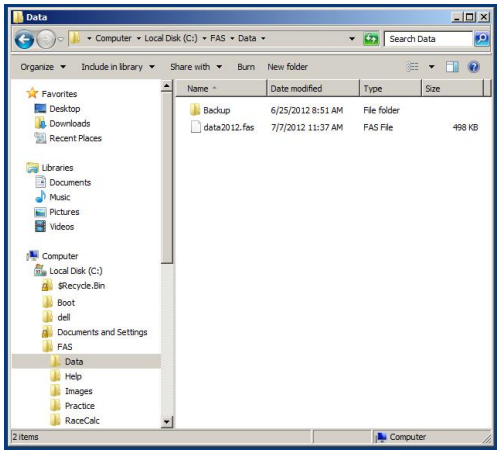
PART VI. SAVING / DELETING / EXPORTING THE DATA

The Facial Software Database

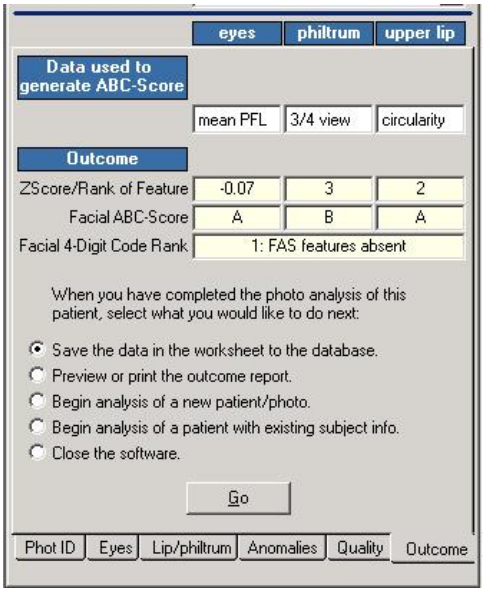
This software program comes with a Microsoft Access database that is specifically designed to store all photo analysis data displayed in the Worksheet, if you choose to save it. The database does NOT store the digital facial photos. Your digital photos are stored in a directory on your hard drive per your specifications. The Access database stores the path that locates where the digital photo was stored on your hard drive, at the time you saved the Worksheet. This stored path allows the database to retrieve the digital photo and display it in the Report, when you ask to view the Report. This stored path also allows the software to locate your photos if you choose to evaluate them again at a later date. The software will not be able to find and display the digital photos if you change their location on your hard drive after you saved the Worksheet data.

When you analyze a set of photographs for a patient, the data is displayed in the Worksheet. When you save the data in the Worksheet, it is saved as a single Record in the database, linked to the patient's last name, birth date, and the file names of up to three images (frontal, ¾ and lateral). If you analyze a second set of photographs for a patient, perhaps photos taken at a different age, this second Worksheet would be saved as a second record for that patient.

The Access database that stores the photo analysis data is named **data2012.fas** by default, when you install the software. Note that this database is saved on your hard drive under C:\FAS\data2012.fas. If you reload the software, an empty data2012.fas file will be installed and overwrite your existing data2012.fas file that contains all your photo analysis data. **Thus, it will be VERY important that you rename the data2012.fas file on your hard drive, and preferably copy the renamed file onto your desktop for safe keeping, before reinstalling the software**. Please see detailed directions for installing the software on our website fasdpn.org.



Saving the Data in the Worksheet to the Facial Software Database



There are two methods to save the data in the Worksheet to the Facial Software Database:

Method 1:

1. Click on the Outcome Tab at the bottom of the Worksheet
2. Click on "*Save the data in the worksheet to the database*".
3. Click the "*GO*" button.

Method 2:

1. Highlight the Worksheet
2. Select *Database* from the top menu bar.
3. Select "*Save current worksheet data from database*.

Deleting Data in the Database

To delete data from the Database:

1. Open the case you want to delete.
2. Click on the top border of the Worksheet.
3. Select *Database* from the top menu bar
4. Select *Delete current worksheet data from database"*.

Exporting Data from the Database

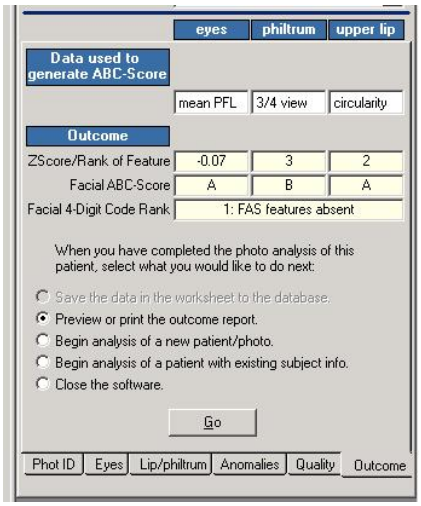
To export one or many patient records into a comma-delimited text file:

1. Select *File* from the top menu bar.
2. Select *Export Records.*
3. In the left window in the pop-up window that appears, browse to the directory where you would like to save the exported file. By default, the exported file will be placed in C:\FAS\Export directory.
4. In the *File Name* box, type in the name you would like to call the exported file. It will automatically be assigned ".txt" as an extension.
5. Click the *Save* button.
6. In the next window, you will see a list of patients whose records have been saved. Double-click on the patient you want to highlight it. If you want to select multiple patients, you may hold down the Ctrl key and click (highlight) as many names as you wish. If you want to select all of the patients, click on the first name, scroll down to the end of the list, hold down the Shift key, and click on the last name.
7. Click the *Export* button.

PART VII. VIEWING / PRINTING THE OUTCOME REPORT AND DATABASE MANAGEMENT

Viewing the Outcome Report

Method 1

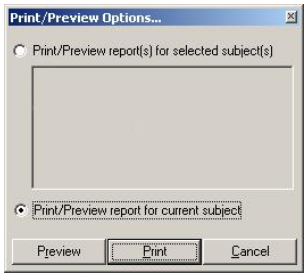


There are two methods to view the Outcome Report.

1. Select the Outcome Tab and select "Preview or Print outcome report"

   A copy of the current subject's Outcome Report will appear.

Method 2



Selecting the current subject's Report

Selecting a previous subject's saved Report

2. Select Report from the top menu bar to open the "Print/Preview Options" window.

   To Select the Current Subject's Report

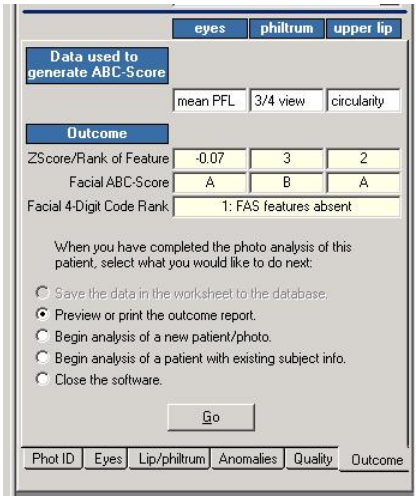
   To preview the Report of the subject whose data is currently showing in the Worksheet, select *Print/Preview report for current subject.*

   To Select Previous Subjects' Reports

   To preview the Report(s) of previous subjects whose data was saved to the Facial Software Database, select *Print/Preview report(s) for selected subject(s).*

Printing the Outcome Report

Method 1



There are two methods to print the Outcome Report

1. Select the Outcome Tab and select "Preview or Print outcome report"

   A copy of the current subject's Outcome Report will appear.

   Click on the Print button in the top menu bar.

Method 2

Printing the current subject's Report

Printing a previous subject's saved Report

2. Select Report from the top menu bar to open the "Print/Preview Options" window.

   To Print the Current Subject's Report

   To print the Report of the subject whose data is currently showing in the Worksheet, select *Print/Preview report for current subject.*

   Then click on the Print button.

   To Print Previous Subjects' Reports

   To preview the Report(s) of previous subjects whose data was saved to the Facial Software Database, select *Print/Preview report(s) for selected subject(s).*

   Then click on the Print button.

Report for Practice Case John Doe

Database Management

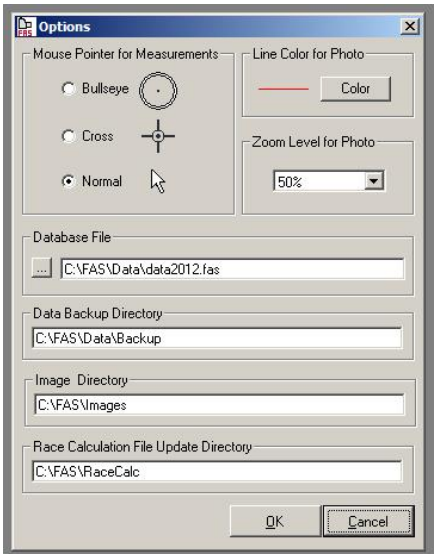

Fig. 7. Options box opened from the Tools tab on the top menu bar.

To Use: Select Data/Logs from the top menu bar and select Database Management from the drop-down menu.

The following database management tools are provided.

1. **Database File**
   Allows you to navigate to the **.fas** database you want to store your photo analysis data in.
2. **Backup Data**
   The Backup Data option makes a backup file of the database currently displayed in the 'Database File' window in the Options box (Fig. 7). The backup file will be named with the date you backed it up followed by data.bak. For example, if you pushed the backup button on July 16, 2012, the file would be named (**7-16-2012data.bak**). This backup file will be stored in the directory displayed/selected in the 'Data Backup Directory' window in the Options box (Fig. 7). If your database file becomes corrupted, you can restore it from any backup files you made.
3. **Restore Data**
   If something happens to the database file you are currently working with [(e.g., the file designated in the Database File window in the Options box (Fig. 7)], the Restore Data option lets you choose from any backup files you may have made and **overwrites** the database file you are currently working with [e.g., the file designated in the Database File window in the Options box (Fig. 7)]), with the restored backup file. The restored database file will only contain data stored before the backup was made. If you have not made any backup files, you will not be able to use this function.
4. **Compact Data**
   The Compact Data option packs data more efficiently in the database file, resulting in a smaller file size. The FAS Facial Analysis software does this for you automatically every time you open the program.
5. **Import New Racial Calculations**
   In future versions, we anticipate providing you with additional racial norms for PFL and inner canthal distance. These new norms would be imported into the software via this route. Please see more about importing new racial calculations below.
6. **Set Password**
   The software program may be password protected with this feature.

View Logs

To Use: Select Data/Logs from the top menu bar and select View Logs from the drop-down menu.

The following logs document all activity regarding Errors, Back up and Restoration.

1. Error Log
2. Back up Log
3. Restore Log

Importing New Racial Calculations for PFL Z-scores

FAS Version 1.0 provided palpebral fissure length (PFL) z-score formulas for Caucasians and African Americans. FAS Version 2.0 software provides PFL z-score formulas for Caucasians, African Americans, Canadians, and Scandinavians. It is important to understand that these formulas are stored IN THE SAME DATABASE as your photo analysis data. The Caucasian and African American formulas are stored in the **data.fas** database for Version 1.0. The Caucasian, African American, Canadian, and Scandinavian formulas are stored in the **data2012.fas** database for Version 2. If you open an older database (e.g., **data.fas**) created by Version 1.0 into the new Version 2 software, the new PFL formulas to compute Canadian and Scandinavian PFL z-scores will be missing. You will discover this when you go to the Eye Tab in the software Worksheet and click on the drop-down menu for "Select Normal PFL Chart". Only Caucasian and African American PFL Charts will be available.

But it is simple to import the new Canadian and Scandinavian PFL z-score formulas into your older Version 1.0 **data.fas** database.

Follow these instructions:

1. It is assumed that the FAS Facial Software Version 2 is open and the Database File selected in the Options window (Fig 3 above) is pointing to an older **data.fas** database that does not currently have the Canadian and Scandinavian PFL formulas in it.
2. Click on the menu item: Data/Logs → Database Management → Import New Racial Calculations.
3. On the **Select File for Update** dialog box, select **the Canadian Male.rcf** file located in C:\FAS\RaceCalc\ and click the **Open** button. (See Fig. 8)
4. A message box will appear showing "New racial calculations have been successfully imported". Click the **OK** button.
5. Repeat step 3, but this time select the **Canadian Female.rcf** file and click the Open Button.
6. A message box will appear again confirming the upload. Click the **OK** button. (See Fig. 8)
7. Click on the menu item: Data/Logs → Database Management → Import New Racial Calculations.
8. On the **Select File for Update** dialog box, select **the Scandinavian Male.rcf** file located in C:\FAS\RaceCalc\and click the **Open** button. (See Fig. 8)
9. A message box will appear showing "New racial calculations have been successfully imported". Click the **OK** button.
10. Repeat step 3, but this time select the **Scandinavian Female.rcf** file and click the Open Button.
11. A message box will appear again confirming the upload. Click the **OK** button (See Fig. 8).
12. Re Start the FAS Facial Software.
13. Go to the Eye Tab in the software Worksheet and click on the drop-down menu for "Select Normal PFL Chart". You should now see all four PFL options available.
14. See our website (fasdpn.org) for guidance on which PFL charts to use.

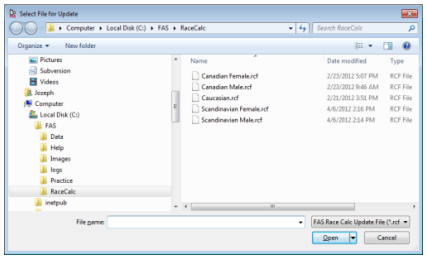

Fig. 8.

DICTIONARY

Anomaly
: A physical feature that is present in less than 2% of an age and race appropriate sample of the population

Circularity
: A quantitative measure (perimeter^2/area) used to objectively measure upper lip thinness. The thinner the upper lip, the greater the circularity. See the Lip Circularity Table on the backside of the Lip-Philtrum Guides.

Clown eyebrows
: Eyebrows that arch upward at the lateral margins. The eyebrow typically follows the superior border of the bony orbital rim. Clown eyebrows are often secondary to microcephaly. See the FAS Face / Other Anomaly Pictorial Guide.

Endocanthion
: The facial landmark demarcating the inner corner of the eye fissure where the eyelids meet. See the Landmark / Rotation Pictorial Guide.

Epicanthal fold: Lateral extension of skin of the nasal bridge over the endocanthion landmark. May be unilateral or bilateral. May be indigenous to some races. More common in very young children of all races. See the Landmark / Rotation Pictorial Guide.

Exocanthion
: The facial landmark demarcating the outer corner of the eye fissure where the eyelids meet. See the Landmark / Rotation Pictorial Guide.

External auditory canal
: The external opening of the ear canal. This is one of two landmarks that demarcate the Frankfort Horizontal plane when viewing the lateral facial photograph. See the Landmark/Rotation Pictorial Guide.

Flat (hypoplastic) midface
: Under-development of the maxilla relative to the nasal process.

Flat nasal bridge
: The bridge of the nose between the eyes is depressed (flattened). May be indigenous to some races and is more common in very young children of all races. See the FAS Face / Other Anomaly Pictorial Guide.

Frankfort horizontal plane
: A plane demarcated by a line drawn from the external auditory canal to the lowest border of the bony orbital rim (orbitale). This plane is used in anthropometry to standardize the positioning of the head. For the purposes of measuring FAS facial features, the camera lens should be placed in the patient's frankfort horizontal plane. See the Landmarks/Rotation Pictorial Guide.

Hypertelorism

Ocular hypertelorism is an abnormal increased distance between the centers of the pupils. This term is also often used to denote an abnormal increased distance between the right and left endocanthion landmarks (or telecanthus).

Hypotelorism

Ocular hypotelorism is an abnormal decreased distance between the centers of the pupils. This term is also often used to denote an abnormal decreased distance between the right and left endocanthion landmarks.

Inner Canthal Distance

The distance between the eyes from the right endocanthion to the left endocanthion. See the Landmark/Rotation Pictorial Guide.

Internal Measure of Scale

The paper sticker (typically ½ to ¾ inch) placed on the patient's forehead to serve as a ruler or internal measure of scale in the photograph. This allows the true PFL and inner canthal distances to be computed. See the Landmark/Rotation Pictorial Guide.

Orbitale

The lowest point on the bony orbital rim. This is one of two landmarks that demarcate the Frankfort Horizontal plane. See the Landmark/Rotation Pictorial Guide.

Overlay

A term used in this software program that refers to the lines that are temporarily drawn on the photograph when distance or circularity measures are being taken. These overlays can be removed from the photograph by clicking on Image/Clear Overlays in the Menu bar.

Palpebral fissure length (PFL)

A measure of the size of the eye. The distance from the exocanthion to the endocanthion landmarks. See the Landmark/Rotation Pictorial Guide.

Phenotype

Physical appearance.

Philtrum

The vertical groove between the nose and upper lip. See the Landmarks/Rotation Pictorial Guide.

Pixels

A unit of measure used in computerized image analysis. A pixel is one dot of light on the computer monitor.

Ptosis

Drooping of upper eyelid. Generally caused by a weakness in the levator palpebrae superious muscle. See the FAS Face / Other Anomaly Pictorial Guide.

Thin upper lip (or thin vermilion border)

When measuring the thinness of the upper lip, the part of the upper lip that is being referred to is the red or vermilion portion of the upper lip. See the Landmarks/Rotation Pictorial Guide.

Tragus

A small extension of tissue in front of the external auditory canal. This is one of two landmarks that demarcate the Frankfort Horizontal plane when viewing the frontal facial photograph. See the Landmark/Rotation Pictorial Guide.

Z-score

The z-score reflects how many standard deviations above or below the population mean the patient's PFL is, based on the patient's age and gender. The z-score is defined as the patient's PFL minus the mean PFL for the normal population divided by the standard deviation of the mean PFL for the normal population.

ABSTRACT The most serious features of fetal alcohol syndrome (FAS) are mental retardation and other behavioral problems resulting from alcohol-induced damage to the developing central nervous system (CNS). The mechanism by which alcohol induces its neuroteratogenic effects is unknown. One hypothesis is that gestational alcohol exposure results in a reduction in neuronal number. This study demonstrates that gestational exposure to ethanol in a non-human primate species induces permanent dose-related deficits in the number of cerebellar Purkinje cells. Ethanol was administered via nasogastric tube once per week to 15 gravid pigtailed macaques (Macaca nemistrina) in one of the following doses: 0.0 (intubated controls), 1.2, 1.8, 2.5, 3.3, and 4.1 g/kg/dose. Offspring were reared with parental surrogates and were sacrificed at 6 months of age; 8-μm-thick parasagittal sections were cut through the paraffin-embedded cerebellar vermis. Purkinje cells were quantified, the length of the Purkinje cell line was determined stereologically, and Purkinje cell linear frequency was calculated. The number of Purkinje cells and their linear frequencies were significantly reduced in the alcohol-treated subjects, and the deficits were dose-dependent. The groups receiving 2.5 g/kg/dose and above were most severely affected and had an average deficit in Purkinje cell number of 11.8%, relative to controls. Alcohol had no effect on the length of the Purkinje cell line. The findings suggest that alcohol-induced reduction in neuronal number may be an important factor underlying the CNS dysfunction in FAS.

Ethanol abuse during pregnancy can have adverse effects on the developing fetus and, in severe cases, results in fetal alcohol syndrome (FAS) (Jones and Smith, '73; Jones et al., '73). The most serious features of FAS are mental retardation and other behavioral abnormalities resulting from damage to the developing central nervous system (CNS) (Clarren, '86; Streissguth et al., '80).

Despite the fact that alcohol abuse is one of the leading known causes of mental retardation in the western world (Abel and Sokol, '91), there is a paucity of human data available concerning the neuroanatomical changes resulting from fetal alcohol exposure. Because FAS was only recently recognized as a distinct clinical entity, and because the syndrome is not usually fatal, few fetuses or infants with recognized FAS have undergone autopsy. Those few autopsied cases that have been published generally describe extreme CNS damage (Clarren, '86; Claren et al., '78). However, many of these cases were accompanied by confounding complications, such as severe congenital heart defects and by maternal abuse of other drugs, making it difficult to determine whether the observed CNS anomalies were due to alcohol directly or to the confounding factors.

The mechanism by which fetal alcohol exposure induces postnatal CNS dysfunction is unknown. One hypothesis is that alcohol exposure results in a reduction in neuronal number—either through interference with neuronal production or through induction of neuronal death—and that the resulting neuronal deficits underlie or contribute to the CNS dysfunction. Through the use of animal models, deficits in neuronal number following developmental alcohol exposure have been demonstrated in the hippocampus (Barnes and Walker, '80), somatosensory cortex (Miller and Potempa, '90), cerebellum (Hamre and West, '93), retina (Clarren et al., '90) and olfactory bulb (Bonthius et al., '92). Furthermore, ethanol-induced neuronal loss has been dem-

onstrated in regions known to influence specific behaviors, and these behaviors have been shown to be abnormal in animals with these neuronal deficits. For example, spatial memory deficits have been correlated with loss of CA1 pyramidal cells in the hippocampus (Goodlett et al., '92). Such results support the hypothesis that neuronal loss associated with ethanol exposure is functionally important.

Nearly all the evidence demonstrating neuronal deficits following developmental alcohol exposure has been derived from rodent models of FAS. The question arises whether the alcohol-induced neuronal deficits in the brains of rats and mice are relevant to the human condition.

Several inherent constraints limit the widespread use of nonhuman primates in biomedical research. Animals are expensive and difficult to acquire; they have long gestational periods, and pre- and postnatal care is complicated. Nevertheless, primate models offer advantages of evaluating the effects of gestational alcohol exposure on the fetus (Riley and Meyer, '84). Among these advantages are the important facts that nonhuman primates are more similar to humans developmentally, ontogenetically, neuroanatomically and behaviorally than are rodents (Bourne, '75; Golub, '79; Hendrickx and Sawyer, '75).

The principal goal of this study was to determine whether prenatal exposure to ethanol can induce permanent neuronal deficits in a primate species. The neuronal population examined in this study is the cerebellar Purkinje cells, a group of neurons known to be exquisitely vulnerable to alcohol-induced cell death in developing rats (Bonthius and West, '90).

The exposure paradigm in the present study was designed to mimic common drinking patterns in humans. Consumption of ethanol once per week has been found to be the most frequent intermittent pattern of drinking by American women (Wilsnack et al., '84). Since the pattern of ethanol exposure during development influences the risk and severity of brain damage (Bonthius and West, '90; Webster et al., '83), it is important to model conditions similar to which a human fetus is likely to be exposed. Therefore, the gravid monkeys in this study were exposed to intoxicating levels of ethanol on a weekly basis.

METHODS

Subjects

The cerebellar tissue evaluated in this study was derived from 15 animals generated as part of a larger project at the University of Washington, the methods and results of which have been described previously (Clarren et al., '88, '90). Ethanol was administered via nasogastric tube once per week to gravid pigtailed macaques (*M. nemestrina*). The ethanol doses were 1.2 (n = 1), 1.8 (n = 4), 2.5 (n = 2), 3.3 (n = 3), and 4.1 (n = 1) g/kg/dose. Animals that were exposed to the lower doses (1.2 and 1.8 g/kg) of ethanol were nasogastrically intubated weekly throughout gestation (weeks 1–24), while animals exposed to the higher doses (2.5–4.1 g/kg) received the ethanol starting with the fifth week of gestation. Delay in administration of the higher doses was necessary because earlier work showed that the higher doses produced insufficient viable offspring in the time allotted for the experiments when administered throughout gestation (Clarren et al., '88). A control group of gravid females (n = 4) received a weekly oral sucrose solution that was isocaloric and isovolumetric to the highest ethanol dose.

Maternal peak plasma ethanol concentrations

Blood samples were taken from each pregnant female once every 8 weeks (three times per pregnancy), and plasma ethanol concentrations were determined as previously described (Clarren et al., '87). The three serum ethanol concentrations for each animal were averaged to provide a mean maternal peak plasma ethanol concentration (MPPEC). The complete MPPEC data for each of these animals have been published previously (Clarren et al., '88).

Tissue preparation

The offspring were reared independently of their mothers, were housed with parental surrogates (diapers) and had daily social experience with groups of like-aged peers. After participating in extensive physical and behavioral evaluations, the offspring were sacrificed at approximately six months of age (329–380 days postconception). Following sedation by intramuscular injections of ketamine, an intravenous line was placed in the saphenous vein through which chloral hydrate was infused. When a deep level of anesthesia was reached, cranial nerves and spinal cord were severed, and the brain was carefully removed. The cerebellar peduncles were cut, separating the cerebellum from the brainstem. The cerebellum was wrapped in gauze and placed in 10% neutral buffered formalin to await further processing.

A 2-mm-thick sagittal slice was taken from each cerebellar vermis. The cuts were made parallel to and 1 mm to either side of the midline so that the entire midcerebellum was included. The 2-mm-thick slices were dehydrated through a series of alcohols, cleared in xylene and embedded in paraffin. Each slice was oriented to allow sectioning in the parasagittal plane.

The blocks were cut as 8-micrometer-thick sections on a rotary microtome, and a 1-in-5 series of sections was saved. The sections were floated in a 37°C water bath for 10 sec, mounted onto gelatin-coated slides and allowed to dry overnight at room temperature. The sections were stained with a combination of safranin O and cresyl violet, dehydrated, cleared in xylene, and coverslipped with Permount.

Cell counting and estimation of line length

From the set of sections saved, three sections from each subject which were free of folds and tears were

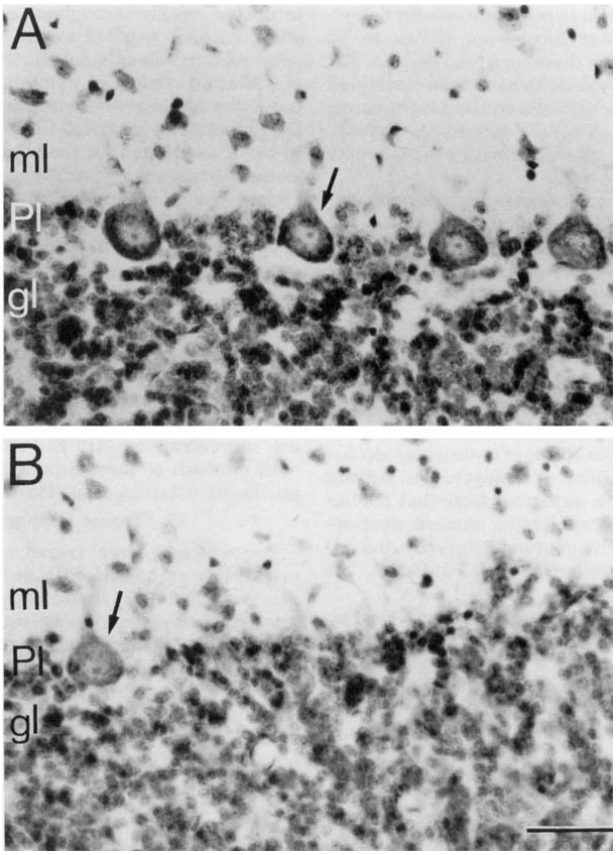

Fig. 1. Photomicrographs of cerebellar cortex from 6-month-old pigtailed macaques. **A:** From a control animal exposed to no alcohol during gestation. The arrow points to a typical Purkinje cell body. Purkinje cells with clearly discernible nuclear membranes were counted in three representative sections per animal. Note that the Purkinje cells in this control section are spaced quite closely together along the length of the Purkinje cell line. **B:** From an animal exposed to weekly doses of 3.3 g/kg of alcohol during gestation. The alcohol exposure has resulted in a diminishment of Purkinje cell number. The deficit in Purkinje cells manifests itself as large gaps in the Purkinje cell line in which few Purkinje cells exist. **Arrow,** points to the only surviving Purkinje cell in this segment of cortex. ml, molecular layer; Pl, Purkinje cell layer; gl, granule cell layer. Bar = 25 μm.

randomly chosen for analysis. In each analyzed section (Fig. 1), Purkinje cells with clearly discernible nuclear membranes were counted manually (Bonthius and West, '90, '91).

In order to determine the length of the Purkinje cell line, a magnified (×125) image of the section was projected onto a square grid consisting of parallel lines separated by a distance of 1 cm. The intersections that the Purkinje cell layer made with each of the two sets of parallel lines making up the grid were counted. The number of intersections (I) provided a direct and unbiased estimate of the length (L) of the Purkinje cell line according to the formula (Harvey and Napper, '88; Weibel, '79):

$$L = I \times \pi/4 \times D \times 1/M$$

where, in this case, D is 1 cm and M is 125. The linear frequency of Purkinje cells was derived by dividing the number of Purkinje cells by the length of the Purkinje cell line.

TABLE 1. Maternal peak plasma ethanol concentrations (MPPECs)[1]

Weekly alcohol dose (g/kg/dose)	n	Gestational weeks of exposure	MPPEC (mg/dl)
0.0	4	1–24	
1.2	1	1–24	140.5 ± 3.5
1.8	4	1–24	208.4 ± 29.1
2.5	2	5–24	262.3 ± 23.4
3.3	3	5–24	431.6 ± 74.4
4.1	1	5–24	548.3 ± 87.8

[1]All measures represent means ± S.D.

Nuclear diameters

In order to correct for potential changes in nuclear fragment number due to differences in nuclear size, the distribution of nuclear fragments was estimated from random, systematically chosen samples of Purkinje cell populations. The long and short axes of each sampled nucleus were measured under oil immersion with a gradicule eyepiece. The axes of 400 nuclear fragments per treatment group were measured. The geometric means of the axial measurements were calculated, pooled, and plotted as nuclear fragment diameter frequency histograms.

Statistical analyses

Cell counts were made from three sections from each animal. For the statistical analyses, the values from each of the three sections were averaged. The number of Purkinje cells per section, Purkinje cell line length, and Purkinje cell linear frequency were analyzed separately by simple linear regression (Wonnacott and Wonnacott, '77). The nuclear diameter frequency histograms were analyzed by chi-square test.

RESULTS

Table 1 demonstrates that the MPPECs ranged from 140.5 mg/dl in the animal exposed to the lowest alcohol dose (1.2 g/kg) to 548.3 mg/dl in the animal exposed to the highest alcohol dose (4.1 g/kg). As expected, as the dose of alcohol increased, so did the MPPEC rise in a stepwise fashion.

The cerebellums of two subjects (one each in the 3.3- and 4.1-g/kg groups) were mechanically damaged during processing; several small lobules were broken and lost. As a result, it was not possible to determine accurately the total number of Purkinje cells per section nor the Purkinje cell line length for these two subjects. It was possible, however, to determine the Purkinje cell linear frequency on the remaining undamaged tissue from these two subjects. Therefore, the data regarding total Purkinje cell number and line length were derived from 13 subjects, while the data regarding Purkinje cell linear frequency were derived from 15 subjects. The mean number of Purkinje cells per section, estimated Purkinje cell line length and calculated Purkinje cell linear frequency for each of the animals is shown in Table 2.

TABLE 2. Purkinje cell number, Purkinje cell line length, and Purkinje cell linear frequency for individual animals[1]

Subject no.	Weekly ethanol dose (g/kg)	Purkinje cell no.	Purkinje cell line length (mm)	Purkinje cell linear frequency (cells/mm)
1	0.0	2202	368	6.00
2	0.0	2371	422	5.62
3	0.0	2346	404	5.82
4	0.0	2467	399	6.18
5	1.2	2421	416	5.83
6	1.8	2084	376	5.45

15[2]	4.1	1576	301	5.20

[1]All measures represent the mean values from three analyzed sections.
[2]Subjects in which the cerebellum was mechanically damaged during processing, resulting in the loss of several small lobules. In these subjects, only the Purkinje cell linear frequency could be determined accurately and was included in the statistical analyses.

Alcohol exposure during gestation induced dose-dependent Purkinje cell deficits. The regression analysis indicated a significant effect of ethanol dose on Purkinje cell number [$F(1,11) = 8.164$; $P < 0.05$]. As shown in Figure 2A and in Table 2, the subjects exposed to the highest doses (2.5 and 3.3 g/kg) were the most severely affected and had an average deficit in Purkinje cell number of 11.8%, relative to controls. A strong inverse correlation existed between the ethanol dose and Purkinje cell number ($r = -0.653$).

The regression analysis also indicated a significant effect of ethanol dose on Purkinje cell linear frequency [$F(1,13) = 9.59$; $P < 0.01$]. As shown in Figure 2B, as the dose of ethanol increased, the linear frequency of Purkinje cells tended to decrease linearly.

The alcohol-induced deficits in Purkinje cell number and linear frequency manifested themselves as gaps in the Purkinje cell line. Whereas control animals had a relatively frequent and uniform presence of Purkinje cells throughout the Purkinje cell line, the alcohol-exposed animals had segments of cortex in which few Purkinje cells existed (Fig. 1). Although the location of these gaps was not systematically analyzed, they seemed to occur in a random pattern, unrelated to any particular rostrocaudal position, cerebellar lobule, or depth within the folia.

The ethanol treatment had no significant effect on the length of the Purkinje cell line (Fig. 2C), indicating

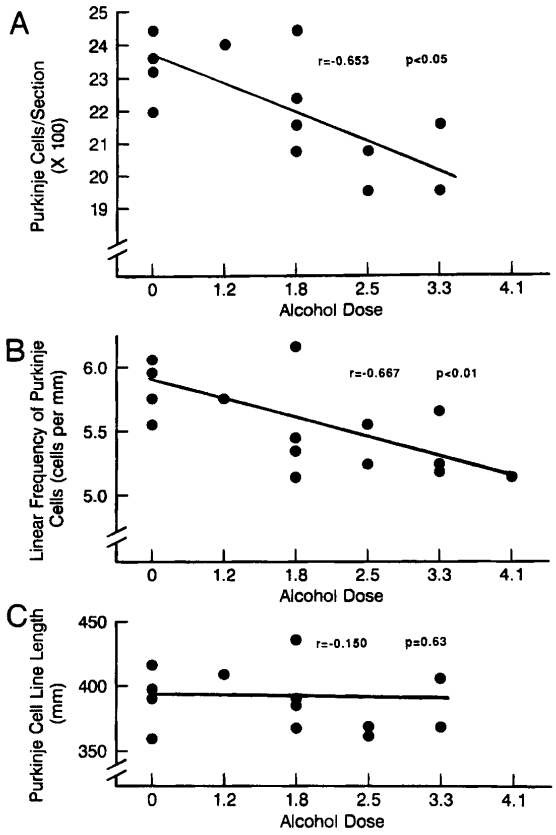

Fig. 2. Effect of gestational alcohol exposure on the number of Purkinje cells, Purkinje cell linear frequency and length of the Purkinje cell line. **A:** Dose-response effect of alcohol on the number of Purkinje cells per sagittal section. Gestational alcohol exposure induced dose-dependent Purkinje cell deficits, with the animals exposed to the highest doses (2.5 and 3.3 g/kg) being most severely affected. **B:** Dose-response effect of alcohol on Purkinje cell linear frequency. As the dose of alcohol increased, the linear frequency of Purkinje cells tended to decrease. **C:** Relationship of alcohol dose to length of the Purkinje cell line. Increasing doses of alcohol had no significant effect on the length of the Purkinje cell line.

that the alcohol-induced reduction in Purkinje cell number was not merely due to a reduced length of cortex along which the cells were counted.

Examination of nuclear fragment diameter frequency histograms indicated no significant differences in modal diameter or in the distribution of diameters among the treatment groups (Fig. 3).

DISCUSSION

The most important findings of this study are that ethanol exposure during gestation in monkeys produces dose-dependent cerebellar Purkinje cell deficits and a corresponding decline in Purkinje cell linear frequency. Other than a multidisciplinary report that included some counts of retinal ganglion cells (Clarren et al., '90), this is the first study to report quantitative evidence of dose-dependent neuronal deficits in the nonhuman primate brain as a consequence of fetal ethanol exposure. These findings of diminished Purkinje cell number and linear frequency support the hypothesis that deficits in neuronal number may underlie or contribute to the cognitive and behavioral problems associated with FAS. Indeed, as described in an earlier report (Clarren, Astley and Bowden, '88), many of the alcohol-exposed animals in this study exhibited substantial motor and cognitive deficits and delays.

A second important finding of this study is that neuronal deficits occurred following patterns of alcohol ex-

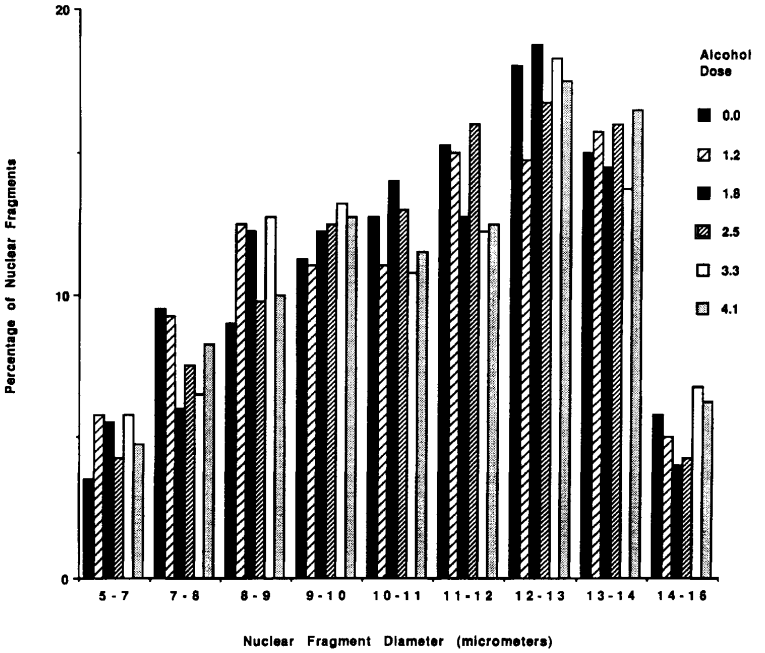

Fig. 3. Nuclear fragment diameter frequency histogram for the Purkinje cell population of 6-month-old pigtailed macaques. The axes of 400 nuclear fragments per treatment group were measured, and the geometric means of the axial measurements were pooled and plotted. The alcohol treatments had no significant effect on the distribution of the nuclear diameters.

posure and blood alcohol concentrations commonly seen in humans. The alcohol in this study was administered once per week. Epidemiological studies have demonstrated that women who drink during pregnancy tend to binge drink—often once per week (Stephens, '85; Little and Streissguth, '78). The findings of the present study demonstrate, as have several rodent studies (Bonthius and West, '90, '91), that binge alcohol consumption during pregnancy can induce substantial and permanent brain injury in the fetus.

The mechanism underlying fetal ethanol-induced damage in general, and Purkinje cell depletion in particular, remains unknown (West et al., '94). Purkinje cells are the earliest generated cells of the cerebellar cortex (Altman and Bayer, '78). In the monkey, Purkinje cell neurogenesis is completed during the first half of pregnancy (Verbitskaya, '69). Since the ethanol exposure in this study occurred throughout all or most of gestation, it encompassed a broad period of brain development including eras preceeding, during and following Purkinje cell neurogenesis. Therefore, the ethanol may have interfered with any of a host of developmental processes upon which the Purkinje cell population depends for generation, differentiation and survival. Ethanol has been shown to interfere with cell proliferation and migration (Borges and Lewis, '83; Miller, '86). However, studies in the rat have shown that Purkinje cells are most vulnerable to alcohol-induced cell death during the period of cellular differentiation—after they have completed the periods of neurogenesis and migration, but before they have reached full maturity (Bonthius and West, '90; Hamre and West, '93; Marcussen et al., '94). Exposure to alcohol for a single day has been shown to be sufficient to kill a substantial number of Purkinje cells during this period of vulnerability (Goodlett et al., '92). In the rat, an altricial species, this period of maximum vulnerability occurs in the early postnatal period (Marcussen et al., '94). The monkey, however, is a precocial species, and its brain is substantially more mature at the time of birth than is the rat's (Dobbing and Sands, '79). Therefore, if maximum vulnerability of the Purkinje cell to alcohol occurs at the same developmental stage of Purkinje cell differentiation in the monkey as it does in the rat, then the monkey Purkinje cell would be expected to be most vulnerable during the final third of pregnancy.

Most of the alcohol-exposed animals in this study, including those exposed to the highest doses of alcohol (≥2.5 g/kg/dose), had no evidence of external dysmor-

phology (for details, see Clarren, Astley and Bowden, 1988). Yet, many of these animals clearly had alcohol-induced neuronal deficits. This finding demonstrates that alcohol-induced brain damage can occur in the absence of external dysmorphology in a primate species and strengthens the troubling notion that children with alcohol-induced brain damage may be far more common than those diagnosable with the full fetal alcohol syndrome.

Development of the FAS Diagnostic and Prevention Network in Washington State

Sterling Clarren and Susan Astley

Introduction

It has not yet been demonstrated that stories and warnings in the media about the adverse impact of drinking alcohol during pregnancy lead directly to a reduction in the incidence of Fetal Alcohol Syndrome (FAS) and related disorders. However, it has become clear to us that every time a widely viewed piece on FAS appears in the press or on television, there is a sharp increase in requests for appointments for FAS diagnosis. Parents seem to recognize their own children's difficulties in the descriptions of patients with FAS and wonder if FAS is, at last, the elusive answer to the enigma that is their child.

We began to receive requests for FAS diagnoses in the late 1970s after the first major articles on FAS had been published (Clarren & Smith, 1978; Hanson, Jones, & Smith, 1976; Jones, Smith, Ulleland, & Streissguth, 1973) and the first major campaign to improve maternal awareness and decrease alcohol use in pregnancy had been mounted (Little, Streissguth, & Guzinski, 1980). For many years, we attempted to serve these patients' diagnostic needs through referrals to existing clinics at Children's Hospital and Medical Center, in Seattle, Washington. Some patients were evaluated in diagnostic clinics such as Medical Genetics, Dysmorphology, Neurology, or Developmental Disabilities. Others were followed in chronic care clinics like the Craniofacial or Neurodevelopmental Programs.

The feedback we received from both patients and faculty was generally neutral to negative. None of these medical settings seemed to meet the needs of many of the patients. The families recognized almost immediately that whether or not they received a specific diagnosis , they had sought much more. They really wanted help with management across four large domains: medical, psychiatric/psychologic, educational, and social, with recommendations for specific interventions by specific individuals in their locality. Funding was almost always a major concern. Most of our faculty were capable of making an accurate medical diagnosis of FAS, but no program was prepared to evaluate and appropriately treat or refer the patients in a comprehensive fashion for the myriad of functional problems that led to the evaluation in the first place.

This paper was supported in part by the Centers for Disease Control Cooperative Agreement # U84/CCU008707-04 and the March of Dimes Birth Defects Foundation.

By the late 1980s it became clear that a new clinic was needed to address the long term management needs of patients debilitated by alcohol teratogenesis. The clinic had to be prepared to evaluate patients of all ages and to handle different types of problems in clients of different ages — because FAS produced ongoing needs across the life span. In infants and children below the age of three years or so, the diagnosis was more important for future planning than for any specific intervention at that time. In children of preschool and primary school years, academic and behavioral problems were a major issue. Academic problems were seen as more important, although in middle school years concern over behavioral problems generally outweighed concern over the ongoing academic issues. In older teens and adults, problems of employment, relationships, and independent living were often the primary concerns. Frequently, the patients' specific problems did not meet specific criteria for help as defined by the schools or the social welfare system.

However, if the birth mother of an affected child was able to have more children and was still drinking, she was at high risk to have other children with alcohol-related problems and was at high risk to have alcohol-related health problems of her own. Issues of alcohol abuse and addiction existed in families of patients of all ages, expressed through the mother's feelings about herself, the other family member's feelings about her, and concern for the patient's own susceptibility to alcohol abuse and addiction. The identification of young FAS patients needed to be attached to a program that would reach out and help the birth mothers. This issue had to be identified and dealt with specifically because it affected all other interventions.

It seemed reasonable that the new clinic would work well if it was based on a traditional multi-disciplinary developmental model that would be responsive to patients and caregivers with varying needs in a context of available local services. We found that such a new clinic for FAS patients was not easy to establish. The majority of the assessments and treatments that were needed were not medical, but

social, educational, psychologic, or related to addictions. As long as the clinic was run from a hospital base and billed as a medical service, the financial reimbursement was so low that the clinic was not viable. Beyond fee for service, no other means of funding a service clinic was readily available to us. Unfortunately, if a clinic is never established because there is no funding mechanism, then the value of the clinic cannot be demonstrated and the financial "Catch-22" cannot be understood and corrected.

In 1990, we responded to a Request for Proposal from the Centers for Disease Control and Prevention (CDC). The CDC was looking for innovative approaches to the primary prevention of FAS. We suggested that an immediate reduction in the incidence of FAS could be accomplished by identifying women who had had an FAS child. If these women could be helped to become clean and sober through any subsequent pregnancies, then pregnancies at the highest risk for producing infants with FAS could be avoided. But who were these women, and what factors in their lives needed to be understood for an effective intervention to work? To this time, there have been no published reports describing the lives of mothers of FAS patients as a group in the general population of the United States. It was clear from our personal experience and the general literature that FAS patients frequently did not live with their birth mothers. A clinic that would make regular, accurate, and consistent diagnoses of FAS and related conditions would demonstrate that the mothers could be found. The birth mothers could then be interviewed as a first step in developing a focused intervention plan.

This project was funded by the CDC. We are now in the fourth year of a five year study. The project allowed us to create the FAS Diagnostic Clinic at the University of Washington's Center for Human Development and Disability, which was the beginning of the development of the FAS Diagnostic and Prevention Network of Washington State.

The CDC funding permitted us to schedule the clinic to meet one day per week. We found that four or five patients could be assessed in a clinic day, and between 160 to 180 patients could be evaluated in a year. Our waiting list grew steadily. At times, 500 or more names were on the waiting list. Clearly, we could never see all of the applicants. The fact that so many families requested appointments, and were willing to wait months to be seen, underlined our previous impression that while numerous facilities were available to assess FAS in the context of some specific discipline or another, and that while most of these families had availed themselves of some of these

services, the families still did not believe that their children had been appropriately understood or directed to appropriate services.

We worked with the March of Dimes Foundation for Healthier Babies to establish two FAS Network sites (in King and Snohomish Counties). These sites were based on our clinic model at the University of Washington, the concept of multiple funding sources, and perceived community interest by professionals and families. Our group provided training and data management and the local staff were responsible for patient assessment and treatment planning. At that same time, the Washington State Legislature, responding to lobbying from concerned parents, wished to develop a model for helping with the perceived unmet needs of patients with FAS and their families. We suggested to a state senator, who was drafting legislation, that our FAS Network idea might make sense for the state. The concept was adopted in Senate Bill 5688 that became state law in 1995. The law provided for the development of several additional sites, which currently is ongoing. Funding was made available for development, training, and data management. The sites remain responsible for finding the resources needed to cover patient care costs.

All clinics will function similarly to the clinic established at the University of Washington. The structure of that clinic is described below.

The Clinic

Staff

The *primary staff* are the core group of professionals needed for diagnosis and treatment plan development for all patients. The ideal team comprises individuals from six disciplines: medicine, psychology, speech and language pathology, social work, public health nursing, and family advocacy. The first three members are largely responsible for the assessments necessary to make the diagnosis and develop the treatment plan; the latter three members more often are responsible for helping to implement the plan.

The *secondary staff* are a larger group of professionals that can be called on to consult in specific cases, but would not necessarily be needed in all cases. Staff members might include (but would not be limited to) medical subspecialties like psychiatry, neurology or genetics, alcohol treatment counselors, educators, educational psychologists, behavioral therapists, family therapists, lawyers, and parent support groups.

Referral Process

Referrals are accepted from any primary sources including physicians, teachers, psychologists, social service agencies, the courts, and the families themselves. In order to gauge the appropriateness of the referral, the family is asked to complete an extensive questionnaire. This document asks for information in all areas that will be pertinent to the diagnosis, including gestational history and gestational exposures to drugs and alcohol, basic genetic historical information, and descriptions of medical, social, educational, and behavioral problems. Photos are requested.

The returned questionnaires are reviewed at weekly meetings and the patients are placed in one of three groups:

Group A. The patient has a documented history of exposure to alcohol in utero and there are physical anomalies and behavior problems present. A diagnosis of FAS, a related condition, or another birth defect syndrome is likely.

Group B. The patient has a documented history of alcohol exposure in utero or physical anomalies and/or behavioral problems so that a diagnosis of FAS or a related condition still may be reasonably considered.

Group C. The patient has no documented history of alcohol exposure in utero and no physical anomalies. Although the patient's behavioral problems might be just as serious as are those of patients in groups A and B, it is unlikely that the clinic will be able to link the etiology to ethanol teratogenesis or reach out to a birth mother in hope of preventing subsequent cases.

Patients in groups A and B are scheduled to be seen at the clinic. Because the clinic currently is funded as a research tool aimed at finding the mothers of FAS patients, patients in group A with the highest likelihood of having FAS, and a birth mother still known to be living in Washington State, are given the highest priority. Conversely, patients in group C are sent a letter suggesting that they be evaluated in another setting. Specific alternate settings are suggested when appropriate.

Clinic Process

The patient's evaluation can be divided into five distinct "phases:"

Phase 0: Collection of old records. Phase 0 occurs between the time the referral is accepted for an appointment and the actual clinic day. Most patients who are evaluated in our program already have had multiple evaluations including medical, psychological, educational, and social-welfare reviews. During this waiting period, the clinic coordinator and possibly the family advocate work with the family to identify and locate copies of these materials.

Phase 1: Clinical assessments. This phase involves the collection of new data by team members. At a minimum, this will include an interview with the family and the patient, and a physical exam emphasizing dysmorphological and neurological conditions. If the old records do not contain current and appropriate psychometric test results, then such tests will need to be obtained as well. The most helpful tests usually are IQ measures, tests of academic performance, tests of language usage, and tests of adaptive ability.

Phase 2: Case conference. The staff meets as a whole to discuss the diagnosis(es) and the etiologies of the diagnosis(es), and to develop an initial treatment plan. The family then is invited into the session, the situation is clarified, and the final treatment plan is developed with input from the family.

Phase 3: Debriefing. The family then meets with a single member of the staff, usually the psychologist, to discuss the emotional impact of the clinical day and the diagnosis. We have found that this phase is critical in helping the family to use the information from the clinic in a positive way. After having been "talked at," families need time to "talk back" and process the situation.

Phase 4: Staff closure. After the debriefing period, the psychologist usually needs to finalize the case with the rest of the staff and arrange for any follow-up with team members that was suggested in Phase 3. This also is an appropriate time to insure that all records have been completed.

Diagnostic Schema

The definition of FAS has changed little in the last twenty years (Clarren & Smith, 1978; Rosett, 1980; Sokol & Clarren, 1989). The condition is typified by growth deficiency, a characteristic set of facial features, and evidence of prenatal alteration in brain function such as microcephaly from birth, neurologic problems without postnatal antecedents, or complex patterns of functional disability that cannot be explained or understood solely in terms of postnatal experiences. The condition is distinctive and can be readily separated from normal and almost all other birth defect syndromes by trained observers (Astley & Clarren, 1995; Clarren et al., 1987). The history of alcohol exposure in gestation is not part of the clinical criteria for the diagnosis of FAS, but rather the history of alcohol supports the diagnosis.

For the trained clinician, there is little difficulty in making the diagnosis of FAS when the abnormalities in growth, face, and brain

are all extreme, and the alcohol exposure history is conclusive and substantial. But the features of the condition are not dichotomous; the clinical features and, indeed, the history of alcohol exposure itself each range along a separate continuum from normal to clearly abnormal. Accurately and fairly characterizing intermediate conditions has posed difficulties. To date, clinicians have not agreed on a simple diagnostic schema to deal with the gradations in exposure and in effects.

In our clinic, several diagnostic terms initially were used to deal with this problem. These are:

FAS with confirmed history of alcohol exposure. These patients met the full published diagnostic criteria of growth deficiency; a full and characteristic set of minor facial anomalies including short palpebral fissures (more than two standard deviations from the mean), and a complex lower facial malformation sequence typified by flat philtrum, thin upper lip and apparent flattening of the midface just medial to the alae of the nose; and evidence of organic brain damage including structural, neurological, or functional stigmata. In these cases, there is clear evidence of exposure to alcohol during gestation by reliable report. Other malformations also may be found and are noted, but do not affect the final diagnosis.

FAS without a confirmed history of alcohol exposure. These patients have the same phenotypic findings as above, but no history of alcohol can be confirmed because the family of origin is not available, the birth records are sealed, or there is some similar situation. (We have never seen a patient with the full FAS phenotype and a confirmed negative history for alcohol exposure in gestation, but if such a patient would be found, they would not have FAS, but rather would be referred to as having an "FAS phenocopy.")

Atypical FAS. These patients have a phenotype that very nearly is complete for FAS and have a confirmed history of alcohol exposure. We place patients in this category when they have the full facial stigmata and brain changes of FAS, but lack growth deficiencies, or when they have growth deficiencies and brain changes of FAS, and most, but not all, of the facial anomalies. Specifically, they have short palpebral fissures and two out of three of the lower facial features, or all of the lower facial features and palpebral fissures that are more than one but less than two standard deviations from the mean. (In the past, we referred to this patient group as "possible FAS" or "partial FAS". Both of those terms proved problematic for patients, as we found that service providers interpreted "possible" FAS to mean an uncertain diagnosis and "partial" FAS to mean a milder form of the disorder.)

"Possible fetal alcohol effects" or "alcohol-related neurodevelopmental disorder." These terms both refer to a needed category(ies) for classifying patients exposed to alcohol in utero, but the terms themselves are less than ideal. The category broadly includes patients with some of the physical, cognitive, and/or behavioral problems that are among the problems seen in patients with FAS and an alcohol exposure history that would support high risk for alcohol teratogenesis. "Fetal alcohol effect" (FAE) was a term that was developed for research studies in humans or in animals when a teratogenic result (that was not full FAS) was clearly associated with alcohol exposure (Clarren & Smith, 1978). This term was needed because alcohol does have broad teratogenic impacts, especially on the brain, that are not necessarily related to obvious physical anomalies. The term "possible FAE" was proposed for clinical work as an entry on the differential diagnosis because the findings in these patients were generally nonspecific for alcohol teratogenesis and alcohol exposure could not be seen with certainty as the only cause. Although the term has been widely used by the public, it has been troubling or confusing to professionals who felt the term was used as a final diagnosis, rather than as a possible diagnosis, and that it overstated the established relationship between cause and effect (Aase, Jones, & Clarren, 1995). Further, what "effect" was being described? The term "alcohol-related birth defects" was proposed as an alternative (Sokol & Clarren, 1989). This term was not widely used because it did not seem to be appropriate to describe patients with functional brain dysfunction of probable organic origin as having a birth defect. Even more recently, the term "alcohol related neurodevelopmental disorder" has been suggested for this category name (Stratton, Howe, & Battaglia, 1996). The term is better in emphasizing the neurodevelopmental nature of the "effect," but this new term, in the end, continues to be problematic in its inherent link of etiology and outcome in the same phrase when the relationship between alcohol exposure and the likelihood of organic brain damage are each on a continuum from minimal to extreme, and the relationship between the two ranges from clinically very likely to clinically very unlikely. Better terminology is still needed and we are actively working on this problem at this time.

Financial Support

Much of the evaluation for FAS and related conditions, and most of the recommendations, are not medical, but rather social, educational, or involve mental health, so it is not wholly surprising that the costs are frequently not borne by medical insurers in total. We are finding that there are two ways to address this problem: build the

model within an existing system while avoiding duplication and develop multiple funding sources. Our clinic sites are establishing themselves within existing facilities in their communities such as public health departments, alcohol treatment facilities, and neurodevelopmental programs within a children's hospital. These organizations have pre-existing infrastructures that provide space, support systems, billing mechanisms, and natural linkages to other needed services. The development of various funding streams includes cash and in-kind contributions from private or government grants, fee-for-service contractual relationships for screening and diagnosing clients within a specific system (such as adoption agencies, schools, courts, and corrections), and support from managed care providers who do not wish to fully gear up to provide these diagnostic services themselves. In-kind support includes coverage of salaries for any of the clinic staff who serve the client population as part of their existing job (especially educational psychology, social work, and public health nursing). In-kind support also can include both professional and nonprofessional volunteers.

Results

In the first three years of clinic operation (January 8, 1993 to December 31, 1995), 1,839 requests were received for appointments to the FAS Diagnostic Clinic at the Center for Human Development and Disability. Of these, 816 families completed and returned the "New Patient Information Form," and 511 patients were evaluated. Among the 511 patients evaluated, 103 (20%) met the criteria for FAS (with or without confirmed exposure) or atypical FAS, and another 304 (60%) were placed in the FAE group. Males were more likely to have an FAS or FAE diagnosis. Sixty-six (64%) of FAS patients were male, and 168 (55%) of FAE patients were male (Table 1).

The racial background of the patients (Table 2) generally reflected the racial mix of Washington State, with the exceptions that patients with Native American ancestry were somewhat over-represented, and patients with Asian ancestry were under-represented.

Children with FAS and FAE generally did not live with their birth mothers (Table 2) . Only 15% of FAS patients and 21% of FAE patients lived with their birth mothers. The birth fathers or other family members cared for each group about 20% of the time. Fifty-five percent of the patients were in foster or adoptive care and 10% were living independently or in group homes. Few were incarcerated.

TABLE 1. Patient ages and gender by diagnosis.

Patient Diagnosis:	FAS (n = 103)	PFAE (n = 304)	Other (n = 104)	All (n = 511)
Age (yrs) at visit mean (s.d.) [min—max]	10.4 (7.5) [0.3—46.3]	10.2 (7.1) [0.6—50.9]	9.9 (8.6) [0.2—48.2]	10.2 (7.5) [0.2—50.9]
Gender M:F (% male)	66:37 (64)	168:136 (55)	54:50 (52)	266:223 (56)

TABLE 2. Selected patient characteristics by diagnosis.

Patient Diagnosis:	FAS (n = 103) n (%)	PFAE (n = 304) n (%)	Other (n = 104) n (%)	All (n = 511) n (%)
Race				
Caucasian	58 (56)	145 (48)	54 (52)	257 (50)
Black	9 (9)	29 (10)	10 (10)	48 (9)
Am/Alask Indian	21 (20)	79 (25)	19 (18)	119 (23)
Other	14 (14)	51 (17)	21 (20)	86 (17)
Unknown	1 (1)	0 (0)	0 (0)	1 (1)
Primary caretaker				
Birth mother	16 (15)	62 (21)	22 (21)	100 (20)
Birth father	8 (8)	27 (9)	6 (6)	41 (8)
Other family member	14 (13)	35 (12)	16 (15)	65 (13)
Foster care	28 (27)	99 (32)	28 (28)	155 (30)
Adoptive care	26 (26)	59 (20)	25 (24)	110 (22)
Other	10 (10)	22 (7)	7 (6)	38 (7)
Accompanied child to clinic				
Birth mother	17 (17)	72 (24)	28 (27)	117 (23)
Birth father	9 (9)	23 (8)	6 (6)	38 (7)
Other family member	9 (9)	37 (12)	12 (12)	58 (11)
Foster parent	31 (30)	86 (28)	24 (23)	141 (28)
Adoptive parent	26 (25)	59 (19)	24 (23)	109 (22)
Other	11 (10)	27 (9)	9 (9)	48 (9)

Approximately 90% of the patients paid for the assessment through Medicaid funding.

Although all of the patients had been assessed by at least one physician and many had seen numerous physicians and other professionals, the diagnosis of FAS had only been suggested in 4 of the 103 patients who met diagnostic criteria. Another 10 patients had been previously diagnosed as FAS but did not meet our diagnostic criteria.

Relatively few patients with FAS had medical problems that required follow-up. Nearly all needed coordinated services involving psychiatry (drug therapy for ADHD and/or mood), educa-

tional/vocational planning, behavioral therapy, family counseling and guidance, and drug and alcohol abuse counseling for older patients.

Discussion

Why is there a need for clinics uniquely devoted to patients with Fetal Alcohol Syndrome and related conditions? In part, the answer seems pragmatic. Our experience would suggest that the patients and their families do not seem to believe that their needs are met elsewhere. In part, the answer lies in the fact that the term "Fetal Alcohol Syndrome" actually identifies two patients. The "fetal alcohol" part of the term is relevant to etiology and is important in recognizing that the birth mother is a patient who is highly vulnerable to produce more affected children and to be judged as a poor caretaker of her current children. The diagnosis should direct us to her so that we can support her in her attempts at sobriety for her sake, and for the sake of her children and her unborn children. The "syndrome" part of the FAS term is relevant to the child who is likely to have complex cognitive and behavioral problems requiring the help of an appropriate team made up largely of educational and mental health professionals. Accurate diagnosis and treatment planning not only is needed for primary prevention and secondary disability prevention, but also is needed for epidemiological studies. Without accurate diagnosis and prevalence figures, the success of prevention programs cannot be gauged nor can appropriate budgets for intervention be calculated.

Our clinic model offers a comprehensive approach to the needs of both mothers and children. The clinic sites will be located conveniently throughout the state. Diagnosis will be consistent and defensible. Treatment planning will be comprehensive. In time, we can determine what services are available, or not available, available but not affordable, and effective or not effective. Clinics will aggressively, but sympathetically, reach out to birth mothers and help to identify factors that need to be addressed so that reductions in recurrent cases of FAS and FAE will occur. Finally, the clinics will be an important tool for surveillance programs.

If FAS screening is to be done, individuals who screen positive need to be evaluated for an accurate diagnosis and an appropriate treatment plan. Social groups and agencies in our state, including juvenile rehabilitation, foster care, and several Native American communities, already have approached the Network and asked to become clients of the system. Photographic screening of facial shape

(Stratton, Howe, & Battaglia, 1996) should be used to select the appropriate patients for clinical assessment.

The development of the FAS Diagnostic and Prevention Network is just underway. At this time, two of the FAS Diagnostic and Prevention Network sites are open and meeting once every other month, and four additional sites are in the training phase. The groups are all enthusiastic and committed. We are very optimistic that the program will be well-received within communities and will offer a much needed service.

Although the Washington State Legislature has only funded us to develop sites within Washington, the system could easily be expanded to a regional or national schema. This should be considered within a year or so, based on the success of the state-wide model.

Cryptosporidiosis — Continued

To better understand the magnitude of cryptosporidiosis, health-care providers should specifically request testing for suspected cryptosporidiosis. Laboratories should consider routinely testing for *Cryptosporidium* as part of their ova and parasite examination protocol. Alternatively, when reporting test results back to health-care providers, laboratories should specifically indicate when *Cryptosporidium* is not tested for as part of a requested ova and parasite examination. Cryptosporidiosis is reportable in 41 states; interpretation of national data would be facilitated by mandatory reporting in all states.

Child Health Month — October 1998

The American Academy of Pediatrics (AAP) has designated October as Child Health Month. This year, the AAP is focusing on the prevention of alcohol use and abuse that affects children and youth. Specific priorities include fetal alcohol syndrome (FAS), underage drinking, children of alcoholics, drinking and driving, and binge drinking.

Alcohol use during pregnancy has been cited as the most common known nongenetic cause of mental retardation among children and youth (*1*). Approximately 700 children aged 0–15 years die each year in alcohol-involved motor vehicle crashes; many of these children were being transported by a drunk driver (*2*). Approximately 80% of high school students have had at least one drink of alcohol, and one third have had five or more drinks on one or more occasions in any given month (*3*). During October, CDC, in collaboration with AAP and other organizations, will highlight the consequences of alcohol use as it relates to children and youth.

Additional information about Child Health Month is available from AAP, telephone (847) 981-7871, or the World-Wide Web, http://www.aap.org; and from the Health Resources and Services Administration, Maternal and Child Health Bureau, World-Wide Web, http://www.hhs.gov/hrsa/mchb. Information about FAS and other alcohol-related birth defects and developmental disabilities is available from CDC's Fetal Alcohol Syndrome Prevention Section, telephone (770) 488-7268, or the World-Wide Web, http://www.cdc.gov/nceh/programs/programs.htm. Information on the role of alcohol in traffic deaths among children and youth is available from CDC's National Center for Injury Prevention and Control, Division of Unintentional Injury Prevention, telephone (770) 488-4652, World-Wide Web, http://www.cdc.gov/ncipc/cmprfact.htm. Information on alcohol-related behaviors among youth is available from CDC's Division of Adolescent and School Health, telephone (770) 488-3168, World-Wide Web, http://www.cdc.gov/nccdphp/dash.

Identification of Children with Fetal Alcohol Syndrome and Opportunity for Referral of their Mothers for Primary Prevention — Washington, 1993–1997

Heavy maternal use of alcohol during pregnancy can cause permanent birth defects, including fetal alcohol syndrome (FAS). Although these alcohol-related defects are entirely preventable, the factors associated with maternal use of alcohol during pregnancy are complex and often resistant to change. In addition, not all women who drink heavily will produce children with FAS (*1*). Although targeting primary prevention efforts to all women at risk for drinking during pregnancy is ideal, limited resources require targeting women at the highest risk for producing children affected by prenatal alcohol exposure. One such population is women who have already given birth to an alcohol-affected child (*2*). This high-risk population is not easily identified because not all children with FAS have their condition diagnosed, and these birth mothers are often separated from their children during the first few years of the child's life, often before a diagnosis of FAS has been considered. However, once identified, these women are receptive to intervention (*3*). To identify a population of women at highest risk for a future alcohol-exposed pregnancy through diagnosing a previously affected birth child, researchers at the University of Washington developed the Fetal Alcohol Syndrome Diagnostic and Prevention Network (FAS DPN). This report summarizes the results of this program and documents the feasibility of identifying persons who may have FAS so their condition can be diagnosed and their birth mothers can be identified and referred to prevention services.

FAS DPN opened its first clinical site at the Center for Human Development and Disability (University of Washington Medical Center, Seattle, Washington) in January 1993. Persons suspected of having FAS were identified through referral by various community sources and by directed screening of high-risk populations (*4*) (Table 1). Patients were then evaluated and their condition diagnosed in a multidisciplinary clinical setting (*5*), and birth mothers who were still at risk for producing additional affected children were identified, enabling referral to community alcohol treatment, family planning, and maternal advocacy programs (*6*).

During 1993–1997, there were 3002 requests for appointments for diagnostic evaluations at FAS DPN. To determine the appropriateness of referrals, parents and other caregivers were given a questionnaire (*7*) asking about the child's developmental and exposure history; 1374 completed the questionnaire. Persons referred for evaluation

Fetal Alcohol Syndrome — Continued

ranged from birth to middle age; the racial distribution was comparable to the general population in Washington, with a slight overrepresentation of American Indians. Approximately 20% lived with their birth mothers, 20% with other biological family members, and more than 50% with foster or adoptive parents. Although all patients had been seen in the health-care system before referral, only 56 of the 1374 caregivers completing the questionnaire reported that a diagnosis of FAS or related conditions had ever been considered and/or previously recorded in the medical or mental health records of the patient. Most diagnostic requests arose from concerns relating to issues of education and social skills (Table 2).

Because of limited capacity at the FAS DPN clinic, priority for diagnostic evaluation was based on responses to questions regarding in utero alcohol exposure and evidence of organic brain damage (based on previous medical and psychologic test results). Of the 1374 patients whose caregivers responded to the questionnaire, 811 were selected to receive diagnostic evaluations. Patients ranged in age from 0–51 years (mean: 10 years). Of these, 573 (71%) were found to have either documentation of in utero alcohol exposure or signs of organic brain damage; the remaining 238 had both. A total of 39 met the clinical criteria for an FAS diagnosis*, which includes elements of the FAS facial phenotype and growth deficiency in addition to in utero

*The FAS DPN uses a 4-Digit Diagnostic Code (*7*) that is consistent with the Institute of Medicine guidelines (*8*), but is a more detailed case definition.

TABLE 2. Number and percentage of reasons for referral to a fetal alcohol syndome (FAS) diagnostic and prevention clinic* — Washington, 1993–1997

Reason	No.	(%)
Problem with adaptation		
Conduct disorders, extreme anger	579	(45.8)
Poor judgement, cannot function independently	241	(19.1)
Poor self control, disorganized, unpredictable	238	(18.8)
Poor social skills	147	(11.6)
Poor parenting skills by patient	9	(0.7)
Problem with learning in school		
Learning disabilities, cognitive delays	400	(31.7)
Poor memory, does not learn from experience	117	(9.3)
Speech and language problems	99	(7.8)
Short attention span	360	(28.5)
Mental health concerns		
Depression, low self esteem	91	(7.2)
Medical concerns		
Face suggests a syndrome	138	(10.9)
Poor growth	40	(3.2)
Minor neurologic concerns	80	(6.3)
Physical or health concerns	122	(9.7)
Concerns about exposure		
Knowledge of alcohol exposure in utero	164	(13.0)
Ongoing drug/alcohol abuse by patient	31	(2.5)
Other		
Relation of possible FAS to a legal matter	32	(2.5)
Relation of possible FAS to placement	24	(1.9)
Patient with possible FAS is pregnant	1	(0.1)

Fetal Alcohol Syndrome — Continued

alcohol exposure and organic brain damage. Only one of these 39 had FAS previously diagnosed.

The mothers of the 238 persons with both in utero alcohol exposure and signs of organic brain damage constitute a high-risk population for intervention to prevent subsequent affected offspring. Most (88%) of these women were aged ≤45 years (i.e., reproductive aged). Although only 51 (21%) birth mothers were living with the affected persons at the time of the diagnostic evaluation, the questionnaire provided sufficient information (i.e., name and location) for FAS DPN to identify 219 (92%) birth mothers.

Reported by: SK Clarren, MD, Dept of Pediatrics, School of Medicine, SJ Astley, PhD, Dept of Epidemiology, School of Public Health and Community Medicine, Univ of Washington, Seattle, Washington. Fetal Alcohol Syndrome Prevention Section, Developmental Disabilities Br, Div of Birth Defects and Developmental Disabilities, National Center for Environmental Health, CDC.

Editorial Note: This report documents one program's efforts to identify a population likely to have undiagnosed effects of in utero alcohol exposure. The birth mothers of these persons are a high-risk target population for primary prevention, although neither the mothers nor their health-care providers may realize their potential for producing subsequent affected children. The University of Washington is implementing a primary prevention intervention for these women that will rely on identification through early diagnosis of FAS in their children. For most patients in this study, an alcohol-related diagnosis had never been considered in any other medical or mental health setting, and only 22% were referred by a health-care care provider for further diagnostic services. This may be because the syndrome manifests itself in ways that may not be recognized in the traditional medical setting (*9*). As a result, multidisciplinary diagnostic clinics staffed by a physician, psychologist, language pathologist, occupational therapist, and social worker may facilitate the proper diagnosis of conditions in patients who have not been appropriately identified in other clinical settings.

The effectiveness of this approach relies on primary health-care providers being aware of the importance of diagnostic referral and on the availability of diagnostic resources. In 1993, the American Academy of Pediatrics (AAP) recommended increased awareness among pediatricians and health-care providers of FAS and other alcohol-related effects and the evaluation of children thought to have such conditions by a pediatrician skilled in the evaluation of neurodevelopmental and psychosocial problems (*10*). This report documents the need for continued efforts to implement these AAP recommendations, including forging stronger communication among parents and health-care providers about prenatal alcohol effects and providing or arranging access to skilled diagnostic assessment. This approach will increase the potential for primary prevention in avoiding subsequent exposures and will be a major protective factor in preventing secondary conditions among affected children (*9*).

ABSTRACT One component of the fetal alcohol syndrome (FAS) facial phenotype is a frontonasal anomaly characterized by a thin upper lip and a smooth philtrum. The expression of this anomaly can diminish with age and occurs infrequently in prenatal alcohol-exposed individuals. This study sought to explain these observations. Standardized craniofacial cephalograms of 18 nonhuman primates exposed weekly to ethanol or sucrose solution in utero were measured at ages 1, 6, 12, and 24 months to assess skeletal changes in craniofacial form with age, cognition, and timing of ethanol exposure. The data suggest that there may be a critical period for induction of alcohol-induced craniofacial alterations that occurs very early in gestation and is very short in duration (gestational days 19 or 20). The alterations were scarcely detectable at age 1 month, were most prominent at 6 months, and diminished progressively at 12 and 24 months in the macaque. The appearance and disappearance of the thin upper lip and smooth philtrum may be explained by underlying changes in skeletal structure with age. The infrequent occurrence of the FAS frontonasal anomaly may be explained, in part, by its short critical period of induction. *Teratology 59:163–172, 1999.* © 1999 Wiley-Liss, Inc.

Fetal alcohol syndrome (FAS) is a permanent birth defect caused by maternal consumption of alcohol during pregnancy (Jones et al., '73, '74; Clarren and Smith, '78). Central nervous system dysfunction, growth deficiency, and a unique cluster of minor facial anomalies characterize FAS. Although FAS is a lifelong disability, the physical features are not always expressed throughout life.

The FAS facial phenotype is typified by small palpebral fissures and a complex lower frontonasal anomaly described by a thin upper lip and a smooth philtrum (Jones et al., '73; Astley and Clarren, '96). The philtrum is the area between the vermilion border of upper lip and subnasion. These frontonasal features are often, but not always, minimally expressed at birth, maximally expressed in childhood, and diminish again in adulthood. Although this variable presentation with age is documented anecdotally in the literature (Spohr et al., '87, '93; Streissguth et al., '91), there are no estimates as to how often these features change with age and there is little understanding of the morphological basis for this variation. The lip and philtrum are soft-tissue structures. One could speculate that the soft-tissue changes are secondary to changes in the underlying bony structures. Much like a smile can stretch a deeply grooved philtrum and thick upper lip into a smooth philtrum and thin upper lip (Fig. 1), so might underlying pressure from early overgrowth of the premaxilla.

Although the facial features are a key diagnostic component of the syndrome, they are minor anomalies, which are usually of little medical consequence to the individual. Of greater significance is the fact that the facial anomalies are midline anomalies derived from the anterior frontal neural crest primordia of the early forebrain. It has long been speculated that some midline facial anomalies are pathognomonic of brain malformation (i.e., the face predicts the brain) (DeMeyer, '75). This speculation is supported by the presence of a proportional increase in midventral forebrain deficiencies and the severity of facial dysmorphia in mice exposed to ethanol early in gestation (Sulik, '84). Earlier work by Sulik and Johnston ('82) also provided compelling evidence that the critical period for the induction of FAS-like craniofacial malformations occurs very early in gestation (gestational day 7 in the mouse, the primitive streak stage in embryogenesis) and is very short in duration (no more than a few hours in the

Fig. 1. Same individual with (**top**) and without (**bottom**) a smile, demonstrating how a smile can transform a deeply grooved philtrum (Likert rank = 2) (Astley and Clarren, '96) and full upper lip (Likert rank = 1, lip circularity [perimeter^2/area] = 40.9) (Astley and Clarren, '96) into a smooth philtrum (Likert rank = 4) and thin upper lip (Likert rank 5, lip circularity [perimeter^2/area] = 191.0).

mouse). Sulik and Johnston ('82) speculated that severe cases of FAS represent the mild end of the holoprosencephaly spectrum. Indeed, the only known nonhuman primate with holoprosencephaly was born after alcohol exposure in this project (Siebert et al., '91).

As form follows function, one could speculate that midline facial anomalies might also serve as markers for cognitive dysfunction. Although there is evidence to suggest that the magnitude of expression of the FAS facial phenotype is correlated with the severity of cognitive dysfunction (Jones et al., '73; Streissguth et al., '78; Streissguth and Dehaene, '93; Majewski, '81), these observations may be biased because the diagnostic criteria for FAS require the presence of both facial features and central nervous system (CNS) dysfunction.

An opportunity to assess variation in craniofacial form with timing of prenatal ethanol exposure, age, and cognitive dysfunction became available with the collection of standardized serial cephalometric radiographs of nonhuman primates (*Macaca nemestrina*) exposed to ethanol during gestation in a previous study (Clarren and Astley, '92; Clarren et al., '92). The primate model provides accurate documentation of timing and level of ethanol exposure, a controlled postnatal rearing environment, and a comprehensive battery of cognitive assessments, conditions which cannot be replicated in a human population (Clarren et al., '87, '88, '92; Clarren and Astley, '92; Astley et al., '95; Sirianni and Swindler, '85).

The present investigation was undertaken to address the following questions: 1) Does weekly prenatal ethanol exposure (1.8 g/kg maternal weight) result in detectable craniofacial malformations in *Macaca nemestrina* offspring? If malformations are detectable: 2) Is the primitive streak stage of embryogenesis a critical period of induction? 3) Does the magnitude of expression of alcohol-related craniofacial malformations change with age? 4) Is cognitive impairment correlated with the magnitude of craniofacial malformation?

MATERIALS AND METHODS

Subjects

A standardized series of cephalometric radiographs were collected at age 1, 6, 12, and 24 months on 18 nonhuman primates (*Macaca nemestrina*) who had been exposed to ethanol or a control solution of sucrose weekly during gestation (Clarren and Astley, '92) (Table 1).

Ethanol exposure

Details of timed-mating procedures, dosing schedules, and management of pregnancies were presented previously (Clarren and Astley, '92). Briefly, the animals were distributed across four exposure groups: 1) offspring exposed weekly to ethanol in the first 3 weeks of gestation, 2) offspring exposed weekly to ethanol in the first 6 weeks of gestation, 3) offspring exposed weekly to ethanol throughout the 24 weeks of gestation, and 4) a control group exposed weekly to sucrose solution, isocaloric and isovolemic to the ethanol dose, throughout gestation. To control for handling, dams in the 3- and 6-week ethanol groups received the sucrose solution weekly in all subsequent weeks of gestation.

Solutions were delivered to the dams via soft nasogastric tubes. All ethanol-exposed dams received ethanol at 1.8 g/kg maternal body weight, which resulted in mean peak plasma ethanol concentrations of 223 $\pm$ 28 mg/dl. These weekly dosing schedules were established to mimic the most common pattern of female drinking, i.e., weekend social drinking which often stops upon confirmation of pregnancy.

Cephalograms

Standardized lateral and frontal cephalograms of each offspring were obtained with the sedated animal seated in a cephalostat designed for nonhuman primate cephalometry (Sirianni and Swindler, '85). Kodak X-Omat TL industrial, high-resolution film was used. The X-ray beam was centered along the Frankfort horizontal plane for both the lateral and frontal cephalograms with a tube-film distance of 49 cm and a subject-film distance of 14 cm. Cephalograms were taken at age 1, 6, 12, and 24 months. This age distribution is approximately equivalent to age 4 months, 2 years, 4–6 years, and 8–10 years in the human.

Each frontal and lateral cephalogram was captured at 640 $\times$ 480 pixel resolution on a 256-unit gray scale using Optimas image acquisition and enhancement computer software (Optimas Corp., Edmonds, WA). The software was used to mark and derive the X, Y Cartesian coordinates of 19 standardized skeletal landmarks (Fig. 2). Basion could not be reliably identified in the cephalograms at age 1 month. A cleared skull with lead-marked landmarks was radiographed to serve as a guide for landmark identification. The X, Y coordinates

of the landmarks were used to calculate 17 linear and 3 angular measurements (Table 2). These measures were selected to best capture the craniofacial form associated with FAS. Head circumference (OFC) and body weight were measured at the time of each X-ray. Brain weight and volume were recorded at the time of sacrifice (age 4.0–5.3 years).

Cognitive assessments

Motor, cognitive, behavioral, and physical development was documented from birth through age 14 months. The comprehensive assessment battery was developed and has been administered at the Infant Primate Research Laboratory for over 20 years. The content and timing of the assessments are described in detail in previous reports (Clarren et al., '88, '92). An unweighted composite score reflecting each animal's developmental impairment was derived by dividing the number of assessments an animal failed by the number of assessments used to summarize each animal's development in Figure 1 as presented in Clarren et al. ('92). Failure for each assessment was defined as performance >2 SDs below the mean performance of the control animals.

Analysis

Repeated-measures analysis of covariance, with adjustment for gender, was used to compare mean distance and angular craniofacial measures between the ethanol-exposed and unexposed groups at age 1, 6, 12, and 24 months. To evaluate the impact of timing of exposure on outcome, the analysis was repeated three times with the animals' exposure status classified in three different ways: 1) in their original four groups based on *duration* of exposure (0, 3, 6, or 24 weeks), 2) in two groups based on *exposed / not exposed* (the 3-, 6-, and 24-week groups were combined and compared to the control group), and 3) in two groups based on *exposed or not exposed on gestational days 19 or 20*. The rationale for these three different exposure classifications is as follows. Facial development is essentially complete by the seventh week of gestation in the macaque, with a potential critical period of vulnerability occurring as early as week 3 (Sulik and Johnston, '83). Since all ethanol-exposed animals started their weekly exposures within the first 13 days of gestation, we hypothesized that classifying the animals by duration of exposure would be least sensitive for identifying craniofacial contrasts, classifying them based on exposed/not exposed would be more sensitive, and that classifying them based on who received ethanol exposure specifically on gestational days 19 or 20 would be the most sensitive. Gestational days 19 and 20 in the macaque correspond with the critical period of induction for FAS facial malformations (gestational day 7 or the primitive streak stage) observed in the mouse (Sulik and Johnston, '83).

Multiple linear regression analyses with adjustment for gender were conducted to detect correlations between craniofacial measures and the overall cognitive impairment score. These analyses were repeated at each of the four ages (1, 6, 12, and 24 months).

It is important to note that the original primate study from which these data were derived was not designed to address the specific questions presented in this study. Due to the small number of animals in each exposure group, only large contrasts between groups were statistically detectable. In general, when a study's power to detect a clinically meaningful contrast drops below 80%, the study is at risk for falsely declaring an absence

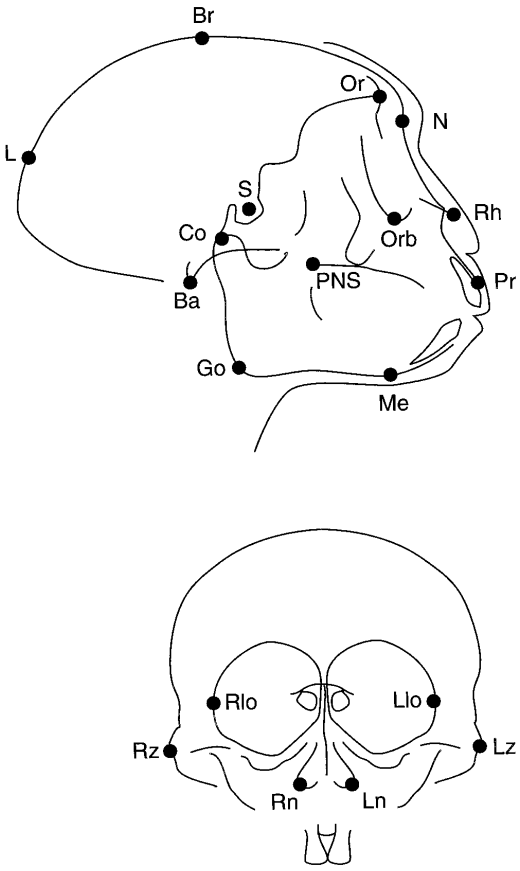

Fig. 2. Landmarks on lateral radiographs. L, lambda, most superior point on the lambdoid suture; Br, bregma, point at junction of coronal and sagittal sutures; S, sella, center of pituitary fossa of the sphenoid bone; Go, gonion, midpoint of angle of mandible; PNS, posterior nasal spine, most posterior point at the sagittal plane on the bony hard palate; Co, condylion, most posterior, superior point on curvature on average of right and left outlines of condylar heads; Ba, basion, most inferior, posterior point on anterior margin of foramen magnum; Or, junction of orbital roof and inner table of the frontal bone; Orb, orbitale, lowest point on average of right and left borders on the bony orbit; Me, menton, most inferior point on the symphyseal outline; N, nasion, junction of frontonasal suture at the deepest point on curve at bridge of nose; Rh, rhinion, most superior, inferior point of nasal bone; Pr, prosthion, most anteroinferior point on upper alveolar margin. of contrast between groups. When between-group contrasts observed in this study failed to achieve statistical significance, these outcomes were accompanied by estimates of the minimum effect sizes that could have been detected at 80% power (Bornstein et al., '97).

Measurement precision

Landmark identification was repeated, 2 weeks apart, on 10 randomly selected cephalograms. The measurements for each set of radiographs were compared and revealed a high degree of precision. The method error was determined by the equation of Dahlberg ('40), where the sum of the squared differences is divided by two times the number of measurements and the square root is calculated. The method error was 0.27 mm for linear and 1° for angular measurements. Error calculated as a percentage of the measurements examined was less than 2%.

RESULTS

Effect of ethanol exposure and age on craniofacial form

When the cephalometric measurements were compared between the 0-week (n = 6), 3-week (n = 5), 6-week (n = 5), and 24-week (n = 2) ethanol exposure groups to test whether craniofacial form and brain size varied as the duration of exposure increased, only one statistically significant trend was detected. At age 6 months, mean cranial length (L-Or) increased linearly from 71.4 mm to 73.9 mm to 75.1 mm to 76.7 mm as duration of exposure increased from 0 to 3 to 6 to 24 weeks, respectively ($P = 0.03$). It is worth noting that the same pattern and relative magnitude of change in cranial length were also observed at ages 1, 12, and 24 months. Increased variability in cranial length dropped the power of detection to less than 35%, which may explain why these trends failed to achieve statistical significance. Mean head circumference was comparable (maximum contrast 5%) between all four groups across

all ages. Mean brain weight and volume were comparable (maximum contrast 10%) between all four groups at sacrifice. This series of analyses had 80% power to detect a ≥2 mm (or 5%) and a ≥2° (or 10%) incremental change in linear and angular craniofacial measures, a ≥9 mm (or 4%) incremental change in OFC, and an ≥8 g or cc (or 10%) incremental change in brain weight or volume.

When the analyses were repeated with the animals reclassified as exposed (n = 12) and not exposed (n = 6) to ethanol, again, only a few contrasts in craniofacial form were detected. All linear measures at each of the four ages were consistently greater in the ethanol-exposed animals relative to the unexposed animals. On average, the 20 linear measures were 3.5 ± 4.9% greater at age 1 month, 4.5 ± 3.1% greater at age 6 months, 2.2 ± 2.3% greater at age 12 months, and 2.5 ± 2.6% greater at age 24 months in the ethanol-exposed animals relative to the nonexposed animals. There was no consistent pattern or direction of change in the three angular measures across the four ages. The only contrasts which achieved statistical significance included an increased orbital distance (Rlo-Llo) by 1.7 mm (or 4%) at ages 6 and 24 months ($P = 0.01$), and an increased cranial length (L-Or) by 3.5 mm (or 5%) at age 6 months ($P = 0.04$) in the ethanol exposed animals relative to the unexposed animals. Mean head circumference was comparable (2–4% difference) between the exposed and unexposed groups across all ages. Mean brain weight and volume were comparable (3% difference) across the two groups at sacrifice. These analyses had an estimated 80% power to detect a ≥3 mm or degree (or 5–10%) difference between the craniofacial measures, a ≥15 mm (or 6%) difference in OFC, and a ≥15 g or cc (or 20%) difference in brain weight or volume between the two exposure groups.

When the analyses were repeated one more time with the animals reclassified as exposed (n = 4) or not exposed (n = 14) to ethanol on gestational days 19 or 20 (the period comparable to gestational day 7 in the mouse found to be important by Sulik and Johnston, '82), substantially more contrasts were identified (Table 3, Fig. 3). On average, the 20 linear measures were 2.8 ± 3.8% greater at age 1 month, 4.8 ± 5.1% greater at age 6 months, 3.2 ± 3.7% greater at age 12 months, and 5.4 ± 1.9% greater at age 24 months in the animals exposed on days 19 or 20 relative to those not exposed on days 19 or 20. On average, the three angular measures were 0.1 ± 2.6% smaller at age 1 month, 4.6 ± 3.0% smaller at age 6 months, 1.1 ± 1.3% smaller at age 12 months, and 0.3 ± 1.4% smaller at age 24 months in the animals exposed on days 19 or 20 relative to those not exposed on days 19 or 20. The number of statistically significant contrasts in craniofacial form between the two groups of animals was minimal at age 1 month, increased substantially at age 6 months, and diminished again at age 12 and 24 months. More specifically, at age 1 month, only 3 of the 20 craniofacial measures were significantly different in the animals exposed on days 19 or 20: head length (L-Or) was 3.7 mm (or 5.5%) greater, OFC was 8.0 mm (or 3.7%) greater, and facial depth (S-Pr) was 2 mm (or 5.7%) greater. At age 6 months, 6 of the 20 measures were significantly different in the animals exposed on days 19 or 20. These included head length (L-Or) greater by 4.2 mm (or 5.8%), midface height (N-Pr) greater by 4.5 mm (or 17.6%), two measures of facial depth (S-Rh greater by 4 mm (or 11%), and S-Pr greater by 2.7 mm (or 6.3%), facial angle (Or-Pr-PNS) smaller by 4.7° (or 7.9%), and internasal width (Rn-Ln) greater by 1.5 mm (or 14.9%). At age 12 months, 3 of 20 measures were significantly greater in the animals exposed on days 19 or 20: cranial length (L-Or) by 4.4 mm (or 5.9%), posterior midface height (S-PNS) by 1.8 mm (or 10.6%), and internasal width (Rn-Ln) by 1.1 mm (or 10.3%). At age 24 months, 4 of the 20 measures were significantly different between the animals exposed and not exposed to ethanol on gestational days 19 or 20. These included cranial length (L-Or) greater by 5.8 mm (or 7.8%), OFC greater by 15.3 mm (or 5.9%), interorbital width (Rlo-Llo) greater by 1.4 mm (or 2.8%), and bizygomatic width (Rz-Lz) greater by 3.1 mm (or 7.3%). The mean brain weight in grams was 94.9 ± 6.3 vs. 84.8 ± 8.8 ($f = 3.2$, $P = 0.11$) in the animals exposed and not exposed to ethanol on gestational days 19 or 20, respectively. The mean brain volume in cubic centimeters was 88.0 ± 5.3 vs. 80.1 ± 8.1 ($f = 2.3$, $P = 0.16$) in the animals exposed and not exposed to ethanol on gestational days 19 or 20, respectively. This series of analyses had 80% power to detect a ≥3 mm (or 5%) or ≥3 degree (or 10%) difference between craniofacial measures, a ≥15 mm (or 5%) difference in OFC, and a ≥15 g or cc (or 20%) difference in brain weight or volume between the two exposure groups.

As further evidence that the critical period of induction may be gestational days 19 or 20 in the macaque, two additional exploratory analyses were conducted, comparing all craniofacial measures between animals exposed and not exposed to ethanol just prior to the critical period (gestational days 17 or 18) and comparing animals exposed and not exposed to ethanol just after the critical period (gestational days 21 or 22). No statistically significant contrasts were identified in either analysis.

Correlations between craniofacial form and cognition

The cognitive impairment score increased as craniofacial linear measures increased and craniofacial angular measures decreased (Table 4, Fig. 4). The directions of these correlations were consistent with the alcohol-related changes observed in the animals exposed to ethanol on gestational days 19 or 20. The proportion of craniofacial measures that correlated significantly with cognitive impairment increased with age: 12% at age 1 month, 21% at age 6 months, 37% at age 12 months, and 32% at age 24 months. The magnitude of the correlations also increased with age. At age 12 months, when the greatest number of correlations was observed, cognitive impairment increased significantly with in-

DISCUSSION

This investigation of craniofacial morphology in *Macaca nemestrina* exposed to ethanol in utero revealed significant craniofacial alterations and substantiates previous reports of teratogenesis with weekly 1.8 g/kg gestational ethanol exposure in nonhuman primates (Clarren et al., '88, '92). To achieve the maternal peak plasma ethanol levels recorded for this sample of nonhuman primates, the average woman would need to consume 6–9 beers in the course of a few hours. In brief summary, the results of this study suggest that there may be a critical period for induction of alcohol-induced craniofacial alterations that occurs very early in the macaque's gestation and is very short in duration (gestational days 19 or 20). The ethanol-induced craniofacial alterations were scarcely detectable at age 1 month, were most prominent at age 6 months, and diminished progressively at ages 12 and 24 months.

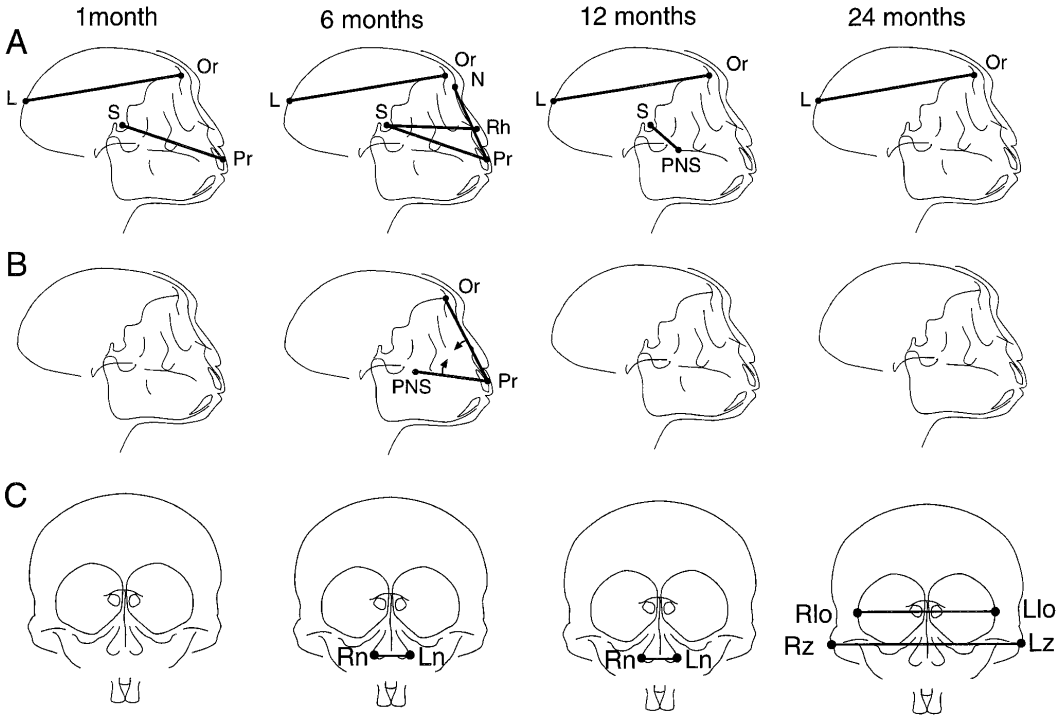

Fig. 3. Overview of craniofacial contrasts at age 1, 6, 12, and 24 months among 4 animals exposed to ethanol on gestational days 19 or 20 relative to 14 animals not exposed on gestational days 19 and 20. **A, C:** Straight lines reflect dimensions that were significantly greater at the $P < 0.05$ level in the 4 animals exposed on gestational days 19 or 20. **B:** The angular measure was significantly smaller in the 4 animals exposed on gestational days 19 or 20. Same abbreviations as in Figure 2.

Finally, the strong correlations observed between alcohol-induced craniofacial alterations and cognitive impairment suggest that midline facial anomalies may be sensitive indicators of brain dysfunction.

Timing of ethanol exposure

As we hypothesized, classifying the animals based on who did or did not receive ethanol exposure on gestational days 19 or 20 resulted in the maximum number of craniofacial contrasts, supporting Sulik ('84), who found that the critical period of induction for FAS-like facial anomalies occurred very early in gestation (gestational day 7 in the mouse, the primitive streak stage) and was very short in duration (just a few hours in the mouse). The findings from these two studies may explain, in part, why only an estimated 1–9% of women who are chronic alcoholics give birth to a child with FAS (Abel and Sokol, '87). A diagnosis of FAS requires the presence of the FAS facial phenotype. If the critical period of induction for the FAS facial phenotype is truly only 1 or 2 days long, even a frequent drinker could fail to expose her fetus on those days.

Sulik and Johnston ('82) also demonstrated that ethanol can induce holoprosencephaly in a mouse model, supporting the speculation that severe cases of FAS represent the mild end of holoprosencephaly. Interestingly, the only documented case of holoprosencephaly in a nonhuman primate occurred in this study, in an animal whose weekly ethanol exposure included exposure on gestational day 19 (Siebert et al., '91).

Craniofacial form and changes with age

The macaques exposed to ethanol on gestational days 19 or 20 had significantly longer midfaces (N-Pr) and protruded premaxillas (S-Rh, S-Pr, and S-PNS). These craniofacial alterations were barely detectable at age 1 month, were most strongly expressed at age 6 months, and progressively diminished at ages 12 and 24 months. These results are not only consistent with observations in the human population (Fig. 1), but may also explain why the soft-tissue anomalies associated with the FAS facial phenotype vary with age. It has long been our belief that the appearance and disappearance of the smooth philtrum and thin upper lip in individuals with

*Corr., Pearson correlation coefficient; R^2, proportion of variance in cognitive impairment score explained by craniofacial measure after adjustment for gender. Reported only when stepwise selection process in the multiple linear regression included craniofacial measure in the model. *P*, *P*-value for craniofacial measure partial correlation coefficient, if craniofacial measure was included in the model. Abbreviations for column 1 are spelled out in Fig 2. Statistically significant outcomes are underlined.

FAS may be secondary to alterations in underlying bony structure with age. Just as a smile can stretch a deeply grooved philtrum and full upper lip into a smooth philtrum and thin upper lip (Fig. 1), protrusion of the premaxilla could have a similar effect. The timing of the onset and regression of the premaxillary protrusion observed in this study closely corresponds with the timing of the appearance and disappearance of smooth philtrums and thin upper lips observed in the human population. It is interesting to note that Martin et al. ('96) identified distinct differences in the structure of the upper lip in a study comparing philtral development in the normal fetus with philtral development in specimens (including a specimen with prenatal alcohol exposure) lacking normal philtral landmarks. These findings, however, do not readily explain why philtrum smoothness varies with age. These contrasts in philtral muscular structure may explain the degree to which philtrums and upper lips are malleable by deformity due to underlying bone growth.

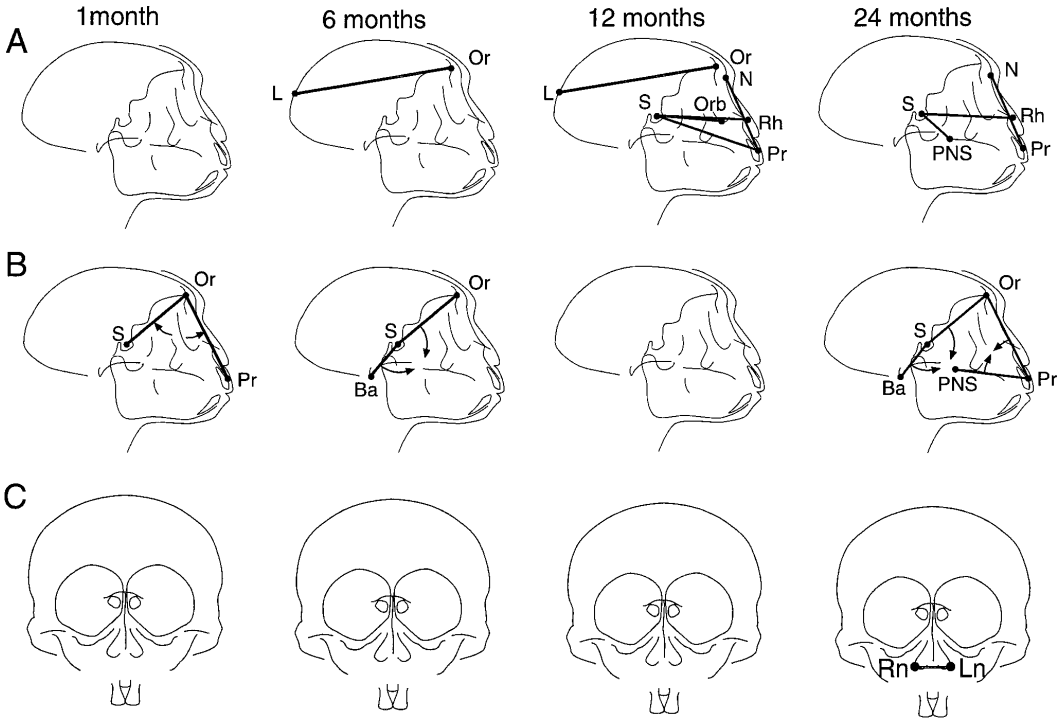

Fig. 4. Overview of craniofacial dimensions which were significantly correlated with cognitive impairment at age 1, 6, 12, and 24 months among all 18 animals ($P < 0.05$). **A, C:** All linear measures increased significantly as cognitive impairment increased. **B:** Angular measures changed in the direction indicated by arrows as cognitive impairment increased. Same abbreviations as in Figure 2.

Cranial size and shape

Interestingly, the OFCs in ethanol-exposed animals were consistently and often significantly larger than in the unexposed animals. This appears to be in contrast to the known relationship between in utero ethanol exposure and decreased brain size (Smith et al., '86; Autti-Ramo et al., '92). Clinically, OFC is used as a proxy measure for brain size, a proxy measure that is valid only if brain shape remains relatively constant. In this study, the increased OFC appears to be influenced more by increased cranial length (L-Or) than by increased brain size. Larger doses of ethanol initiated later in gestation have resulted in microcephaly and scaphocephaly in earlier nonhuman primate studies (Inouye et al., '85; Sheller et al., '88). Inouye et al. ('85) reported a tendency for increased cranial length in two macaques exposed to 2.5 g/kg and 4.1 g/kg ethanol on a weekly basis from 30 days postconception to birth. These findings suggest that ethanol may not only have an influence on the size of the cranium, but on cranial shape as well.

Correlations between midline craniofacial form and cognitive dysfunction

The strong correlations observed between the alcohol-induced craniofacial alterations and cognitive impairment further support the idea that midline craniofacial anomalies may be sensitive indicators of brain dysfunction (DeMeyer, '75). The FAS facial phenotype varies on a continuum and if measured on a continuous scale could serve as a more sensitive indicator of teratogenic outcome than the current practice of recording the FAS facial phenotype as simply present or absent. Preliminary analyses (unpublished) found strong, statistically significant correlations between increasing magnitude of expression of FAS facial phenotype and decreasing intelligence quotient (full-scale, performance, and verbal IQ) among children with prenatal alcohol exposure. The facial phenotype was measured on a continuous scale called the D-score (Astley and Clarren, '96) that reflects the combined magnitude of expression of palpebral fissure length, smooth philtrum, and upper lip thinness.

ABSTRACT

The effects of prenatal exposure to ethanol on the number of callosal axons were examined. Pregnant *Macaca nemestrina* were treated with ethanol (1.8 g/kg b.wt.) 1 day per week during the first 6 weeks (Et6) or full 24 weeks (Et24) of gestation. Control macaques were intubated with an isocaloric amount of sucrose water (Ct). The mid-sagittal area of the corpus callosum in 4- to 5-year-old offspring was examined in magnetic resonance (MR) images and in fixed brains. The number of callosal axons was determined by using electron microscopy. In both MR images and fixed brains of macaques treated with ethanol, the corpus callosum was 26% larger than in the controls. The rostral portion was particularly affected by ethanol; it was 55% larger in Et6- and Et24-treated macaques. Axonal size and myelin thickness were unaffected by ethanol, but ethanol-treated macaques had more callosal axons (13.7×10^7) than did controls (9.4×10^7 axons). The increase in the rostral corpus callosum suggests that parietal and frontal cortices are particularly susceptible to ethanol. The altered callosal connectivity may be a component of the structural abnormalities that underlie executive processing problems associated with fetal alcohol syndrome. J. Comp. Neurol. 412:123–131, 1999.

Indexing terms: alcohol; axonal pruning; callosal axons; fetal alcohol syndrome; microencephaly; prefrontal cortex

One common manifestation of fetal alcohol syndrome (FAS) and models of FAS is microencephaly (e.g., Jones et al., 1973; Randall et al., 1977; Clarren et al., 1978; Miller, 1988a, 1996a). This reduced size is reflected in the numbers of neurons in the neocortex (Miller and Potempa, 1990; Mooney, 1997). For example, the total numbers of neurons in the primary somatosensory cortices of ethanol-treated rats are 33% fewer than those in control rats. A similar reduction is evident in each cortical layer and in the numbers of glia in each layer. A decreased size of brain is not inevitable in alcohol teratogenesis.

Despite generalized reductions in cell number, the brains of ethanol-treated rats are not miniaturized brains. For example, ethanol exposure affects the mix of neurons in each cortical layer. Ethanol-treated brains commonly have ectopic neurons, i.e., neurons with a specific phenotype that are located at inappropriate sites (e.g., Clarren et al., 1978; Miller, 1986a, 1988a, 1993, 1997; Miller et al., 1990). The connectivity of cortical neurons is also affected by ethanol exposure. The scope of dendritic trees (Shapiro et al., 1984; Pentney et al., 1984; Fabregues et al., 1985; Miller et al., 1990), the morphology of dendritic spines

[1]Three principal groups of macaques were examined: those treated with ethanol once per week for 6 weeks or for 24 weeks and controls (treated with sucrose and water once per week). Subjects scanned for magnetic resonance images are noted by asterisks.

(Stoltenburg-Didinger and Spohr, 1983; Miller et al., 1990), the density of cortical efferents (Miller and Al-Rabiai, 1994), and cortical synaptology (Al-Rabiai and Miller, 1989) are altered.

One of the major cortical pathways is the system of interhemispheric connections, i.e., the callosal system. The callosal system is responsible for giving the subject a unified, seamless image of the sensory world. Various reports show that a small number of children with severe FAS exhibit agenesis or dysgenesis of the corpus callosum (e.g., Clarren et al., 1978; Peifer et al., 1979; Pratt and Doshi, 1984; Schaefer et al., 1991; Riley et al., 1995; Swayze et al., 1997; Roebuck et al., 1998). It has been estimated that 6.8% of children with FAS have callosal defects as compared with 0.3% of the general population and 2.3% of those afflicted with developmental disabilities. In one sample, however, as many as 6 of 10 children with FAS exhibited partial or full callosal agenesis (Swayze et al., 1997).

Many data from animal studies support the clinical findings of callosal defects. For example, immature, ethanol-treated rodents have smaller corpora callosa than do controls (Wainwright and Gagnon, 1985; Wainwright and Fritz, 1985; Zimmerberg and Scalzi, 1989). Interestingly, these reductions are absent in mature animals suggesting that the corpus callosum is vulnerable to an ethanol-induced developmental delay. Recent evidence suggest that this delay is followed by an overshoot and that mature rats prenatally exposed to ethanol have more callosal projection neurons than do controls (Miller, 1997). To examine the apparent discrepancy between the human and experimental animal findings, we examined the corpora callosa of non-human primates that were treated with ethanol prenatally.

MATERIALS AND METHODS

Subjects

The subjects were pigtail macaques (*Macaca nemestrina*). These were a subset of the animals used in previous studies (Clarren and Astley, 1992; Clarren et al., 1992; Astley et al., 1995). The macaques that had been exposed for 3 weeks were not included in the present study because only one survived to 4–5 years of age. Brain tissue was obtained from 15 animals and magnetic resonance images were taken from 12 of these macaques (Table 1).

Care and feeding

The primates were clustered into three groups; two groups were exposed to ethanol prenatally and the third group was a control group. Care and handling of the animals was in accordance with institutional guidelines. Details about the care and feeding of the macaques have been described (Clarren and Astley, 1992; Clarren et al., 1992).

The dams of the ethanol-treated groups received a single dose of ethanol (1.8 g/kg b.wt.; Et) once a week for 6 weeks (Et6; i.e., the first quarter of gestation) or for 24 weeks (Et24; i.e., throughout the pregnancy). The Et6-fed animals were fed a sucrose solution (that was isocaloric/isovolumetric to the ethanol dose) once per week for the last 18 weeks of the pregnancy (i.e., from prenatal weeks 7 to 24). The dams of the control-treated macaques were given the sucrose solution (Ct) one day in each week of gestation.

All pregnant macaques were fed chow and water ad libitum. Nonhuman primates were consistently provided their aliquots of the Et or Ct on the same day of the week; for example, on gestational day (G) 3, G10, G17. . . , or on G5, G12, G19. . . In the cadre of nine Et-treated macaques used in the present study, the dosing was initiated on G3, G5, G6, or G7. On the eve of a dosing day (at 5:00 PM), all chow and water was removed. In the morning, the pregnant macaques were weighed and at 8:00 AM the animals were dosed. All pregnant animals were administered with the Et or Ct over a 5-minute period by means of soft nasogastric tubes. Chow and water was reintroduced at 5:00 PM.

Blood ethanol concentrations (BEC) were determined from each mother (Clarren et al., 1992). Samples of blood (1.0 ml) were taken 40–400 minutes post-dosing and BEC was measured with gas chromatography. Based on previous studies (Clarren and Astley, 1992; Clarren et al., 1992), peak BEC was attained 100 minutes after the Et was administered. At this time, the Et6- and Et24-treated macaques had mean BECs of 231 ± 18 mg/dl and 234 ± 14 mg/dl, respectively.

Magnetic resonance imaging

Animals lived in a complex community structure and were routinely subjected to psychometric tests (the outcome of some of these tests have been published elsewhere; Clarren et al., 1992). When the macaques were 3–5 years old, 12 of them (see Table 1) were sedated with an intramuscular injection of ketamine and xylazine (10 mg/kg b.wt.).

The procedures for obtaining the magnetic resonance (MR) images were the same as those described by Astley and colleagues (1995). Briefly, the macaques were placed in a prone position and aligned with the Frankfort horizontal plane perpendicular to the horizontal axis of a General Electric Signa whole body MR Scanner. The heads were placed inside a knee coil to accommodate the small size of a macaque head. A standard cranial series was obtained including T1-weighted images in the mid-sagittal plane (repetition time of 400–500 msec and echo time of 12 msec) were taken. A 16-cm field of view was used with a slice thickness of 3–4 mm. The images were analyzed with a Bioquant Image Analysis System, R & M Biometrics, Nashville, TN) to determine the cross-sectional area of the corpus callosum.

Tissue preparation

At the completion of the original study (Clarren et al., 1992), the 15 surviving macaques (the 12 used in the MR imaging study plus an additional one per treatment group; see Table 1) were euthanized for neuroanatomic evaluation. The macaques were 3.56–5.32 years old. Then, brain samples were prepared for electron microscopy by standard protocols. Briefly, animals were anesthetized with ketamine and xylazine and then killed by a three-stage intracardial perfusion. Each macaque was perfused with 200–300 ml of 0.10 M phosphate buffer (pH 7.4) in saline (PBS), 2–3 liter of 4.0% paraformaldehyde in 0.10 M phosphate buffer, and finally with 1 liter of 10% sucrose in PBS. The brain was removed from the cranium and stored in buffered 30% sucrose.

The brainstem and cerebellum were removed and the forebrain was hemisected. The wet weight of each whole brain was measured. The medial surface of the brain was imaged with the Bioquant System and the cross-sectional area of the corpus callosum was determined.

Electron microscopy

Samples from three sites in the corpus callosum (from the right hemisphere) were removed: the genu, body, and splenium. These areas interconnect the prefrontal cortex, primary and secondary somatosensory cortices, and primary and secondary visual cortices, respectively (LaMantia and Rakic, 1990a). Each block measured 1 mm high by 2 mm wide by 1 mm deep. The blocks were dehydrated, osmicated, and embedded in plastic. A series of ultrathin sections was taken from each block. Every eighth to tenth section was used in the analysis. These sections were cut in a sagittal plane to generate cross-sections of the corpus callosum.

A micrograph was taken of 5 non-overlapping fields (15μm × 15μm) in each of five representative sections per animal. Thus, a total of 25 micrographs was made for each callosal site for each animal. Three measures describing the composition of the corpus callosum in each field were taken by using the Bioquant System. (1) The size of each axon in the field was measured. This constituted the area within the outer aspect of the axolemma. (2) The thickness of the myelin was determined. Three independent measures from each myelin profile were examined and the mean was taken as the value for that axon. Each measurement was made at a site where the laminations were regular and parallel. (3) The number of axons included in each field was counted. Only axonal profiles that were fully within the defined area or intersected two of four sides of the measuring box (10μm x 10μm) were included in the tallies.

Analysis

In all phases of the study, the investigators were blind to the source of the sample. The mean values for the five non-overlapping fields per section were calculated. In turn, the mean (± the standard error of the mean) for the five sections from each callosal segment (i.e., the genu, body, and splenium) was determined. The latter mean was considered representative of the callosal segment that was used in the statistical analyses. Analyses of variance were used to assess differences among locations within the corpus callosum by prenatal treatment group. In cases where significant differences were detected, post-hoc Student-Newman-Keuls tests were performed.

TABLE 2. Effect of the Duration of Ethanol Exposure on Body and Brain Weight[1]

Parameter	Ct (n = 6)	Et6 (n = 5)	Et24 (n = 4)
Age (yr)	4.80 ± 0.18	4.95 ± 0.09	4.31 ± 0.32
Body weight (kg)	5.3 ± 0.8	6.9 ± 0.5	5.2 ± 0.6
Brain weight (g)	85.2 ± 8.7	88.3 ± 4.0	87.6 ± 4.8

[1]The age, body weight, and brain weight at sacrifice are given for macaques in the five treatment groups. The offspring of macaques were fed a sucrose control (Ct), fed ethanol once per week for 6 weeks (Et6), or fed ethanol once a week for 24 weeks (Et24). Each value is a mean (± the standard error of the mean).

RESULTS

Body and brain size

Data on the age, body weight, and brain weight of the macaques at sacrifice are provided in Table 2. Mean body weight was significantly ($P < 0.05$) greater in the Et6-treated animals than in the Ct- and Et24-treated macaques. The brain weight was unaffected by the prenatal exposure to ethanol.

Size of the corpus callosum

Magnetic resonance images of the living brain. The corpus callosum was measured in mid-sagittal MR images of 12 macaques (Fig. 1; Table 1). The mid-sagittal area of the corpus callosum was significantly ($F_{2,11} = 6.78$; $P < 0.019$) larger in the animals prenatally exposed to ethanol (Table 3). Student-Newman-Keuls tests show that the corpora callosa of both Et6- and Et24-treated macaques were significantly ($P < 0.05$) larger than those of the Ct-treated macaques. Differences between the two Et-treated groups were not statistically significant.

Planimetry of the corpus callosum in fixed brains. The corpus callosum was measured on the medial surface of each hemisphere of the 15 fixed brains (Fig. 2). No significant differences between the sizes of the sectioned corpora callosa in each hemisphere (i.e., in comparisons between the right and left sides from the same brain) were detected in any treatment group (Table 3). Although this was expected, the small differences (less than 2.0%) indicate that experimental error was inconsequential. The data from the two hemispheres were pooled and grand means (designated as "total" in Table 3) were generated based on animal units. An analysis of variance of these pooled data showed that the corpus callosum was larger in the Et6- (23.6%) and Et24-treated (22.3%) primates than in the controls ($F_{2,14} = 5.25$; $P < 0.023$).

The ethanol-induced increase was not even throughout the rostrocaudal extent of the corpus callosum. The corpus callosum was divided into two portions; the border between the two portions was at the level of the rostral thalamus where the body of the corpus callosum and the body of the fornix diverged. The size of the caudal segment was similar in Ct-, Et6-, and Et24-treated macaques. On the other hand, the rostral segment was significantly ($P < 0.05$) larger in the Et6- (62.6%) and Et-treated (50.3%) macaques than in the controls.

The corpus callosum in the fixed brains was smaller than it was in the MR images. It is interesting to note, that the difference was consistent among all of the treatment groups; about 8% (i.e., fixation ratios of about 0.92; see Table 3). The implications from these data were (1) that the fixation process caused a small amount of shrinkage independent of ethanol treatment and (2) that prenatal treatment did not affect the fixation ratio.

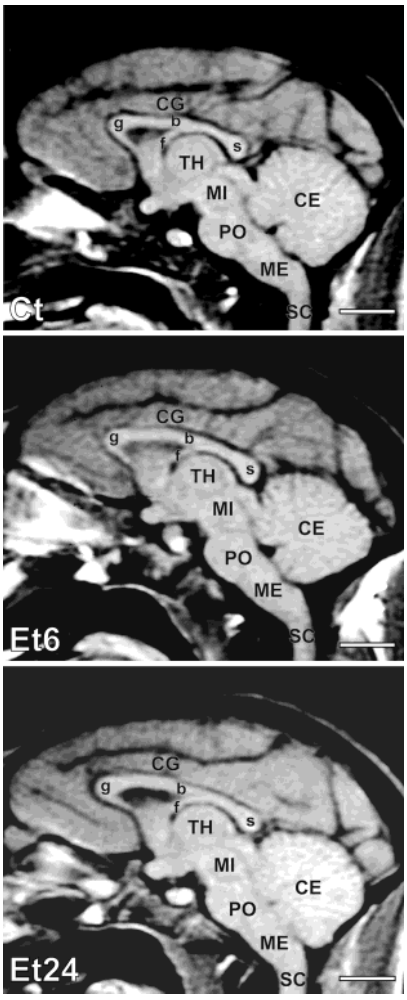

Fig. 1. MR images of ethanol- and control-treated macaques. These MR scans of the mid-sagittal planes of the brains of Ct- (top), Et6- (middle), and Et24-treated (bottom) macaques were taken within 0.5 years of the time of death. Scale bars = 1.0 cm.

TABLE 3. Size of the Corpus Callosum in Magnetic Resonance Images and Fixed Brains[1]

	Ct (n = 6)	Et6 (n = 5)	Et24 (n = 4)
MR images			
Right hemisphere ($\times 10^6$ µm^2)	86.2 ± 5.5	112 ± 4*	109 ± 10*
Rostral segment ($\times 10^6$ µm^2)	37.4 ± 3.3	60.8 ± 6.3*	56.2 ± 5.2*
Caudal segment ($\times 10^6$ µm^2)	48.8 ± 3.9	51.2 ± 4.5	53.0 ± 5.5
Fixed brains			
Right hemisphere ($\times 10^6$ µm^2)	81.1 ± 2.3	102 ± 6*	100 ± 8*
Rostral segment ($\times 10^6$ µm^2)	35.2 ± 1.8	54.9 ± 3.6*	52.9 ± 3.2*
Caudal segment ($\times 10^6$ µm^2)	45.8 ± 1.1	47.4 ± 2.5	47.0 ± 2.2
Left hemisphere ($\times 10^6$ µm^2)	82.3 ± 3.8	100 ± 4*	100 ± 8*
Total ($\times 10^6$ µm^2)	81.7 ± 3.5	101 ± 5*	100 ± 8*
Fixation ratio	0.941 ± 0.061	0.911 ± 0.054	0.917 ± 0.059

[1]The rostral and caudal segments were demarcated by the junction/separation of the body of the corpus callosum and the body of the fornix. The total size of the corpus callosum was compiled from the pooled data for the size of the corpus callosum in each hemisphere. The fixation ratio for the corpus callosum in the right hemisphere was calculated as the size of the corpus callosum in the fixed brains to the callosal size in the magnetic resonance images. Ct, sucrose control; Etb, fed ethanol once per week for 6 weeks; Et24, fed ethanol once per week for 24 weeks.
*Asterisks denote statistically significant ($P < 0.05$) differences relative to the size in the Ct-treated macaques.

Composition of the corpus callosum

The cross-sectional area of callosal axons, the thickness of the myelin, and the axonal density were measured in electron micrographs of the corpus callosum (Fig. 3). Each feature was examined at three locations, the genu, body, and splenium of the corpus callosum. Regardless of the treatment group and callosal location, only 10–15% of the callosal axons were non-myelinated.

In the control macaques, axonal size varied among the three locations. Axons in the genu were at best half the size of those at the other two locations (Fig. 4). This difference was statistically significant ($F_{2,4} = 36.2$; $P < 0.001$). A similar pattern was evident in the Et6- and Et24-treated macaques.

The mean thickness of the myelin sheaths paralleled the mean size of the axons (Fig. 5). Thus, the axons in the genu had the thinnest myelin and those in the splenium the thickest ($F_{2,4} = 16.1$; $P < 0.001$). At a particular callosal site, no differences among the Ct-, Et6-, and Et24-treated macaques were detected.

The mean axonal density was calculated as the quotient of the mean number of axons counted in a 100 µm^2 square. An analysis of variance ($F_{2,4} = 64.4$; $P < 0.001$) showed that density was affected by both the treatment group and the location in the corpus callosum. Regardless of the treatment group, the density was greatest in the genu and lowest in the splenium (Fig. 6). The only site where the axonal density was affected by an ethanol treatment was in the body. Here the density was significantly ($P < 0.05$) higher in the Et6- and Et24-treated macaques than in the controls.

An estimate of the total number of axons was calculated as the product of the size of the corpus callosum and the mean axonal density (Fig. 7). The latter value was determined as the mean of the axonal density at the three sites. Accordingly, the Et6- and Et24-treated macaques had significantly more (48.8% and 41.2%, respectively) axons than did the controls ($F_{2,12} = 14.4$; $P < 0.001$). No differences between the two ethanol treatment groups were observed; that is, the duration of the ethanol exposure had no effect.

DISCUSSION

Size and axonal content of the corpus callosum in normal non-human primates

The corpus callosum is the largest commissure in the primate brain. Its cross-sectional area in the *M. nemestrina* is 81.7 mm^2. This is similar to the size of the corpus callosum in the *M. mulatta* (76.4 mm^{2}d Rakic, 1990a). In both the *M. nemestrina* and the rhesus monkey, axonal density varies with location; the density in the genu is about twice that in the body and the splenium. On the other hand, regardless of location, the present study shows that the density of axons in the corpus callosum of the *M.*

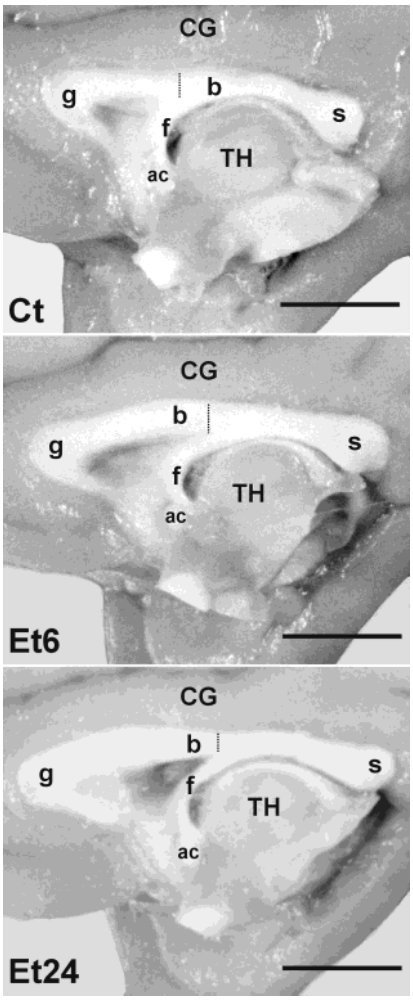

Fig. 2. Corpora callosa of macaques prenatally exposed to ethanol. The medial aspects of the same brains as those depicted in Figure 1 are shown; Ct- (top), Et6- (middle), and Et24-treated (bottom) macaques. The dotted line through the body of the corpus callosum identifies the border between the rostral and caudal segments. ac, anterior commissure; b, body of the corpus callosum; CG, cingulate gyrus; g, genu of the corpus callosum; f, fornix; s, splenium of the corpus callosum; TH, thalamus. Scale bars = 1.0 cm.

nemestrina (1.18 axons/μm^2 is 40–50% greater than in the rhesus monkey (0.766 axons/μm^2; LaMantia and Rakic, 1990a). The net result is that the estimated number of callosal axons in the *M. nemestrina* (94.2×10^6 axons) is 68.2% higher than in the *M. mulatta* (56.0×10^6 axons; LaMantia and Rakic, 1990a). It must be kept in mind that the weights of the mature brains of the two macaque species are similar (*cf.* the present results and Holloway and Heilbroner, 1992). The inter-species differences be-

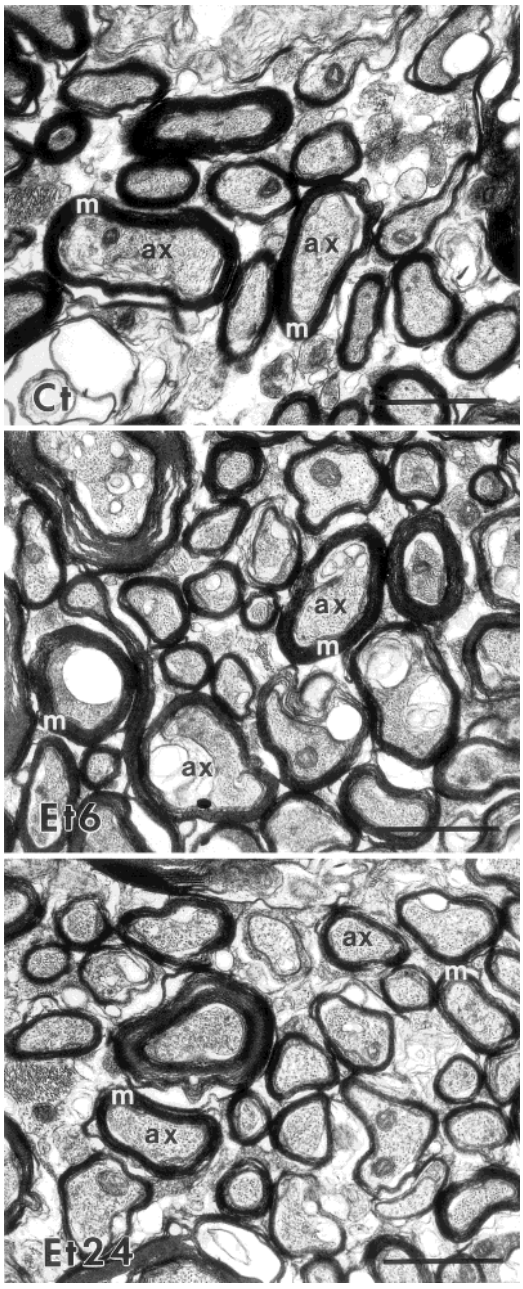

Fig. 3. Ultrastructure of the genu of the corpus callosum. Myelinated axons (ax) are the most common feature of the corpus callosum in Ct- (top), Et6- (middle), and Et24-treated (bottom) macaques. m, myelin. Scale bars = 2.0 μm.

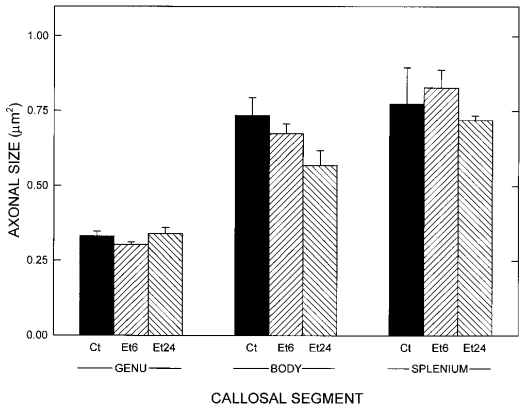

Fig. 4. Axonal size. The mean cross-sectional area of axons in a 100 μm² box (± the standard error of the mean) was plotted for the five treatment groups. A separate mean was calculated for axons in the genu (left), body (middle), and splenium (right) of the corpus callosum. At each callosal site, no differences among treatment groups were detected.

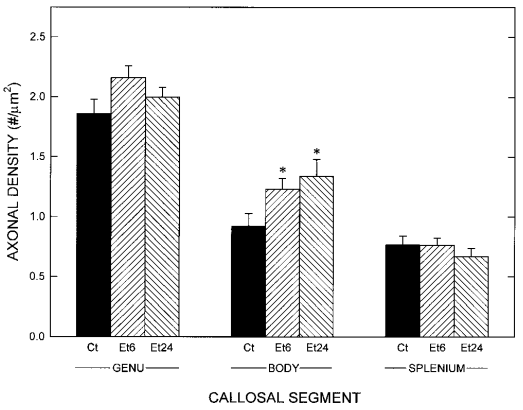

Fig. 6. Axonal density. The packing density of axons varied with the location; the density was greatest rostrally and lowest caudally. Prenatal treatment only had a significant effect ($P < 0.05$; noted by asterisks) on axonal density in the body of the corpus callosum. There, the density of callosal axons was greater in all animals treated with the Et, regardless of the presentation (e.g., Et6 or Et24).

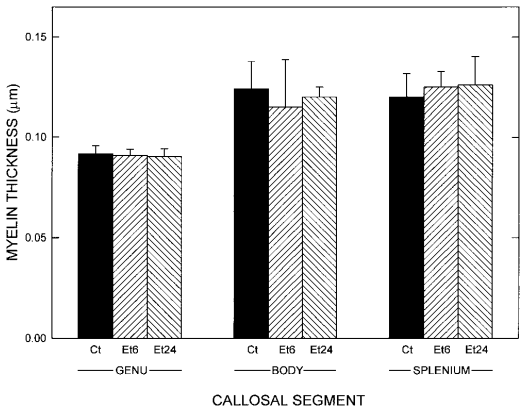

Fig. 5. Myelin thickness. At each callosal site, the mean thickness of the myelin sheath was not significantly different in the Ct-, Et6-, and Et24-treated macaques. T-bars denote the standard errors of the means.

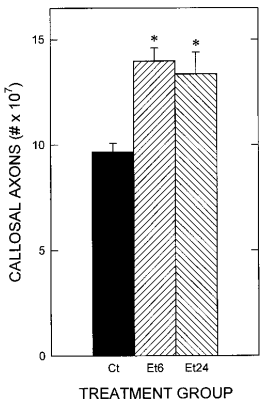

Fig. 7. Total number of axons in the corpus callosum. Regardless of whether the Et was provided over 6 weeks (Et6) or 24 weeks (Et24), the estimated total number of callosal axons was greater in the Et-treated macaques than it was for controls. Statistically significant differences ($P < 0.05$) are noted by asterisks.

tween the *M. nemestrina* and the *M. mulatta* in callosal size are small. After all, despite no change in brain weight, the size of the corpus callosum in the *M. mulatta* is 42.7% larger than cross-sectional area of the corpus callosum in another macaque, the *M. fascicularis* (Holloway and Heilbroner, 1992).

Species differences in ethanol-induced changes in callosal size

Exposure to moderate amounts of ethanol, once per week during gestation for as little as 6 weeks, increases the size of the corpus callosum in the macaque. This ethanol-induced increase in callosal size results from an increase in the number of callosal axons. Furthermore, the increase occurs regardless of how long the fetus is exposed to ethanol (i.e., 6 or 24 weeks).

In addition to the present study, data from rat investigations also show that prenatal exposure to ethanol increases the number of callosal projection neurons (Miller, 1997). Such findings are at variance with the data from various studies of children with severe brain alterations in FAS (e.g., Clarren et al., 1978; Peifer et al., 1979; Pratt and Doshi, 1984; Schaefer et al., 1991; Riley et al., 1995; Swayze et al., 1997). These clinical studies show that such children with severe brain abnormalities have a higher incidence of callosal agenesis or dysgenesis than that for

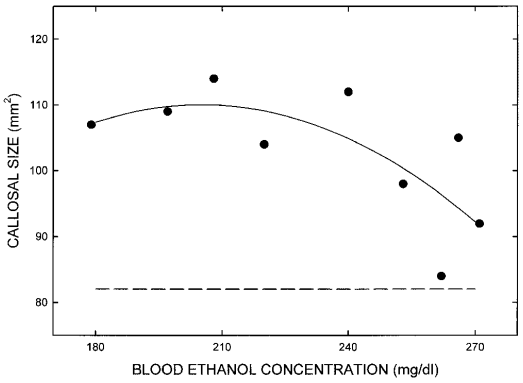

Fig. 8. Effects of blood ethanol concentration on callosal size. The data on the callosal size were plotted against peak blood ethanol concentration for each animal. The solid line depicts the second order curve that best fits the data ($P < 0.05$) and the dashed line describes the mean callosal size in the controls.

the general population. Such clinical data, however, must be interpreted with caution. There is the great risk that by focusing on children with FAS who have the more severe or obvious brain disruptions, the data sample may not be generalizable to all children with fetal alcohol damage. The clinical studied are biased in that they present data from severely affected children. The monkeys in the present study evidently are less severely affected because they are not microencephalic. The results of a recent MR imaging study support this contention (Streissguth and Bookstein, personal communication). In this study, children with a wide range in severity of CNS dysfunction in FAS and alcohol-related neurodevelopmental disorder were examined. The range of callosal defects varies widely; in fact, some of the children exhibit enlarged corpora callosa.

One key factor determining the effect of ethanol on callosal size may be the peak BEC. Ethanol-treated macaques and rodents with larger corpora callosa (Miller, 1997; present study) had BECs of <250 mg/dl. In contrast, the mothers of rodents and people exhibiting callosal damage likely had BECs of >250 mg/dl. Interestingly, a curious relationship emerges when the data for the callosal size are plotted against BEC (Fig. 8). Exposure to moderate BEC results in a modest increase in callosal size. The maximal effect is evident with BEC between 205 and 240 mg/dl. At BEC of >250 mg/dl, callosal size falls with BEC. These data should be interpreted with caution, however, because all animals in the present study were treated with the same amount of ethanol and peak BEC can vary within an individual animal by 25% or more (Bonthius and West, 1990). Nevertheless, the data are compelling and it is important to note that dose-dependent effects for dopamine neurochemistry in macaques (Astley et al., 1995) and for hippocampal morphology in rats (Miller, 1995) have also been described.

Critical windows of ethanol exposure

The timing of ethanol exposure may have profound teratogenic effects. Sulik has shown that mice treated with ethanol on G7 exhibit the full array of craniofacial malformations that are characteristic of FAS (Sulik, 1984). The brains of these animals also are malformed, particularly midline structures such as the septal nuclei and the corpus callosum (e.g., Sulik and Johnston, 1982; Schambra et al., 1989). The BEC of these mice was extremely high, 500–600 mg/dl. Rats exposed to ethanol through much of the prenatal period (including G8 and G9; the days when gastrulation occurs in the rat) also have callosal damage (Zimmerberg and Scalzi, 1989; Miller, 1997).

It is difficult to draw parallels between the timing of rat and macaque development. If we use the time of gastrulation and the timing of cortical neuronogenesis as bases of comparisons, however, some meaningful conclusions can be drawn. Gastrulation occurs on G8 or G9 in the rat and on G19 or G20 in the macaque. Cortical neurons in macaques are generated between G45 and G102 (Rakic, 1974, 1978) and between G12 and G21 in the rat (Bruckner et al., 1976; Miller, 1988a,b). Thus, based on studies with mice (Sulik, 1984), it can be predicted that macaques exposed to ethanol on G19 or G20, would experience craniofacial and midline brain damage. Data show that the macaques exposed to ethanol on G19 or G20 do, in fact, exhibit craniofacial anomalies (Astley et al., 1999).

The data for the macaque and the rodent are not wholly consistent. The lack of a difference between the Et6- and Et24-treated macaques suggests that brain alterations can result from episodic ethanol exposure before embryonic implantation, but before the period of cortical neuronogenesis. In contrast, cortical damage in the rat may not be caused by such early exposure. For example, the proliferation of cortical progenitors in the rat is unaffected by exposure to ethanol between G6 and G9, whereas exposure between G12 and G15 or between G18 and G21 significantly alters cell proliferation (Miller, 1996b).

Regional specific effects of ethanol

The rostral portion of the macaque corpus callosum is the most affected by prenatal exposure to ethanol. This segment interconnects the frontoparietal lobes in the two hemispheres. In the rat we know that both motor (frontal) and somatosensory (parietal) cortices are profoundly affected by ethanol (e.g., Miller, 1987, 1997; Miller and Potempa, 1990). Although no comparable data are available for the non-human primate, there is reason to suspect that somatosensory cortex in the macaque brain is also targeted by prenatal ethanol treatment.

Evidence implicating the frontal lobe is interesting in light of data from children with FAS. The size of frontal cortex is disproportionately altered in children with FAS (S.N. Mattson, personal communication). By itself, this reduction may be meaningless, but such children also exhibit abnormalities in executive functions (Kodituwakku et al., 1995; Kopera-Frye et al., 1996) and executive functions have been attributed to prefrontal processing (e.g., Eslinger et al., 1992; Bechara et al., 1996, 1998). Thus, the abnormal structure of frontal cortex and likewise the altered numbers of axons in the rostral segment of the corpus callosum may underlie prefrontal dysfunction of executive activities.

Ethanol-induced overgrowth of axons and dendrites

Studies in the rodent show that early exposure to ethanol can promote the growth of axons. Prenatal exposure to ethanol induces an increase (1) in the number of callosal projection neurons in the somatosensory cortex of

the rat (Miller, 1997), (2) in the number of corticospinal projection neurons in somatosensory and motor cortices (Miller, 1987), and (3) in the number of their descending axons in the lower pyramidal tract (Miller and Al-Rabiai, 1994). Recent evidence shows that ethanol treatment promotes axonal growth by cultured hippocampal neurons (Clamp and Lindsley, 1998).

Ethanol-induced overgrowth is not restricted to axonal systems. Prenatal exposure to ethanol also can induce the postnatal hypergrowth of dendrites. Corticospinal projection neurons in somatosensory cortex of Et-treated rats and cerebellar Purkinje neurons have more complex dendritic trees (i.e., more branches) and longer dendrites than do neurons in controls (Pentney et al., 1984; Miller et al., 1990). These data were based on rats that were treated with ethanol from G6 to G21. Similar data were garnered from mice exposed to ethanol only on G10 and G11 (R.F. Mervis, personal communication), that is, early in the period of cortical neuronogenesis (Angevine and Sidman, 1961; Bruckner et al., 1976; Gardette et al., 1982; Miller, 1988a,b).

Callosal (e.g., O'Leary et al., 1981; Ivy and Killackey, 1982; LaMantia and Rakic, 1990b) and corticospinal axons (e.g., Stanfield et al., 1982; O'Leary and Stanfield, 1986) and the dendrites of cortical pyramidal neurons (Miller, 1981, 1986b, 1988b) undergo considerable pruning during early development. We hypothesize that ethanol reduces the pruning process. Various data support this hypothesis. In the developing macaque, the number of callosal axons reaches a maximum of 3.5-fold more than that in the adult (LaMantia and Rakic, 1990b). Et-treated macaques have only 0.45-fold more callosal axons than do controls. This is consistent with the notion that the pruning of callosal axons that normally occurs in all developing macaques is partially blocked by prenatal exposure to ethanol. Further support comes from a study of pyramidal tract axons in developing rats. The number of these axons falls during early postnatal development, but the fall is not as precipitous or profound in Et-treated rats as it is in controls (Miller and Al-Rabiai, unpublished results). The increases in axonal and dendritic fields could be affected (1) by blocking the action of a pruning regulator (e.g., Sato et al., 1994; Frisen et al., 1998) or (2) by facilitating the action of an agent(s) that promotes neuritic growth such as a neurotrophin. Interestingly, ethanol potentiates neurotrophin activity in vitro so that the ethanol-treated cultured neurons elaborate more neurites (Messing et al., 1993; Zou et al., 1993, 1995).

In summary, macaques exposed to moderately high levels of ethanol exhibit increases in the sizes of their corpora callosa and in the numbers of callosal axons. These alterations likely result from interference with substances that regulate normal neuronal growth, e.g., neurotrophins. It is generally assumed that cognitive deficits result from reductions in axonal and/or dendritic fields, however, evidence that ethanol-induced cognitive deficits are caused by an overabundance of axons and dendrites is building.

We wish to acknowledge our colleagues Sharon Beck, M.Ed., Educational Counselor, Heather Carmichael Olson, Ph.D., Developmental Psychologist, Sandra G. B. Clarren, Ph.D., Educational Psychologist, Truman Coggins, Ph.D., Language Pathologist, and Tracy Jirikowic, MS, OTR/L Occupational Therapist who use this Guide weekly and have helped us to hone the material on an ongoing basis. Their helpful criticism and thoughtful insights have been invaluable. We also wish to thank Kathleen Tharp, Julie Gelo, and Kathy Briggs-Jones who readily offered their assistance when needed. Finally, a very special thanks is extended to all of our patients and their families who have contributed a wealth of knowledge and information to the development of this guide.

Preface

This Diagnostic Guide is a work-in-progress. Based on our own experience and feedback from others, we continue to make modifications that enhance accuracy, improve clarity, and increase ease of usage. Until now, the volume has been formatted in a ring binder to ease revisions, but the large demand for copies had led to our decision to reproduce the work in this format at this time. It remains our plan to update this Guide on an annual basis. We hope you will find this new approach to fetal alcohol exposure diagnosis helpful and broadly applicable.

I. Introduction

Fetal alcohol syndrome (FAS).

FAS is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The definition of the fetal alcohol syndrome has changed little since the 1970's when the condition was first described and refined. The condition has been broadly characterized by pre- and/or postnatal growth deficiency, a characteristic set of minor facial anomalies, and evidence of prenatal alteration in brain function such as microcephaly from birth, neurologic problems without postnatal antecedents, or complex patterns of functional disability.

The difficulty with diagnosing FAS and other disabilities associated with in utero alcohol exposure.

For the trained clinician, dysmorphologist, or clinical geneticist there is little difficulty in making the diagnosis of FAS when the anomalies in growth, face, and brain are all extreme and the alcohol exposure is conclusive and substantial. But the features are not dichotomous, that is either normal or clearly abnormal. Rather, the features, and indeed the history of alcohol exposure, all range along separate continua from normal to clearly abnormal and distinctive.

In the absence of accurate, reproducible and unbiased methods for measuring and recording the severity of exposure and outcome in individual patients, diagnoses will continue to vary widely from clinic to clinic. From a clinical perspective, diagnostic misclassification leads to inappropriate patient care, increased risk for secondary disabilities and missed opportunities to achieve prevention. From a public health perspective, diagnostic misclassification leads to inaccurate estimates of incidence and prevalence. Inaccurate estimates thwart efforts to allocate sufficient social and health care services to this high risk population and preclude accurate assessment of primary prevention intervention efforts. From a clinical research perspective, diagnostic misclassification reduces the power to identify between-group contrasts within studies. Non-standardized diagnostic methods limit the ability to compare outcomes between studies.

A new approach to diagnosis.

This manual introduces a new approach to diagnosis; the "*4-Digit Diagnostic Code*". The four digits reflect the magnitude of expression of four key diagnostic features of FAS in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) brain dysfunction, and (4) gestational alcohol exposure. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic" presence of the FAS feature.

Benefits of the new diagnostic approach.

This new approach:

1. Greatly increases diagnostic precision and accuracy.
2. Better characterizes the disabilities of alcohol exposed individuals who do not have FAS.
3. Documents the presence of alcohol exposure without judging its causal role.
4. Utilizes a clinical nomenclature that separates a patient's functional disabilities from their exposure history.

While this document might at first appear overly complex and perhaps daunting, one will find that this new diagnostic approach is logical and easy to use and will greatly facilitate the proper description and classification of patients presenting with all possible combinations of outcomes and exposure.

Other syndromes

The methods of diagnosing fetal alcohol syndrome and related conditions arise from the larger fields of teratology and dysmorphology (clinical genetics). It is essential to remember that isolated features in many birth defect syndromes overlap with FAS. A few examples of conditions often easily confused with FAS include Aarskog syndrome, fragile-x syndrome, fetal hydantoin syndrome and Noonan syndrome. Furthermore it is likely that this diagnostic approach to organizing dysmorphic features and issues of cognitive and behavioral problems could be used for patients exposed to other potentially teratogenic substances instead of or in addition to alcohol. This diagnostic guide is "FAS specific" but this in no way should imply that the diagnostician need not consider alternate syndromic diagnoses and medical conditions at all times.

II. FAS Diagnostic Evaluation Form

The FAS Diagnostic Evaluation Form guides the clinical team in the collection, recording, and interpretation of all key information required to make an accurate and precise alcohol related diagnosis. The form also serves as a template for efficient generation of the final medical summary note. This form is a "work-in-progress". It continues to be revised based on the collective experience of the Washington State FAS Diagnostic and Prevention Network, to improve accuracy, clarity and ease of use.

Where is the information for the Diagnostic Form obtained from?

The information recorded in the Diagnostic Form is obtained from four primary sources:

1. The New Patient Information Form completed by the caregivers (Appendix).
2. Previous medical / psychological / educational assessments.
3. Assessments administered by the clinical staff at the time of the diagnostic evaluation.
4. The caregiver/patient interview conducted at the time of the diagnostic evaluation

When is the form completed and by whom?

The form is completed by the clinical staff before and during the patient's clinic visit.

Was the birth mother ever diagnosed with alcoholism? 612	___	_____	___	_____
Was the birth mother ever reported to have a problem with alcohol? 613	___	_____	___	_____
Did the birth mother ever receive treatment for alcohol addiction? 614	___	_____	___	_____

Who reported the mother's alcohol use during pregnancy? 615 ____ birth mother, ____ a direct observer, ____ an individual or source that did not directly observe drinking during pregnancy

Reported use of alcohol during pregnancy is:616 ___reliable, __questionably reliable, __of unk. reliability

Other information:617 _____

_____

Summary Measure of Alcohol Exposure

Circle the 4-Digit Diagnostic Code Rank in the table below that best reflects the patient's gestational Alcohol Exposure Category.

4-Digit Diagnostic Code Rank	Gestational Alcohol Exposure Category	Description
4	High Risk	• Report by the birth mother or directly from other individual who saw the mother drink during pregnancy *and* • Report of exposure likely to produce BAC's over 100mg% weekly, early in pregnancy.
3	Some Risk	• Report by birth mother, other direct observer, or reliable source *and* • Drinking occurred in gestation in frequencies and volumes less than in category (4) or otherwise unspecified.
2	Unknown Risk	• Gestational exposure is simply not known or information is of uncertain reliability
1	No Risk	• The mother reliably acknowledges no exposure to alcohol in pregnancy, or minimal exposure

III. Diagnostic Evaluation Form Instructions

A. The 4-Digit Diagnostic Code

What are the 4 Digits?

The four digits reflect the magnitude of expression of four key diagnostic features of FAS in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) brain dysfunction, and (4) gestational alcohol exposure. The 4-Digit Diagnostic Code is generated at the completion of the diagnostic evaluation using information recorded on the FAS Diagnostic Evaluation Form. The code is created by filling in the grid below which appears on page one of the Diagnostic Form.

4-Digit Diagnostic Code Grid

				3	4	4		4		
significant	severe	definite	(4)		X	X		X	(4)	high risk
moderate	moderate	probable	(3)	X					(3)	some risk
mild	mild	possible	(2)						(2)	unknown
none	absent	unlikely	(1)						(1)	no risk
Growth Deficiency	**FAS Facial Features**	**Brain Dysfunction**		Growth	Face	Brain		Alcohol		**Gestational Alcohol**

Figure 1. 4-Digit Diagnostic Code grid. This grid is filled in to illustrate how the Diagnostic Code 3444 is derived. This code is one of eight which qualifies as a diagnosis of FAS.

How are the 4 Digits ranked?

The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic" presence of the FAS feature. Specific guidelines for ranking the magnitude of each of the FAS features are presented in Section III.B.

How many 4-Digit Diagnostic Codes are there?

There are 256 possible 4-Digit Diagnostic Codes ranging from 1111 to 4444. The 256 codes and their corresponding clinical names are listed in numerical order in Section VI.

We have created diagnostic categories for all potential codes, even though to date we do not expect to see all of these situations in clinic. For example, 1111 reflects a normal exam in an individual who was definitely not exposed to alcohol. Such patients are seen by primary physicians daily, but are unlikely to be referred to an FAS clinic. Other codes like 4441 would represent a “classic” clinical presentation of FAS with a confirmed absence of alcohol exposure during gestation. We have never seen such a case (or phenocopy), but we may some day.

How many different Clinical Diagnostic Categories are there?

Each 4-Digit Diagnostic Code falls into one of 22 unique Clinical Diagnostic Categories (labeled A through V). A list of the 22 Diagnostic Categories is presented in Section IV. A list of the 4-Digit Diagnostic Codes, which fall within each Clinical Diagnostic Category, is presented in Section V.

What are the names of the Clinical Diagnostic Categories?

A series of terms are used in varying combinations to name the 22 diagnostic categories. They include:

- **Sentinel Physical Findings:**
  The adjective *"sentinel"* refers to key physical findings that, in combination, are highly sensitive and specific to in utero alcohol exposure. These include a unique cluster of minor facial anomalies (short palpebral fissures, thin upper lip and a smooth philtrum) and growth deficiency. These sentinel features serve as necessary and sufficient criteria for establishment of the physical component of an FAS diagnosis. Other physical findings may be detected instead of or in addition to the sentinel findings which may suggest alternate or additional conditions. The findings may also present as isolated features which may or may not be caused by in utero alcohol. There are places on the Diagnostic Evaluation Form to record and interpret other physical findings.

- **Static Encephalopathy:**
  The term *"encephalopathy"* refers to any physical abnormality in the brain. Such abnormalities can vary in magnitude from structural defects that are apparent on an image like a CT scan to micro-cellular abnormalities that can only be confirmed with tissue samples or neurochemical analysis. The term *"static"* means that the physical abnormality in the brain is unchanging, neither progressing or regressing. The term *"static encephalopathy"* is used in this diagnostic system when the patient presents with cognitive/behavioral dysfunction which is accompanied by structural, neurologic, and/or psychometric measures which strongly support the presence of structural brain abnormalities. The term does not define or suggest any specific pattern of structural abnormality or cognitive/behavioral dysfunction.

- **Neurobehavioral Disorder:**
  This term is used in this diagnostic system when the patient presents with cognitive/behavioral dysfunction, but structural, neurologic and psychometric measures do not unequivocally support the presence of structural brain abnormalities. Reasonably specific conditions like attention deficit disorder and dyslexia, for example could be referred to as neurobehavioral disorders.

- **Alcohol (Exposed, Not Exposed, Exposure Unknown):**
  This term is used to reflect the exposure status of the fetus. It is <u>not</u> to be used to link alcohol exposure to outcome.

- **Fetal Alcohol Syndrome:**
  The term FAS is used to refer to patients who present with the full compliment of sentinel physical findings, static encephalopathy and were alcohol exposed.
- **Atypical Fetal Alcohol Syndrome:**

This term is introduced for use with a relatively small group of patients who have static encephalopathy, most of the sentinel physical findings of FAS, and were alcohol exposed. Given the fact that variable presentation is the rule rather than the exception after teratogenic exposure in gestation, we felt it was appropriate to establish this marginal category.

The names assigned to each diagnostic category reflect the patient's clinical outcome and alcohol exposure. The names are listed in Sections IV and V. The first three categories (A through C) meet the criteria for a clinical diagnosis of FAS and are named as such. The fourth category (D) applies to the patient who presents with all of the features of FAS, but has a confirmed *absence* of gestational alcohol exposure. This category is referred to as an FAS Phenocopy and has yet to be observed.

The remaining 19 categories (E through V) do not meet the minimum criteria for FAS and are subsequently named to reflect the Likert ranking of each digit in the 4-Digit Diagnostic Code. For example, a code of 4342 is the Diagnostic Category called "*sentinel physical findings / static encephalopathy (alcohol exposure unknown)*". Many of these patients might have previously been referred to variably as having possible fetal alcohol effects (PFAE), alcohol related birth defects (ARBD), or alcohol related neurodevelopmental disorder (ARND). This new nomenclature supersedes all of these terms.

The following nomenclature pattern is used:

- Growth deficiency and facial characteristics are physical features. When either feature receives a rank of 3 or 4, the patient is referred to as having a *sentinel physical finding*.

- When brain dysfunction receives a rank of 2, the condition is referred as a *neurobehavioral disorder*. When brain dysfunction receives a rank of 3 or 4, the condition is referred to as *static encephalopathy*

- When alcohol exposure receives a rank of 1, there is a *confirmed absence of gestational alcohol exposure*. When alcohol exposure receives a rank of 2, *alcohol exposure is unknown.* When alcohol exposure receives a rank of 3 or 4, *gestational alcohol exposure is confirmed.*

Which new Diagnostic Categories represent the category we use to call FAE?

Diagnostic Categories E through I would have previously been referred to as "fetal alcohol effects", "alcohol related birth defects" or "alcohol related neurobehavioral disorder". Categories J through V are new categories which describe a large number of patient groups who have never been adequately classified or described in the past.

How do you explain the diagnosis to the patient?

At the end of this manual (Section VII) are summary explanations for each of the 22 Clinical Diagnostic Categories. These summaries can be used as the first page of the patient's final medical summary note.

III. Diagnostic Evaluation Form Instructions

B.1. Scoring Growth Deficiency

What type of growth deficiency are we looking for?

We are looking for growth deficiency characteristic of a teratogenic insult, not characteristic of postnatal environmental factors such as nutritional deprivation or chronic illness. We want to answer the question *'What is the patient's growth potential after controlling for parental height and postnatal environmental influences?'* Growth deficiency of teratogenic origin is likely to present as a relatively consistent impairment over time (i.e., the patient's growth follows the normal curve, but is below genetic expectation for family background). In contrast, growth deficiency due to postnatal environmental influences is likely to present as periodic fluctuations in the curve. *Separating the two growth patterns requires astute clinical judgment.*

The method described below allows one to rank a patient's overall growth pattern on a single 4-point Likert scale with 1 equaling normal and 4 equaling significantly deficient. Not all patients will have complete growth curves available, therefore, a guide is provided below for prioritizing the ranking of the patient's growth over time

Method for ranking the growth component of the 4-Digit Diagnostic Code

A. Height should be age and gender adjusted and should be adjusted for parental height, if possible.

B. Weight should be age and gender adjusted. Weight is not adjusted for height. Normal growth charts are provided in Section VIII.

C. For ranking purposes, the growth curve is separated into two parts:
   1. Prenatal growth (birth measures)
   2. Postnatal growth (all measures collected after birth)

   Select the part with the greatest deficiency in height.

   If the prenatal height centile is lower than all postnatal height centiles, proceed to section D for instructions on how to rank prenatal growth.

   If any of the postnatal height centiles are lower than the prenatal height centile, select the point or consecutive points on the curve that reflect the lowest height centiles which cannot be attributed to postnatal environmental influences such as nutritional deprivation or chronic illness. If the height deficiency is reflected in a series of points on the curve, as opposed to a single point, rank the level of deficiency based on the centile range where the majority of the points fall. Proceed to section D for instructions.

D. Rank the level of deficiency of the height and weight centiles for the section of the curve with greatest height deficiency by circling A, B or C in the ABC Summary Score table at the bottom of page 1 of the FAS Diagnostic Evaluation Form. This ABC Summary Score table is duplicated below as Table 1.

Table 1: Deriving the ABC Summary Score

ABC Rank	Centile Range	Circle the ABC-Score for: Height	Weight
C	$\leq 3^{rd}$	C	C
B	$>3^{rd}$ and $\leq 10^{th}$	B	B
A	$>10^{th}$	A	A

E. Next, refer to Table 2 to determine the *4-Digit Diagnostic Code Rank* of the Height-Weight ABC Score Combination recorded in Table 1. Transfer the resulting 4-Digit Diagnostic Code Rank for growth to the 4-Digit Diagnostic Code Grid at the top of page 1 of the FAS Diagnostic Evaluation Form.

Table 2: Converting the ABC-Score to a 4-Digit Diagnostic Code Rank

4-Digit Diagnostic Code Rank	Growth Deficiency Category	Height-Weight ABC-Score Combinations
4	Severe	CC
3	Moderate	CB, BC
2	Mild	CA, BB, AC
1	None	BA, AB, AA

Example for Scoring Growth Deficiency

Patient's Growth Record:

	Age (years)	Height Centile	Weight Centile
birth	0.0	5 %	2 %
	1.5	10 %	15 %
	5.0	12 %	20 %
	7.0	12 %	10 %
	15.5	15 %	30 %

Let's say clinical records rule-out any environmental influence on postnatal measures.

Scoring:

- Priority would be placed on ranking the birth measures because the birth height centile is lower than all postnatal height centiles recorded.
- Birth height would be ranked **$>3^{rd}$ and $\leq 10^{th}$** (or Rank B) in Table 1.
  Birth weight would be ranked **$\leq 3^{rd}$** (or Rank C) in Table 1.

Table 1: Deriving the ABC Summary Score

		Circle the ABC-ScoreS for:	
ABC Rank	Centile Range	Height	Weight
C	$\leq 3^{rd}$	C	**C**
B	$>3^{rd}$ and $\leq 10^{th}$	**B**	B
A	$>10^{th}$	A	A

- The Height-Weight ABC-Score Combination would be **BC** according to Table 2.
- The Growth Deficiency Category would be **Moderate** according to Table 2.
- Moderate growth deficiency receives a rank of **3** in the 4-Digit Diagnostic Code in Table 2.

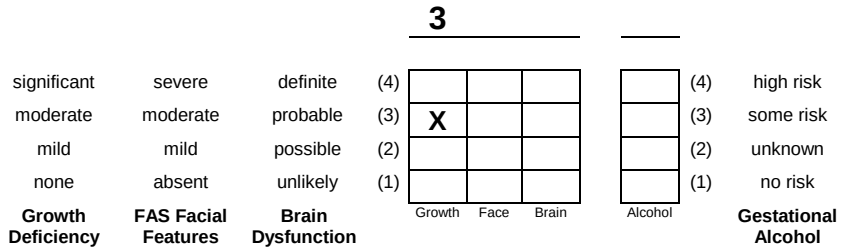
Table 2: Converting the ABC-Score to a 4-Digit Diagnostic Code Rank

4-Digit Diagnostic Code Rank	Growth Deficiency Category	Height-Weight ABC-Score Combinations
4	Severe	CC
3	**Moderate**	CB, **BC**
2	Mild	CA, BB, AC
1	None	BA, AB, AA

The number **3** would be transferred to the 4-Digit Diagnostic Code Grid on page 1 of the FAS Diagnostic Evaluation Form (as duplicated below).

Result:

4-Digit Diagnostic Code Grid



III. Diagnostic Evaluation Form Instructions

B.2. Scoring the Facial Phenotype

Method for ranking the facial phenotype component of the 4-Digit Diagnostic Code

A. Palpebral fissure lengths are measured in standard deviations from the norm. The palpebral fissures are adjusted for age and when possible, race. More precise measures are obtained from upward-looking eyes. Use the Hall (1989) palpebral fissure length chart provided in Section VIII.

B. The upper lip and philtrum are measured on 5-point photographic Likert scales using Figure 1 from the Astley & Clarren (1996) which is duplicated on the next page. Lips should be gently closed with no smile (Figure 2).

C. Rank the level of expression of the fissures, philtrum, and upper lip by circling A, B, or C in each column in the ABC Summary Score table at the bottom of page 2 of the FAS Diagnostic and Evaluation Form. This table is duplicated below as Table 3.

Table 3: Deriving the ABC Summary Score

5-Point Likert Scale for Philtrum & Lip	Standard Deviation Scale for Fissures	Circle the ABC-Scores for: Palpebral Fissures	Smooth Philtrum	Thin Upper Lip
4 or 5	≤ -2 SD	C	C	C
3	>-2 SD and ≤ -1 SD	B	B	B
1 or 2	> -1 SD	A	A	A

D. Next refer to Table 4 to determine the *4-Digit Diagnostic Code Rank* based on the ABC-Score Combination derived from Table 3. Transfer the resulting 4-Digit Diagnostic Code Rank for face to the 4-Digit Diagnostic Code Grid on page 1 of the FAS Diagnostic Evaluation Form.

Table 4: Converting the ABC-Score to a 4-Digit Diagnostic Code Rank

4-Digit Diagnostic Code Rank*	Level of Expression of FAS Facial Features	Palpebral Fissure - Philtrum - Lip ABC-Score Combinations
4	Severe	CCC
3	Moderate	CCB, CBC BCC
2	Mild	CCA, CAC, CBB, CBA, CAB, CAA BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	Absent	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

* If facial measures are available at more than one age, score the age when the FAS phenotype is expressed the most. If FAS features are never expressed, score the face between the ages of 3 and 10 years, or at any age if this age range is not available.

Philtrum/Upper Lip	Philtrum Likert Scale	Upper Lip Likert Scale	ABC Scale
	5	5	C
	4	4	C
	3	3	B
	2	2	A
	1	1	A

Figure 1. Pictorial examples of the 5-point Likert scales and the ABC scale used to rank upper lip thinness and philtrum smoothness. It is important that the individual's lips are gently closed with no smile.

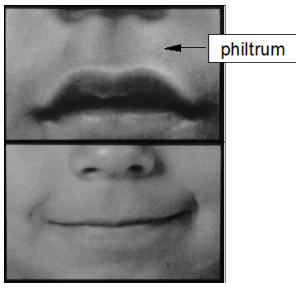


Figure 2. This is the same person with and without a smile. A smile can make the philtrum and upper lip appear smoother and thinner respectively than they truly are.

Example for Scoring Facial Phenotype

Patient measurements at 10 years of age:

- Palpebral fissure lengths = 2.5 cm which is < -2 SD's from the norm.
- Philtrum smoothness received a score of 5 on the 5-Point photographic Likert scale in Figure 1.
- Upper lip thinness received a score of 3 on the 5-Point photographic Likert scale in Figure 1.

Scoring

- The palpebral fissure lengths receive a Score of “C” in Table 3.

  A philtrum score of 5 corresponds to a score of “C” in Table 3.

  A lip score of 3 corresponds to a score of “B” in Table 3.

- The ABC-Score Combination for Fissure - Philtrum - Lip is **CCB**.

Table 3: Deriving the ABC Summary Score

5-Point Likert Scale for Philtrum & Lip	Standard Deviation Scale for Fissures	Circle the ABC-Scores for: Palpebral Fissures	Smooth Philtrum	Thin Upper Lip
4 or 5	≤ -2 SD	**C**	**C**	C
3	>-2 SD and ≤ -1 SD	B	B	**B**
1 or 2	> -1 SD	A	A	A

- A score of CCB indicates that the level of expression of the FAS Facial Features is **MODERATE**.

- A MODERATE expression of the FAS facial features receives a rank of **3** in the 4-Digit Diagnostic Code.

Table 4: Converting the ABC-Score to a 4-Digit Diagnostic Code Rank

4-Digit Diagnostic Code Rank	Level of Expression of FAS Facial Features	Palpebral Fissure - Philtrum - Lip ABC-Score Combinations
4	Severe	CCC
3	**Moderate**	**CCB**, CBC BCC
2	Mild	CCA, CAC, CBB, CBA, CAB, CAA, BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	Absent	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

- Transfer the number **3** to the 4-Digit Diagnostic Code Grid on page 1 of the FAS Diagnostic Evaluation Form (duplicated below).

Result

4-Digit Diagnostic Code Grid

				3					
significant	severe	definite	(4)					(4)	high risk
moderate	moderate	probable	(3)		X			(3)	some risk
mild	mild	possible	(2)					(2)	unknown
none	absent	unlikely	(1)					(1)	no risk
Growth Deficiency	**FAS Facial Features**	**Brain Dysfunction**		Growth	Face	Brain	Alcohol		**Gestational Alcohol**

III. Diagnostic Evaluation Form Instructions

B.3. Scoring Brain Dysfunction

Method for ranking the brain dysfunction component of the 4-Digit Diagnostic Code

A. Rank Definitions

Brain dysfunction is the most significant disability for individuals with FAS and related conditions and accuracy in this area is important and yet often elusive. The 4-point Brain Dysfunction Scale (Table 5) allows the clinician to separate patients with clear evidence of organic brain damage (static encephalopathy, category 4) from patients without evidence of organic brain damage (category 1). It also introduces two intermediate categories for describing patients who, in the clinician's judgment, cannot be clearly placed in categories 1 or 4.

Category 4

It is our impression that "organic brain damage" or static encephalopathy is readily diagnosed by clinicians when structural anomalies of the brain are detected or when permanent neurologic findings of presumed prenatal origin are found. Many, but not all, clinicians will also accept evidence of mental retardation (i.e., I.Q. score ≤ 60) as an alternate diagnostic confirmation.

Any positive finding(s) recorded under the Structural or Neurologic headings of the Organic Brain Dysfunction section (page 3) of the FAS Diagnostic Evaluation Form are sufficient to classify a patient as Category 4.

Category 3

Through our experience with hundreds of patients who have been exposed to potentially teratogenic doses of ethanol, we have found that many would not qualify as having static encephalopathy using the definition above, but neither could the possibility that they have static encephalopathy be dismissed out of hand. These are typically patients with IQ scores that are above the range clearly indicative of mental retardation, but who often have wide variations in IQ subtest scores, and in addition, have problems with executive functioning, memory and learning, language pragmatics, social adaptation, attention, and/or hyperactivity. These patients have problems that seem likely due to underlying brain structure or function rather than to adverse postnatal environmental experiences, yet do not meet the criteria for Category 4. Patients should be scored in category 3 when they do not meet the criteria for category 4, yet have enough psychometric data to strongly suggest to the clinician that organicity is probable.

Deficiencies recorded under the Functional (“Objective” Indicators) heading of the Organic Brain Dysfunction section (pages 3 and 4) of the FAS Diagnostic Evaluation Form serve to support a Category 3 classification. To date, criteria for the number of deficiencies that must be present to warrant a Category 3 classification has not been established. Classification in this category is made through clinical judgment and the overall weight of evidence obtained. As data from patients in

this category are reviewed over time, we anticipate that the categorical determinants will be more specifically defined. In using this category, care must be taken that sufficient evidence is available to justify "probable" CNS dysfunction.

Category 2

This score should be given to two subgroups of patients. All patients in category 2 have histories of behavioral and/or cognitive problems that strongly suggest organic brain dysfunction should be a consideration. One group of patients has not yet had the types of testing that would move them into Categories 3 or 4 if positive. The reason for this lack of testing is usually because the patients are too young to be tested. The other group of patients are those who have had testing that did not reveal compelling evidence for category 3 or 4 classification, and yet, in the clinician's judgment, a strong possibility of organicity can not be wholly dismissed. Alternative testing and/or later date testing should usually be considered. If adequately sensitive and appropriate testing has been carried out without clear evidence of CNS dysfunction, it is unlikely a Category 2 classification would be given.

Deficiencies recorded under the Functional (“Subjective” Indicators) heading of the Organic Brain Dysfunction section (page 5) of the FAS Diagnostic Evaluation Form serve to support a Category 2 classification. To date, criteria for the number of deficiencies that must be present to warrant a Category 2 classification have not been established. The classification is made through clinical judgment and the overall weight of evidence obtained.

Category 1

Patients are placed in this category when no problems in the areas of behavior and learning are discerned.

B. Completing the Organic Brain Dysfunction section of the FAS Diagnostic Evaluation Form

The organic brain dysfunction section appears on pages 3 through 5 of the FAS Diagnostic Evaluation Form.

Structural, Neurologic and Objective Functional Indicators (Pages 3 and 4)

Structural, neurologic, and “objective” functional indicators of organic brain damage are recorded on pages 3 and 4 of the diagnostic form. These pages serve as a place to record pertinent structural, neurologic, and psychometric information available on the patient to date.

The clinician is asked to rank the level of abnormality of each outcome on the following Likert scale: 0 = unable to judge, 1 = normal, 2 = mildly abnormal and 3 = severely abnormal. This ranking process is based solely on the clinician’s clinical judgment and serves to guide him/her in classifying overall organic brain damage into Category 3 or 4 (static encephalopathy) if appropriate.

Subjective Functional Indicators (Page 5)

"Subjective" functional indicators of organic brain dysfunction are recorded on page 5 of the diagnostic form. The findings on this page are used as a guide to support a Category 2 (neurobehavioral disorder) classification. The literature on the behavioral characteristics of individuals with FAS and related conditions suggests that common problem areas are among those listed page 5. The literature also implies that these areas are problematic because of aberrations in brain processing rather than the result of oppositionality or other emotional disturbance (a concept to be further tested).

Within each "problem area" are a list of key indicators. The clinician is asked to record which indicators are present in the patient, after considering age, by circling **Y**es, **N**o, **U**nknown or **T**oo young to assess. The clinician is also asked to rank the overall likelihood that each "problem area" is explained in part or in whole by organic brain dysfunction using the following scale:

Very Likely	**(3)**	The caregiver and/or patient are able to provide complete information in the interview and the information they provide strongly supports the problem area is organic in origin because the patient can not perform in that area at an appropriate level for age and intelligence rather than will not perform.
Somewhat Likely	**(2)**	The distinction between the patient can not perform and the patient will not perform is less clear because the person being interviewed is unable to provide adequate information or because the origin of the problem is mixed.
Unlikely	**(1)**	Adequate information is available and there is no evidence of a brain processing deficit.
Unable to Judge	**(0)**	Information in this area is not available either because assessments have not been made yet or the child is too young to be assessed in the area.

Table 5: Deriving the 4-Digit Diagnostic Code Rank for Organic Brain Dysfunction

4-Digit Diagnostic Code Rank*	Organic Brain Dysfunction Scale	Confirmatory Findings
4	**Definite** *referred to as static encephalopathy*	● microcephaly, OFC ≤ -2 S. D. *and / or* ● abnormalities on brain images diagnostic of prenatal alteration *and / or* ● evidence of persistent neurologic findings likely to be of prenatal origin *and / or* ● I. Q. score ≤ 60
3	**Probable** *referred to as static encephalopathy*	● Substantial deficiencies or discrepancies across multiple areas of brain performance such as cognition, achievement, adaptation, neurologic "soft" signs, and language. Generally three or more areas should be found aberrant.
2	**Possible** *referred to as neurobehavioral disorder*	● Historical information / personal observations strongly suggest that the possibility of an "organic" condition exists, but data to this point does not permit a category 3 or 4 classification.
1	**Absent**	● No problems likely to have an organic component are presented.

* Transfer the resulting 4-Digit Diagnostic Code Rank for Organic Brain Dysfunction to the 4-Digit Diagnostic Code Grid on page 1 of the FAS Diagnostic Evaluation Form.

III. Diagnostic Evaluation Form Instructions

B.4. Scoring Alcohol Exposure

Table 6: Deriving the 4-Digit Diagnostic Code Rank for Alcohol Exposure

4-Digit Diagnostic Code Rank*	Gestational Alcohol Exposure Category	Description
4	High Risk	● Report by the birth mother or directly from another individual who saw the mother drink during pregnancy *and* ● Report of exposure likely to produce blood alcohol concentrations > 100mg% weekly, early in pregnancy.
3	Some Risk	● Report by birth mother, other direct observer, or reliable source *and* ● Drinking occurred in gestation in frequencies and volumes less than in category (4) or otherwise unspecified.
2	Unknown Risk	● Gestational exposure is simply not known or information is of uncertain reliability
1	No Risk	● The mother reliably acknowledges no exposure to alcohol in pregnancy, or minimal exposure (i.e. 1 drink less than once per month)

* Transfer the resulting 4-Digit Diagnostic Code Rank for Alcohol Exposure to the 4-Digit Diagnostic Code Grid on page 1 of the FAS Diagnostic Evaluation Form.

IV. Diagnostic Categories

The 256 Diagnostic Codes can be logically grouped into 22 Diagnostic Categories

Category	Name
A	Fetal alcohol syndrome (alcohol exposed)
B	Fetal alcohol syndrome (alcohol exposure unknown)
C	Atypical fetal alcohol syndrome (alcohol exposed)
D	Fetal alcohol syndrome phenocopy (no alcohol exposure)
E	Sentinel physical findings / static encephalopathy (alcohol exposed)
F	Static encephalopathy (alcohol exposed)
G	Sentinel physical findings / neurobehavioral disorder (alcohol exposed)
H	Neurobehavioral disorder (alcohol exposed)
I	Sentinel physical findings (alcohol exposed)
J	No cognitive/behavioral or sentinel physical findings detected (alcohol exposed)
K	Sentinel physical findings / static encephalopathy (alcohol exposure unknown)
L	Static encephalopathy (alcohol exposure unknown)
M	Sentinel physical findings / neurobehavioral disorder (alcohol exposure unknown)
N	Neurobehavioral disorder (alcohol exposure unknown)
O	Sentinel physical findings (alcohol exposure unknown)
P	No cognitive/behavioral or sentinel physical findings detected (alcohol exposure unknown)
Q	Sentinel physical findings / static encephalopathy (no alcohol exposure)
R	Static encephalopathy (no alcohol exposure)
S	Sentinel physical findings / neurobehavioral disorder (no alcohol exposure)
T	Neurobehavioral disorder (no alcohol exposure)
U	Sentinel physical findings (no alcohol exposure)
V	No cognitive/behavioral or sentinel physical findings detected (no alcohol exposure)

V. 4-Digit Diagnostic Codes Within each Diagnostic Category

Category	Diagnostic Name and Codes
A	Fetal alcohol syndrome (alcohol exposed) 3433 4433 3434 4434 3443 4443 3444 4444
B	Fetal alcohol syndrome (alcohol exposure unknown) 3432 4432 3442 4442
C	Atypical fetal alcohol syndrome (alcohol exposed) 1443 1434 2434 3334 4334 2443 1444 2444 3344 4344
D	Fetal alcohol syndrome phenocopy (no alcohol exposure) 3431 4341 4441 3441 4431
E	Sentinel physical findings / static encephalopathy (alcohol exposed) 1333 1433 2344 3143 3243 4133 4233 4333 1334 2333 2433 3144 3244 4134 4234 4343 1343 2334 3133 3233 3333 4143 4243 1344 2343 3134 3234 3343 4144 4244
F	Static encephalopathy (alcohol exposed) 1133 1144 1243 2134 2233 2244 1134 1233 1244 2143 2234 1143 1234 2133 2144 2243

VII. Clinical Summaries
For each of the 22 Diagnostic Categories

Clinical summaries for each of the 22 Diagnostic Categories are presented on the following pages listed alphabetically from A through V. A complete list of the 22 categories is presented in Section IV.

These summaries can be used as the first page of the final diagnostic report. They often require minor alterations or additions to conform to the specifics of an individual case.

A

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Fetal Alcohol Syndrome**
(2) Alcohol exposed

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of organic brain damage which occur in individuals exposed to alcohol during gestation. On the attached sheets are the specific findings in this patient's case which led to our conclusion that there was sufficient evidence to make the diagnosis of fetal alcohol syndrome.

Although we believe that the patient clearly has fetal alcohol syndrome, this does not mean that alcohol exposure during pregnancy is the only cause of the patient's current problems. A number of other factors could be contributing to the present situation, such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. Such factors may partly explain why there is so much variability in the kinds of specific difficulties that patients with FAS have.

Individuals with FAS have organic brain damage as a major component of their cognitive and behavioral problems and should be viewed individuals with disabilities. The fetal alcohol syndrome diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific concerns that have been identified that need attention.

C

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Atypical Fetal Alcohol Syndrome**
(2) Alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies and evidence of organic brain damage occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS. Indeed, many patients who have been exposed to alcohol show most, but not all, of the classic features of this syndrome. We use the term "atypical fetal alcohol syndrome" when a patient's characteristic features are very close to the classic features of FAS and the alcohol history strongly suggests that alcohol exposure during gestation was at high risk and likely to have played a role in the syndrome. Patients with atypical FAS either have the full set of facial anomalies found with FAS and evidence of organic brain damage, but do not have growth deficiency; or they have growth deficiency and evidence of organic brain damage, and most but not all of the FAS facial features. As you can see from the enclosed list of features found in this patient, the patient meets the criteria for atypical FAS. Patients diagnosed with atypical FAS must have confirmed exposure to high levels of alcohol during gestation.

In addition to gestational exposure to alcohol, a number of other factors could be contributing to the patient's current problems, such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. Such factors may partly explain why there is so much variability in the kinds of specific difficulties that patients with FAS experience.

Patients with atypical FAS have organic brain damage as a major component of their cognitive and behavioral problems and should be viewed as having a disability. The diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific concerns that have been identified that need attention.

D

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Fetal Alcohol Syndrome Phenocopy**
(2) No alcohol exposure

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies and evidence of organic brain damage occurring in patients exposed to alcohol during gestation. On the attached sheets are the specific findings in this patient's case which led to our conclusion that the patient has all of the features of FAS. However, there is good reason to believe this patient was not exposed to alcohol during gestation.

Most syndromes can occasionally arise from an alternate cause. Presumably, this is the situation here. A number of other factors could be contributing to the present situation, such as the patient's genetic background and other potential exposures or problems during pregnancy, and various experiences since birth.

Whatever the cause of this patient's syndrome, there is organic brain damage which is a major component of their cognitive and behavioral problems and the patient should be viewed as a person with a disability. The syndrome diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific concerns that have been identified that need attention.

E

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Static encephalopathy**
(2) Sentinel physical findings
(3) Alcohol exposed

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of organic brain damage in individuals exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, some but not all of the characteristic growth and facial features associated with FAS were present and there was evidence of organic brain damage as you will see noted on the attached pages. There was also a clear history of exposure to significant amounts of alcohol during gestation. In this situation, we use the terms "static encephalopathy" and "sentinel physical findings" to describe the patient's condition. Static encephalopathy literally means non-progressive brain dysfunction. The diagnoses of "static encephalopathy and sentinel physical findings" in the presence of alcohol exposure do not mean that alcohol is the only cause of the problem. A number of other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during gestation, and various experiences since birth. These kinds of differences may partly explain why there is so much variability in the kinds of specific difficulties that patients with static encephalopathy and alcohol exposure have.

The diagnoses made today are based on the information available at the time of this assessment. If this patient's alcohol exposure was considered "low risk" and new information is uncovered which documents higher exposures; or if the patient's facial features, growth, or neurobehavioral problems were judged "probable" and further growth or development suggest a "definite" problem is present, then reconsideration of the diagnosis of fetal alcohol syndrome would be appropriate. Alternately other birth defect syndromes not related to alcohol exposure may also need reconsideration.

Individuals with static encephalopathy have organic brain damage which is a major component of their cognitive and behavioral problems and they should be viewed as individuals with disabilities. The static encephalopathy diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

G

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Neurobehavioral disorder**
(2) Sentinel physical findings
(3) Alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies and evidence of organic brain damage occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS. On the attached sheets you will find our specific observations in this case. We found that some, but not all, of the characteristic physical findings seen in patients with FAS were present. There was not strong evidence that the patient's cognitive/behavioral problems were clearly due to organic brain damage, but there were suggestions that this was the case. In this situation we use the term "neurobehavioral disorder" to emphasize the possibility that the problems may not be entirely due to postnatal experiences. Certainly a number of other factors could be contributing to the patient's condition such as genetic background, other potential exposures or problems during pregnancy, and various experiences since birth.

The diagnoses made today are based on the information at hand. If further testing is done which makes the likelihood of organic brain damage of prenatal cause more likely, then an alternate diagnosis could be considered. Alternately other birth defect syndromes not related to alcohol exposure may also need consideration.

In any event, the diagnosis of neurobehavioral disorder means that issues of abnormal brain structure and brain impairment need to be considered with implications for educational planning, societal expectations, and health. On the attached sheet, you will find a list of specific problems that have been identified that need attention.

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Sentinel physical findings**
(2) Alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies and evidence of organic brain damage occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS. Some individuals have the growth deficiency and/or facial characteristics, but do not have evidence of organic brain damage. We refer to this condition as "Sentinel physical findings / Alcohol exposed". On the attached sheets are the specific findings in this patient's case which indicate that the characteristic growth deficiencies and/or facial features are, to some extent, compatible with FAS, but at this time there is no clear evidence of cognitive or behavioral problems that strongly suggest organic brain damage. At such time in the future that organic brain damage is found through images of the brain, neurologic testing or cognitive behavioral assessment, then the diagnosis of fetal alcohol syndrome should be reconsidered. Other birth defect syndromes that are not related to alcohol exposure should also be considered as alternate explanations for the patient's problems.

Q

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis
(1) Static encephalopathy
(2) Sentinel physical findings
(3) No alcohol exposure

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of organic brain damage in individuals exposed to alcohol during gestation.

In this patient's case, some but not all of the characteristic growth and facial features associated with FAS were present, there was evidence of organic brain damage, and the patient was reportedly not exposed to alcohol during gestation. Based on these observations, which are documented on the attached pages, this patient does not have FAS, but does have static encephalopathy and some of the physical characteristics found after alcohol exposure. Static encephalopathy literally means non-progressive brain dysfunction. A number of factors other than alcohol could be contributing to the patient's current cognitive/behavioral problems such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. The physical findings may suggest that other syndrome diagnoses be considered.

The diagnosis made today is based on the information available at the time of this assessment. In the event that a confirmed history of alcohol exposure is obtained, or if the patient's facial features or growth become more abnormal, then further diagnostic consideration would be appropriate. . Alternately other birth defect syndromes not related to alcohol exposure may also need reconsideration.

Individuals with static encephalopathy have organic brain damage which is a major component of their cognitive and behavioral problems and they should be viewed as a person with a disability. The static encephalopathy diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Static encephalopathy**
(2) No alcohol exposure

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies and evidence of organic brain damage occurring in patients exposed to alcohol during gestation.

In this patient's case, no growth deficiency or characteristic set of facial features were found and the patient was not exposed to alcohol during gestation so the patient does not have FAS, but there was evidence of organic brain damage as you will see noted on the attached pages. In this situation, we use the term "static encephalopathy" to describe the patient's condition. Static encephalopathy literally means non-progressive brain dysfunction. On the attached sheets are the specific findings in this patient's case which led us to this conclusion. A number of factors could be contributing to the patient's current cognitive/behavioral problems such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth.

The diagnosis made today is based on the information available at the time of this assessment. In the event that a confirmed history of alcohol exposure is obtained, or if the patient's facial features or growth become more abnormal, then further diagnostic consideration would be appropriate. . Alternately other birth defect syndromes not related to alcohol exposure may also need reconsideration.

Individuals with static encephalopathy have organic brain damage which is a major component of their cognitive and behavioral problems and they should be viewed as individuals with disabilities. THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis
(1) Neurobehavioral disorder
(2) Sentinel physical findings
(3) No alcohol exposure

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies and evidence of organic brain damage occurring in patients exposed to alcohol during gestation.

On the attached sheets you will find our specific observations in this case. We found that some, but not all, of the sentinel physical findings seen in patients with FAS were present and the patient was reportedly not exposed to alcohol during gestation. There was not strong evidence that the patient's cognitive/behavioral problems were clearly due to organic brain damage, but there were suggestions that this may be the case. In this situation we use the term "neurobehavioral disorder" to emphasize the possibility that the problems may not be entirely due to postnatal experiences. The patient also had some of the physical characteristics often found with alcohol exposure. In this case, however, there was no alcohol exposure, therefore, these physical findings might suggest that other syndrome diagnoses be considered. Certainly a number of factors could be contributing to the patient's condition such as genetic background, other potential exposures or problems during pregnancy, and various experiences since birth.

The diagnosis made today is based on the information available at the time of this assessment. In the event that a confirmed history of alcohol exposure is obtained, or if the patient's facial features or growth become more abnormal or if further testing finds further evidence of organic brain damage, then further diagnostic consideration would be appropriate.

In any event, the diagnosis of neurobehavioral disorder means that issues of abnormal brain structure and brain impairment need to be considered with implications for educational planning, societal expectations, and health. On the attached sheet, you will find a list of specific problems that have been identified that need attention.

We wish to acknowledge our colleagues Diane Bailey, R.N., M.S.N., Pediatric Nurse Practitioner, Sharon Beck, M.Ed., Educational Counselor, Heather Carmichael Olson, Ph.D., Developmental Psychologist, Sandra G. B. Clarren, Ph.D., Educational Psychologist, Truman Coggins, Ph.D., Language Pathologist, Julie Gelo, Family Advocate, Tracy Jirikowic, MS, OTR/L Occupational Therapist and Tina Talbot, M.S.W., Social Worker who use this Guide weekly and have helped us to hone the material on an ongoing basis. Their helpful criticism and thoughtful insights have been invaluable. We also wish to thank Kathleen Tharp, Kathy Briggs-Jones and Heather Grigg B.A. who readily offered their assistance when needed. Finally, a very special thanks is extended to all of our patients and their families who have contributed a wealth of knowledge and information to the development of this guide.

Preface

This Diagnostic Guide is the second edition. Based on our own experience and feedback from others, we continue to make modifications that enhance accuracy, improve clarity, and increase ease of usage. We hope you will find this new approach to the diagnosis of individuals with fetal alcohol exposure helpful and broadly applicable.

I. Introduction

Fetal alcohol syndrome (FAS).

FAS is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The definition of the fetal alcohol syndrome has changed little since the 1970's when the condition was first described and refined [1,2,3,4]. The condition has been broadly characterized by pre- and/or postnatal growth deficiency, a characteristic set of minor facial anomalies, and evidence of prenatal alteration in brain function such as microcephaly from birth, neurologic problems without postnatal antecedents, or complex patterns of functional disability.

The difficulty with diagnosing FAS and other disabilities associated with in utero alcohol exposure.

For the trained clinician, dysmorphologist, or clinical geneticist there is little difficulty in making the diagnosis of FAS when the typical anomalies in growth, face, and brain are all extreme and the alcohol exposure is conclusive and substantial. But the physical, cognitive and behavioral features are not dichotomous, that is either normal or clearly abnormal. Rather, the features, and indeed the history of alcohol exposure, all range along separate continua from normal to clearly abnormal and distinctive.

In the absence of accurate, reproducible and unbiased methods for measuring and recording the severity of exposure and outcome in individual patients, diagnoses will continue to vary widely from clinic to clinic. From a clinical perspective, diagnostic misclassification leads to inappropriate patient care, increased risk for secondary disabilities[5] and missed opportunities to achieve prevention. From a public health perspective, diagnostic misclassification leads to inaccurate estimates of incidence and prevalence. Inaccurate estimates thwart efforts to allocate sufficient social and health care services to this high-risk population and preclude accurate assessment of primary prevention intervention efforts. From a clinical research perspective, diagnostic misclassification reduces the power to identify between-group contrasts within studies. Non-standardized diagnostic methods limit the ability to compare outcomes between studies.

The primary limitations in the current practice of diagnosing individuals with prenatal alcohol exposure include:

1. There is no standardized clinical definition of FAS. Rather, there are diagnostic guidelines that physicians and medical researchers are encouraged to follow, but the guidelines are not sufficiently *specific* to assure diagnostic accuracy or precision.

   According to the latest proposed diagnostic guidelines published by Sokol and Clarren[3] which are a minor modification of the 1980 definition of FAS by the Fetal Alcohol Study Group of the Research Society for Alcoholism [6]:

"The diagnosis of FAS can only be made when the patient has signs of abnormality in each of the three categories: 1) Prenatal and/or postnatal growth retardation (weight and/or length below the 10th percentile when corrected for gestational age), 2) central nervous system involvement (including neurological abnormality, developmental delay, behavioral dysfunction or deficit, intellectual impairment and/or structural abnormalities, such as microcephaly (head circumference below the 3rd percentile) or brain malformations found on imaging studies or autopsy and 3) a characteristic face, currently qualitatively described as including short palpebral fissures, an elongated midface, a long and flattened philtrum, thin upper lip, and flattened maxilla."

Although these descriptions do provide guidance, they are not sufficiently specific to assure diagnostic accuracy and precision. The guidelines for CNS dysfunction do not address how many areas of deficit must be present, how severe the deficits must be or what level of documentation must exist to substantiate the presence of the deficit (i.e., parental history, psychometric testing or structural imaging). The guidelines for the facial phenotype are equally nonspecific. How many facial features must be present, how severe must the features be and what scale of measurement should be used to judge their severity? One need only read the clinical literature or review medical records, birth certificates, birth defect registries or ICD-9 codes to see how variably these criteria are interpreted, applied and reported [7,8,9,10,11].

2. There is a lack of objective, quantitative scales to measure and report the magnitude of expression of key diagnostic features.

   For example, although a thin upper lip and smooth philtrum are key diagnostic features[12], quantitative measurement scales have never been used to measure thinness or smoothness and guidelines have never been established for how thin or smooth the features must be. Objective quantitative scales would not only improve accuracy and precision, but would also establish a common descriptive language for communicating outcomes in medical records and the medical literature.

3. The term FAS fails to convey the diversity of disability present in individuals with FAS.

   No two individuals with FAS present with the same constellation of anomalies and disabilities. Growth, facial phenotype, CNS dysfunction and alcohol exposure all vary along separate continua. The term FAS only conveys that the condition is permanent and was caused by prenatal alcohol exposure. The term does not convey what the individual's disabilities are. A nomenclature that better conveys the diversity of outcomes among individuals with prenatal exposure would benefit both the patient's caregivers and their medical/social/educational care network.

4. The term fetal alcohol effects (FAE) is broadly used and poorly defined.

   The term 'suspected fetal alcohol effects' was first introduced into the medical literature in 1978 and was defined as 'less complete partial expressions' of FAS in individuals with prenatal alcohol exposure[2]. Based on this definition, an individual whose mother drank a few glasses of wine

intermittently throughout pregnancy and presented with attention deficit hyperactivity disorder would be diagnosed FAE. So would an individual whose mother drank a fifth of vodka daily throughout pregnancy and presented with microcephaly, severe mental retardation, cleft palate and severe growth deficiency. The broad use of this term and the reluctance to abandon it points to the clear need to develop diagnostic terms for individuals with prenatal alcohol exposure who present with physical anomalies and/or cognitive/behavioral disabilities, but do not have FAS. New diagnostic terms, which more finely differentiate the variable exposures and outcomes of these individuals without implying alcohol as the sole causal agent, are needed.

5. Clinical terms like FAE[13], alcohol related birth defects (ARBD)[4] and alcohol related neurodevelopmental disorder (ARND)[4] inappropriately imply a causal link between exposure and outcome in a given individual. Leading dysmorphologists in the field of FAS diagnosis have formally requested that the term FAE no longer be used for this reason[13].

   With the likely exception of the facial phenotype, no other physical anomalies or cognitive/behavioral disabilities observed in an individual with prenatal alcohol exposure are necessarily specific to (caused only by) their prenatal alcohol exposure. Features such as microcephaly, neurological abnormalities, attention deficit, mental retardation and growth deficiency often occur in individuals with prenatal alcohol exposure, but also often occur in individuals with no prenatal alcohol exposure.

A new approach to diagnosis.

Each of the above limitations has been overcome with the development the "*4-Digit Diagnostic Code*" introduced in this guide. The four digits reflect the magnitude of expression of four key diagnostic features of FAS in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) brain dysfunction, and (4) gestational alcohol exposure. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic" presence of the FAS feature.

Benefits of the new diagnostic approach.

This new approach:

1. Greatly increases diagnostic precision and accuracy through the use of objective, quantitative measurement scales and specific case definitions.

2. Better characterizes the full spectrum of disabilities of alcohol exposed individuals who do and do not have FAS.

3. Documents the presence of alcohol exposure without judging its causal role.

4. Provides a quantitative measurement and reporting system that can be used independent of the clinical case definitions.

While this document might at first appear overly complex and perhaps daunting, one will find that this new diagnostic approach is logical and easy to use and will greatly facilitate the proper description and classification of patients presenting with all possible combinations of outcomes and exposure.

Other syndromes

The methods of diagnosing fetal alcohol syndrome and related conditions arise from the larger fields of teratology and dysmorphology (clinical genetics). It is essential to remember that isolated features in many birth defect syndromes overlap with FAS. A few examples of conditions often easily confused with FAS include Aarskog syndrome, fragile-x syndrome, fetal hydantoin syndrome and Noonan syndrome. Furthermore it is likely that this diagnostic approach to organizing dysmorphic features and issues of cognitive and behavioral problems could be used for patients exposed to other potentially teratogenic substances instead of or in addition to alcohol. This diagnostic guide is "FAS specific" but this in no way should imply that the diagnostician need not consider alternate syndromic diagnoses and medical conditions at all times.

II. FAS Diagnostic Evaluation Form

The FAS Diagnostic Evaluation Form guides the clinical team in the collection, recording, and interpretation of all key information used to derive an accurate and precise diagnosis. Although the most accurate diagnoses are derived when complete information is available across all domains, complete information is not always available or obtainable. This is especially true with psychometric assessments. Although space has been provided to record a full complement of assessments, we are not implying that all of these assessments must be conducted to derive a diagnosis. It is the responsibility of the clinical team to select the most appropriate psychometric assessment battery.

The form also serves as a template for efficient generation of the final medical summary note.

Where is the information for the Diagnostic Form obtained from?

The information recorded in the Diagnostic Form is obtained from four primary sources:

1. The New Patient Information Form completed by the caregivers (Appendix 1).
2. Medical/psychological/educational assessments conducted prior to the diagnostic evaluation.
3. Assessments administered by the clinical staff at the time of the diagnostic evaluation.
4. The caregiver/patient interview conducted at the time of the diagnostic evaluation

When is the form completed and by whom?

The form is completed by the clinical staff before and during the patient's clinic visit. Typically, the clinician completes the following sections: growth, structural and neurologic brain function, facial features, alcohol exposure and co-morbidities. The occupational therapist, psychologist and language pathologist complete the psychometric measures of brain function and the results of the caregiver interview are completed by the clinician and psychologist.

MATERNAL ALCOHOL USE

Alcohol consumption of the birth mother

Before pregnancy: Average number of drinks per drinking occasion: _____

Maximum number of drinks per occasion: _____

Average number of drinking days per week: _____

Type of alcohol consumed ___Wine, ___ Beer, ___ Liquor, ___ Unk., ___ Other *(specify)* _____

During pregnancy: Average number of drinks per drinking occasion: _____

Maximum number of drinks per occasion: _____

Average number of drinking days per week: _____

Type of alcohol consumed ___ Wine, ___ Beer, ___ Liquor, ___ Unk., ___ Other *(specify)* _____

Trimester(s) in which alcohol was consumed ____ 1st ____ 2nd ____ 3rd ____ Unk. ____ None

	No	Suspected	Yes	Unknown
Was the birth mother ever diagnosed with alcoholism?	___	_____	___	_____
Was the birth mother ever reported to have a problem with alcohol?	___	_____	___	_____
Did the birth mother ever receive treatment for alcohol addiction?	___	_____	___	_____
Was alcohol use during this pregnancy positively confirmed?	___	_____	___	_____

If, yes, source of confirmation _____

Reported use of alcohol during pregnancy is: ___ Reliable, ___ Somewhat reliable, ___ Of unknown reliability

Other information about alcohol use during pregnancy: _____

_____

_____

4-DIGIT RANK for Alcohol Exposure

4-Digit Diagnostic Code Rank	Gestational Alcohol Exposure Category	Description
4	High Risk	● Alcohol use during pregnancy CONFIRMED *and* ● Exposure pattern is consistent with the medical literature placing the fetus at "high risk" (generally high peak blood alcohol concentrations delivered at least weekly in early pregnancy).
3	Some Risk	● Alcohol use during pregnancy CONFIRMED *and* ● Drinking occurred in gestation in frequencies and volumes less than in category (4) or exact amounts unknown.
2	Unknown Risk	● Gestational exposure is simply not known or information is of questionable reliability
1	No Risk	● Alcohol use during pregnancy is CONFIRMED to be completely ABSENT.

Circle the 4-Digit Diagnostic Code Rank in the table above that best reflects the patient's gestational Alcohol Exposure Category

III. Diagnostic Evaluation Form Instructions

A. The 4-Digit Diagnostic Code

What are the 4 Digits?

The four digits reflect the magnitude of expression of the four key diagnostic features of FAS in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) brain dysfunction, and (4) gestational alcohol exposure. The 4-Digit Diagnostic Code is generated at the completion of the diagnostic evaluation using information recorded on the FAS Diagnostic Evaluation Form. The code is derived following the directions in Sections III. B. 1 through B. 4.

4-Digit Diagnostic Code Grid

3 4 4 4

Growth Deficiency	FAS Facial Features	Brain Dysfunction		Growth	Face	Brain	Alcohol		Gestational Alcohol
significant	severe	definite	(4)		X	X	X	(4)	high risk
moderate	moderate	probable	(3)	X				(3)	some risk
mild	mild	possible	(2)					(2)	unknown
none	absent	unlikely	(1)					(1)	no risk

The 4-Digit Diagnostic Code 3444 inserted in the grid is one of twelve that qualifies as a diagnosis of FAS.

How are the 4 Digits ranked?

The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic" presence of the FAS feature. Specific guidelines for ranking the magnitude of each of the FAS features are presented in Section III.B.

How many 4-Digit Diagnostic Codes are there?

There are 256 possible 4-Digit Diagnostic Codes ranging from 1111 to 4444. The 256 codes and their corresponding clinical names are listed in numerical order in Section VI.

We have created diagnostic categories for all potential codes, even though to date we do not expect to see all of these situations in clinic. For example, 1111 reflects a normal exam in an individual who was definitely not exposed to alcohol. Such patients are seen by primary physicians daily, but are unlikely to be referred to a FAS clinic. Other codes like 4441 would represent a “classic” clinical presentation of FAS with a confirmed absence of alcohol exposure during gestation. We have never seen such a case (or phenocopy), but we may some day.

How many different Clinical Diagnostic Categories are there?

Each 4-Digit Diagnostic Code falls into one of 22 unique Clinical Diagnostic Categories (labeled A through V). A list of the 22 Diagnostic Categories is presented in Section IV. A list of the 4-Digit Diagnostic Codes, which fall within each Clinical Diagnostic Category, is presented in Section V.

What are the names of the Clinical Diagnostic Categories?

The following terms are used in varying combinations to name the 22 diagnostic categories. They include:

- **Sentinel Physical Findings:**
  The adjective *"sentinel"* refers to physical findings that are key diagnostic features of FAS. These include a unique cluster of minor facial anomalies (short palpebral fissures, thin upper lip and a smooth philtrum) and growth deficiency. Other physical findings (major or minor anomalies) may be detected instead of or in addition to these sentinel findings that may suggest alternate or additional conditions. There are places on the Diagnostic Evaluation Form to record and interpret other physical findings.

- **Static Encephalopathy:**
  The term *"encephalopathy"* refers to any physical abnormality in the brain. Such abnormalities can vary in magnitude from structural defects that are apparent on an image like a CT scan to micro-cellular abnormalities that can only be confirmed with tissue samples or neurochemical analysis. The term *"static"* means that the physical abnormality in the brain is unchanging, neither progressing nor regressing. The term *"static encephalopathy"* is used in this diagnostic system when the patient presents with cognitive/behavioral dysfunction which is accompanied by structural, neurologic, and/or psychometric measures which strongly support the presence of structural brain abnormalities. The term does not define or suggest any specific pattern of structural abnormality or cognitive/behavioral dysfunction.

- **Neurobehavioral Disorder:**
  This term is used in this diagnostic system when the patient presents with cognitive/behavioral dysfunction, but structural, neurologic and psychometric measures do not unequivocally support the presence of structural brain abnormalities.

- **Alcohol (Exposed, Not Exposed, Exposure Unknown):**
  This term is used to reflect the exposure status of the fetus. It is reported independent of outcome and does not imply a causal association between exposure and outcome.

- **Fetal Alcohol Syndrome:**
  The term FAS is used to refer to patients who present with one of twelve 4-Digit Diagnostic Code combinations reflecting growth deficiency, the FAS facial phenotype and brain dysfunction.

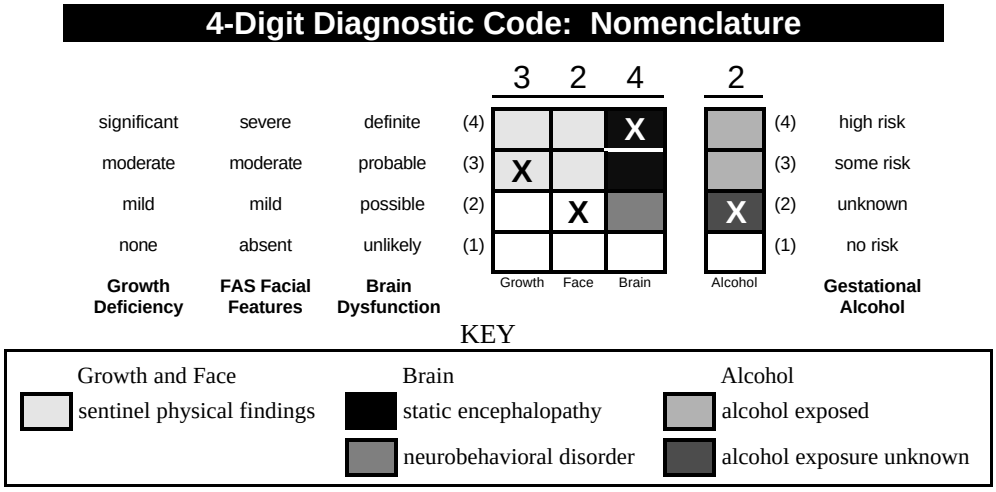
- **Atypical Fetal Alcohol Syndrome:**
  This term is introduced for use with a relatively small group of patients who have static encephalopathy, most of the sentinel physical findings of FAS, and were alcohol exposed. Given the fact that variable presentation is the rule rather than the exception after teratogenic exposure in gestation, we felt it was appropriate to establish this marginal category.

The names assigned to each diagnostic category reflect the patient's clinical outcome and alcohol exposure. The names are listed in Sections IV and V. The first three categories (A through C) meet the criteria for a clinical diagnosis of FAS and are named as such. The fourth category (D) applies to the patient who presents with all of the features of FAS, but has a confirmed *absence* of gestational alcohol exposure. This category is referred to as a FAS Phenocopy and has yet to be observed.

The remaining 19 categories (E through V) do not meet the minimum criteria for FAS and are subsequently named to reflect the Likert ranking of each digit in the 4-Digit Diagnostic Code. For example, a code of 4333 is the Diagnostic Category called "*sentinel physical findings / static encephalopathy (alcohol exposed)*". Many of these patients might have previously been referred to variably as having possible fetal alcohol effects (PFAE), alcohol related birth defects (ARBD), or alcohol related neurodevelopmental disorder (ARND). This new nomenclature supersedes all of these terms.

How are the Clinical Diagnostic Category names constructed?

- Growth deficiency and facial characteristics are physical features. When either feature receives a rank of 3 or 4, *sentinel physical findings* is placed at the beginning of the name.
- When brain dysfunction receives a rank of 2, the term *neurobehavioral disorder* is included in the name. When brain dysfunction receives a rank of 3 or 4, the term *static encephalopathy* is included in the name.
- When alcohol exposure receives a rank of 3 or 4, (*alcohol exposed*) is placed at the end of the name. When alcohol exposure receives a rank of 2, (*alcohol exposure unknown*) is placed at the end of the name.



The 4-Digit Code 3242 would receive the clinical name *sentinel physical findings / static encephalopathy / alcohol exposure unknown.* A code of 1223 would receive the clinical name *neurobehavioral disorder / alcohol exposed.*

Which new Diagnostic Categories represent the category we use to call FAE?

Diagnostic Categories E through I would have previously been referred to as "fetal alcohol effects", "alcohol related birth defects" or "alcohol related neurobehavioral disorder". Categories J through V are new categories that describe a large number of patient groups who have never been adequately classified or described in the past.

How do you explain the diagnosis to the patient?

At the end of this manual (Section VII) are summary explanations for each of the 22 Clinical Diagnostic Categories. These summaries can be used as the first page of the patient's final medical summary note.

III. Diagnostic Evaluation Form Instructions

B.1. Scoring Growth Deficiency

What type of growth deficiency are we looking for?

We are looking for growth deficiency characteristic of a teratogenic insult, not characteristic of postnatal environmental factors such as nutritional deprivation or chronic illness. We want to answer the question '*What is the patient's growth potential after controlling for parental height and postnatal environmental influences?'* Growth deficiency of teratogenic origin is likely to present as a relatively consistent impairment over time (i.e., the patient's growth follows the normal curve, but is below genetic expectation for family background). In contrast, growth deficiency due to postnatal environmental influences is likely to present as periodic fluctuations in the curve. Separating the two growth patterns requires astute clinical judgment.

The method described below allows one to rank a patient's overall growth pattern on a single 4-point Likert scale with 1 equal to normal and 4 equal to significantly deficient. Not all patients will have complete growth curves available, therefore, a guide is provided below for prioritizing the ranking of the patient's growth over a lifetime

Method for ranking the growth component of the 4-Digit Diagnostic Code

A. Height should be age and gender adjusted and should be adjusted for parental height, if possible.

B. Weight should be age and gender adjusted. Weight is not adjusted for height. Normal growth charts are provided in Section VIII.

C. For ranking purposes, the growth curve is separated into two parts:
   1. Prenatal growth (birth measures)
   2. Postnatal growth (all measures collected after birth)

   Select the part of the growth curve with the greatest deficiency in the height centile.

   If the prenatal height centile is lower than all postnatal height centiles, proceed to section D for instructions on how to rank prenatal growth.

   If any of the postnatal height centiles are lower than the prenatal height centile, select the point or consecutive points on the curve that reflect the lowest height centiles that cannot be attributed to postnatal environmental influences such as nutritional deprivation or chronic illness. If the height deficiency is reflected in a series of points on the curve, as opposed to a single point, rank the level of deficiency based on the centile range where the majority of the points fall. Proceed to section D for instructions.

D. Rank the level of deficiency of the height and weight centiles for the section of the curve with greatest deficiency in the height centile by circling A, B or C in the ABC-Score table at the bottom of page 1 of the FAS Diagnostic Evaluation Form. This ABC-Score table is duplicated below as Table 1.

Table 1: Deriving the ABC-Score for Growth

Centile Range	Circle the ABC-Score for: Height	Weight
≤ 3rd	C	C
>3rd and ≤ 10th	B	B
>10th	A	A

E. Next, refer to Table 2 to determine the *4-Digit Diagnostic Code Rank* of the Height-Weight ABC-Score recorded in Table 1. Transfer the resulting 4-Digit Diagnostic Code Rank for growth to the 4-Digit Diagnostic Code Grid at the top of page 1 of the FAS Diagnostic Evaluation Form.

Table 2: Converting the Growth ABC-Score to a 4-Digit Diagnostic Code Rank for Growth

4-Digit Diagnostic Code Rank	Growth Deficiency Category	Height-Weight ABC-Score Combinations
4	Severe	CC
3	Moderate	CB, BC
2	Mild	CA, BB, AC
1	None	BA, AB, AA

Example for Scoring Growth Deficiency

Patient's Growth Record:

	Age (years)	Height Centile	Weight Centile
birth	0.0	5 %	2 %
	1.5	10 %	15 %
	5.0	12 %	20 %
	7.0	12 %	10 %
	15.5	15 %	30 %

Assume the clinical records rule-out any environmental influence on postnatal measures.

Scoring:

- Priority would be placed on ranking the birth measures because the birth height centile is lower than all postnatal height centiles recorded.
- Birth height would be ranked **> 3rd and ≤ 10th** (or Rank B) in Table 1.
  Birth weight would be ranked **≤ 3rd** (or Rank C) in Table 1.

Table 1: Deriving the ABC Score for Growth

	Circle the ABC-Scores for:	
Centile Range	Height	Weight
≤ 3rd	C	**C**
>3rd and ≤ 10th	**B**	B
>10th	A	A

- The Height-Weight ABC-Score would be **BC** according to Table 2.
- The Growth Deficiency Category would be **Moderate** according to Table 2.
- Moderate growth deficiency receives a rank of **3** in the 4-Digit Diagnostic Code in Table 2.

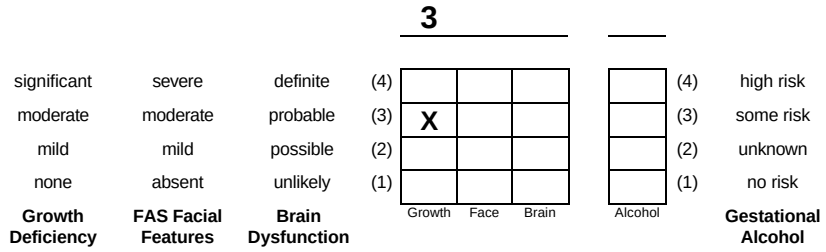
Table 2: Converting the Growth ABC-Score to a 4-Digit Diagnostic Code Rank for Growth

4-Digit Diagnostic Code Rank	Growth Deficiency Category	Height-Weight ABC-Score Combinations
4	Severe	CC
3	**Moderate**	CB, **BC**
2	Mild	CA, BB, AC
1	None	BA, AB, AA

The number **3** would be transferred to the 4-Digit Diagnostic Code Grid on page 1 of the FAS Diagnostic Evaluation Form (as duplicated below).

Result:

4-Digit Diagnostic Code Grid



III. Diagnostic Evaluation Form Instructions

B.2. Scoring the Facial Phenotype

Method for ranking the facial phenotype component of the 4-Digit Diagnostic Code

A. The largest palpebral fissure length (PFL) is measured and ranked according to its z-score (or how many standard deviations above or below the norm it is). The palpebral fissures are adjusted for age and when possible, race. Eyes must be wide open to obtain accurate measures[16, 17]. A normal palpebral fissure length chart is provided in Section VIII[18].

B. The upper lip and philtrum are measured independently using the 5-point pictorial Likert scale presented on the Lip-Philtrum Guide (Figure 1). Lips must be gently closed with no smile to obtain accurate measures (Figure 2)[17]. The physician's eyes must be in the patient's Frankfort Horizontal plane (represented by a line drawn from the external auditory canal to the lower border of the orbital rim). This is crucial for accurate measurement of upper lip thinness (Figure 3)

C. Rank the size, smoothness and thinness of the fissures, philtrum, and upper lip respectively by circling A, B, or C in each column in the ABC-Score table at the bottom of page 2 of the FAS Diagnostic and Evaluation Form. This table is duplicated below as Table 3.

Table 3: Deriving the ABC-Score for Facial Phenotype

5-Point Likert Scale for Philtrum & Lip	Z-score* for Largest Palpebral Fissure	Circle the ABC-Scores for: Palpebral Fissure	Philtrum	Upper Lip
4 or 5	≤ -2 SD	C	C	C
3	>-2 SD and ≤ -1 SD	B	B	B
1 or 2	> -1 SD	A	A	A

* z-score = (patient PFL - normal population PFL)/(normal population PFL standard deviation)

D. Next, refer to Table 4 to determine the *4-Digit Diagnostic Code Rank* based on the ABC-Score derived from Table 3. Transfer the resulting 4-Digit Diagnostic Code Rank for face to the 4-Digit Diagnostic Code Grid on page 1 of the FAS Diagnostic Evaluation Form.

Table 4: Converting the Facial ABC-Score to a 4-Digit Diagnostic Code Rank for Face

4-Digit Diagnostic Code Rank*	Level of Expression of FAS Facial Features	Palpebral Fissure - Philtrum - Lip ABC-Score Combinations
4	Severe	CCC
3	Moderate	CCB, CBC BCC
2	Mild	CCA, CAC, CBB, CBA, CAB, CAA BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	Absent	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

* If facial measures are available at more than one age, score the age when the FAS phenotype is expressed the most. If FAS features are never expressed, score the face between the ages of 3 and 10 years, or at any age if this age range is not available.

Lip – Philtrum Guide 5-Point Likert Ranks	ABC-Scores Philtrum Smoothness	Upper Lip Thinness	Upper Lip Circularity[12]
	C	C	178
	C	C	80
	B	B	65
	A	A	50
	A	A	35

Figure 1. Pictorial examples of the 5-point Likert scales and the ABC scale used to rank upper lip thinness and philtrum smoothness. It is important that the individual's lips are gently closed with no smile as illustrated in Figure 2.

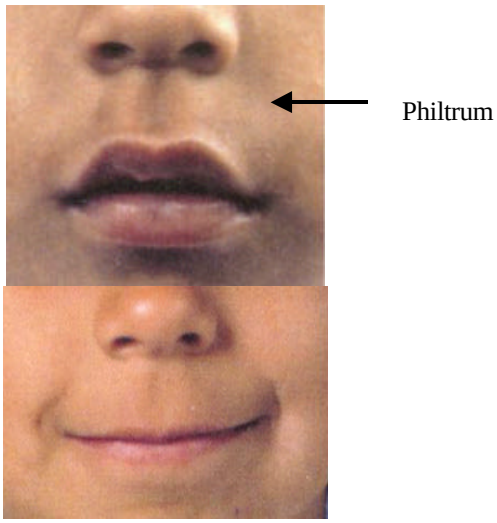


Figure 2. This is the same person with and without a smile. Note that without the smile, the lip and philtrum would both receive a correct Likert rank of # 1. With a smile[19], the lip and philtrum would both receive an incorrect Likert rank of # 5.

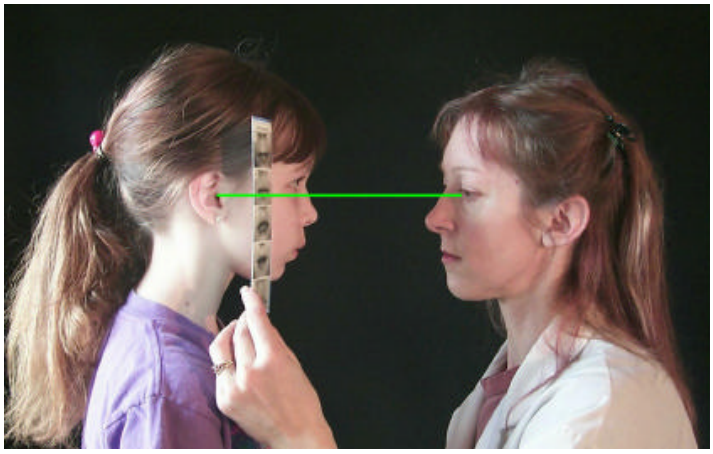

Figure 3. Illustration of a physician aligned in the patient's Frankfort Horizontal plane while using the Lip-Philtrum Guide to rank upper lip thinness and philtrum smoothness. The Frankfort Horizontal plane is defined by a line that passes through the patient's external auditory canal (marked by the tragion) and the lowest border of the bony orbital rim (orbitale). The physician's eyes (or camera lens) should be directly in line with this plane.

Example for Scoring Facial Phenotype

Patient measurements at 10 years of age:

- Palpebral fissure lengths = 2.5 cm which are < -2 SD's from the norm.
- Philtrum smoothness received a score of 5 on the 5-Point photographic Likert scale in Figure 1.
- Upper lip thinness received a score of 3 on the 5-Point photographic Likert scale in Figure 1.

Scoring

- The palpebral fissure lengths receive a Score of “C” in Table 3.

  A philtrum score of 5 corresponds to a score of “C” in Table 3.

  A lip score of 3 corresponds to a score of “B” in Table 3.

- The ABC-Score Combination for Fissure - Philtrum - Lip is **CCB**.

Table 3: Deriving the ABC-Score for Facial Phenotype

5-Point Likert Scale for Philtrum & Lip	Z-score for Largest Palpebral Fissure Length	Circle the ABC-Scores for: Palpebral Fissure	Smooth Philtrum	Thin Upper Lip
4 or 5	≤ -2 SD	**C**	**C**	C
3	>-2 SD and ≤ -1 SD	B	B	**B**
1 or 2	> -1 SD	A	A	A

- A score of CCB indicates that the level of expression of the FAS Facial Features is **MODERATE**.

- A MODERATE expression of the FAS facial features receives a rank of **3** in the 4-Digit Diagnostic Code.

Table 4: Converting the Facial ABC-Score to a 4-Digit Diagnostic Code Rank

4-Digit Diagnostic Code Rank	Level of Expression of FAS Facial Features	Palpebral Fissure - Philtrum - Lip ABC-Score Combinations
4	Severe	CCC
3	**Moderate**	**CCB**, CBC BCC
2	Mild	CCA, CAC, CBB, CBA, CAB, CAA, BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	Absent	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

- Transfer the number **3** to the 4-Digit Diagnostic Code Grid on page 1 of the FAS Diagnostic Evaluation Form (duplicated below).

Result

4-Digit Diagnostic Code Grid

3 ____

				Growth	Face	Brain		Alcohol		
significant	severe	definite	(4)						(4)	high risk
moderate	moderate	probable	(3)		X				(3)	some risk
mild	mild	possible	(2)						(2)	unknown
none	absent	unlikely	(1)						(1)	no risk
Growth Deficiency	**FAS Facial Features**	**Brain Dysfunction**								**Gestational Alcohol**

III. Diagnostic Evaluation Form Instructions

B.3. Scoring Brain Function

Method for ranking the brain function component of the 4-Digit Diagnostic Code

A. Rank Definitions

Brain dysfunction is the most significant disability for individuals damaged by prenatal alcohol exposure. Accurately quantifying and qualifying it is important for both diagnosis and treatment planning. Brain damage can be defined in a large number of ways that are each associated with a broad spectrum of disability. The 4-point Brain Dysfunction Scale (Table 5) allows the clinician to differentiate patients with clear evidence of brain damage (static encephalopathy, Rank 4) from patients without evidence of brain damage (Rank 1). It also introduces two intermediate categories for describing patients who, in the clinician's judgment, cannot be classified as Rank 1 or 4. The higher the number the more *certain* the clinician is that the patient's cognitive and behavioral problems stem from brain damage, but a higher score does not necessarily mean a more severe expression of functional disability. Patients with severe brain dysfunction may not have good evidence for damage at the levels that we can currently study the brain. A patient could simultaneously meet the criteria for both a Rank 3 and 4 on this brain scale. When two scores are both applicable, the higher score is selected for diagnostic purposes because that reflects the level of certainty that there is brain damage.

Brain Rank 4

This rank is selected when the evidence for brain damage is defined through a traditional medical approach. It is our impression that "brain damage" or static encephalopathy is readily diagnosed by clinicians when structural anomalies of the brain are detected or when permanent neurologic findings of presumed prenatal origin are found. Evidence for brain damage includes microcephaly, structural abnormalities of the brain of presumed prenatal origin on a brain image (including, but not limited to hydrocephaly, heterotopias, agenesis of the corpus callosum, etc.), neurologic conditions like seizures which are not due to a postnatal insult or other process, other hard neurologic signs, or a full scale IQ of less than 60.

In this system, at this time, microcephaly is defined as a measurement that is ≤ 2 standard deviations from the mean. Head circumference ≤ 2 standard deviations from the mean has been associated with mental deficiency in the literature[20]. Microcephaly is measured independently of height and weight (i.e. children with height and weight that are less than the second centile and a head circumference of less than the second centile are considered to have the same degree of microcephaly as children who have greater somatic growth).

An IQ of 60 or less was selected for this rank because many experts regard mild mental retardation (IQ of 60-70) as potentially representing the low end of the normal range, while IQ's below 60 seem much more reliably related to true brain abnormality.

Ranking Criteria: One or more positive findings recorded under the Structural or Neurologic headings of the Brain Function section (page 3) of the FAS Diagnostic Evaluation Form are sufficient to classify a patient as Rank 4. A 'positive finding' is defined as a 'Severity of Outcome' score equal to 3.

Brain Rank 3

Through our experience with hundreds of patients who have been exposed to potentially teratogenic doses of ethanol, we have found that many would not qualify as having static encephalopathy using the definition above, but neither could the possibility that they have static encephalopathy be dismissed out of hand. These are typically patients with IQ scores that are above the range clearly indicative of mental retardation, but who often have wide variations in IQ subtest scores, and in addition, have problems with executive functioning, memory and learning, language pragmatics, social adaptation, attention, and/or activity level. These patients have problems that seem likely due to underlying brain structure or function rather than to adverse postnatal environmental experiences.

Ranking Criteria: Three or more significant deficiencies recorded under the Psychometric heading of the Brain Function section (pages 3 and 4) of the FAS Diagnostic Evaluation Form are sufficient to classify a patient as Rank 3. A 'significant deficiency' is defined as a 'Severity of Outcome' score equal to 3.

Brain Rank 2

This score should be given to two groups of patients. All patients in Rank 2 should have histories of behavioral and/or cognitive problems that strongly suggest underlying brain dysfunction. One group of patients has not yet had the types of testing that would move them into Ranks 3 or 4 if positive. The reason for this lack of testing is usually because the patients are too young to be tested (i.e., less than 6 years of age). The other group of patients is those who have had testing that did not reveal compelling evidence for Rank 3 or 4 classification, and yet, in the clinician's judgment, a strong possibility of brain damage can not be wholly dismissed. Alternative testing and/or follow-up testing should usually be considered. If adequately sensitive and appropriate testing has been carried out without clear evidence of brain dysfunction, it is unlikely a Rank 2 classification would be given.

Ranking Criteria: Deficiencies recorded under the Caregiver Interview heading of the Brain Function section (page 5) of the FAS Diagnostic Evaluation Form serve to support a Rank 2 classification. To date, criteria for the number of deficiencies that must be present to warrant a Rank 2 classification have not been established. The classification is made through clinical judgment and the overall weight of evidence obtained.

Brain Rank 1

Patients are classified as Rank 1 when no structural, neurologic or cognitive/behavioral problems measured by psychometric assessment or caregiver interview are discerned.

B. Completing the Brain Function section of the FAS Diagnostic Evaluation Form

The Brain Function section appears on pages 3 through 5 of the FAS Diagnostic Evaluation Form. These pages serve as a place to record pertinent structural, neurologic, pyschometric and caregiver interview data available on the patient. Although space has been provided to record a full complement of assessments, we are not implying that all of these assessments must be conducted to derive a diagnosis. It is the responsibility of the clinical team to select the most appropriate assessment battery. Recording data for the structural, neurologic and psychometric sections is self explanatory. The Caregiver Interview section warrants further explanation.

An important aspect of the FAS evaluation is an in depth interview of the caregivers of the patient. This interview takes approximately one hour and is conducted jointly by the physician and psychologist while the child is being formally assessed by the other clinical staff members. There are several questions that need to be addressed. What are the problems that led to the diagnostic referral? What do the caregivers hope to gain from the assessment? What are the caregivers' views of the patient's overall strengths and weaknesses? What is the child's social and medical history? In addition, we have found it very useful to methodically ask age-appropriate questions that review the patient's functional abilities in domains that are commonly problematic for alcohol exposed individuals according to the literature. These domains (planning, behavioral regulation/sensory motor integration, abstract thinking/judgment, memory/learning/information processing, spatial memory, social skills/adaptive behavior and motor control) are presented on the FAS Diagnostic Evaluation Form (page 5). Routinely asking these questions serves several purposes. First, the caregivers' ability to answer the questions gives insight into their capability of interpreting the patient's behaviors and their general relationship with the patient. Second, it is often helpful to compare this subjective assessment to the psychometric profile to see if discrepancies or deficiencies are present. Third, abnormalities in these domains serve to differentiate Brain Rank 2 from Brain Rank 1. That is, the data needed to establish a Rank 3 or 4 classification is not found, but the reported behaviors of the patient cannot be dismissed as normal variants or transient emotional responses to environmental problems (i.e., depression, post traumatic stress, etc.).

Severity of Outcome Scale [0, 1, 2, 3]

Along the left margin of each page is a Severity of Outcome scale. The clinician is asked to rank the level of abnormality of each outcome as follows: 0 = unable to judge, 1 = normal, 2 = mildly abnormal and 3 = severely abnormal. This ranking process is based on the clinician's clinical judgment and serves to guide him/her in ranking brain dysfunction. For outcomes measured on standardized scales, outcomes ≥ 2 S.D.'s from the norm would be judged severely abnormal.

Table 5: Deriving the 4-Digit Diagnostic Code Rank for Brain Function

4-Digit Diagnostic Code Rank*	Brain Dysfunction Scale	Confirmatory Findings
4	**Definite** *referred to as static encephalopathy*	● Microcephaly, OFC ≤ -2 S. D. *and / or* ● Abnormalities on brain images diagnostic of prenatal alteration *and / or* ● Evidence of persistent neurologic findings likely to be of prenatal origin *and / or* ● I. Q. score ≤ 60
3	**Probable** *referred to as static encephalopathy*	● Substantial deficiencies or discrepancies across multiple areas of brain performance such as cognition, achievement, adaptation, neurologic "soft" signs, and language. Generally three or more areas should be found aberrant.
2	**Possible** *referred to as neurobehavioral disorder*	● Historical information / personal observations strongly suggest the possibility of brain damage, but data to this point does not permit a Rank 3 or 4 classification.
1	**Absent**	● No problems likely to reflect brain damage are presented.

* Transfer the resulting 4-Digit Diagnostic Code Rank for Brain Function to the 4-Digit Diagnostic Code Grid on page 1 of the FAS Diagnostic Evaluation Form.

III. Diagnostic Evaluation Form Instructions

B.4. Scoring Alcohol Exposure

Table 6: Deriving the 4-Digit Diagnostic Code Rank for Alcohol Exposure

4-Digit Diagnostic Code Rank*	Gestational Alcohol Exposure Category	Description
4	High Risk	● Alcohol use during pregnancy CONFIRMED *and* ● Exposure pattern is consistent with the medical literature placing the fetus at "high risk" (generally high peak blood alcohol concentrations delivered at least weekly in early pregnancy).
3	Some Risk	● Alcohol use during pregnancy CONFIRMED *and* ● Drinking occurred in gestation in frequencies and volumes less than in Rank (4) or exact amounts unknown.
2	Unknown Risk	● Gestational exposure is simply not known or information is of questionable reliability
1	No Risk	● Alcohol use during pregnancy is CONFIRMED to be completely ABSENT.

* Transfer the resulting 4-Digit Diagnostic Code Rank for Alcohol Exposure to the 4-Digit Diagnostic Code Grid on page 1 of the FAS Diagnostic Evaluation Form.

III. Diagnostic Evaluation Form Instructions

B.5. Scoring Co-Morbidities

The co-morbidity scales are added for clinical clarification. It is rare that other pre- and/or postnatal factors have not played a role in creating the specific disabilities in a patient with prenatal alcohol exposure. These factors are often helpful in explaining the specific problems faced by the patient and helpful in development of a treatment plan.

A. Prenatal Co-Morbidity Rank Definitions

High Risk (Likert Rank 4):
This Rank is reserved for alternate genetic conditions (e.g., Fragile X, Noonans syndrome, velocardiofacial syndrome, etc.) or teratogenic exposures (e.g., hydantoin, etc.) that have been clearly shown to produce abnormalities.

Some Risk (Likert Rank 3):
This category is used for potential genetic conditions, teratogenic exposures or prenatal conditions that have been associated with physical or neurodevelopmental problems in a less well-established way. Examples of conditions that would be placed in this category would include poor prenatal care; patients whose parents have mild mental retardation, attention deficit, significant learning disabilities or learning problems thought to be due to a non-specific (and non-teratogenic) source; exposure to drugs like marijuana or heroin, in otherwise non-specified frequencies and quantities; and cigarette smoking.

Unknown Risk (Likert Rank 2):
This category is used when the details of the family background and gestation are unknown – generally in the circumstance of a closed adoption.

No Risk (Likert Rank 1):
On occasion, the genetic, teratogenic, and prenatal histories are well documented and no factors can be identified that would explain the abnormalities found in the patient.

B. Postnatal Co-Morbidity Rank Definitions

High Risk (Likert Rank 4):
This Rank is used to note postnatal circumstances that have been shown to have a significant adverse effect on development in most instances. Examples would include physical and sexual abuse, multiple disrupted placements, neglect resulting in failure to thrive, serious head injury, or medical conditions which lead to brain damage (i.e. kernicterus or persistent neonatal apnea).

Some Risk (Likert Rank 3):
This Rank is used to note conditions akin to those in Rank 4, but the circumstances are less severe and so less likely to be a definite factor in the patient's present condition. Obviously, clinical judgment is needed in judging the magnitude of a postnatal problem and interpreting this information into a Rank 3 or 4 placement.

Unknown Risk (Likert Rank 2):
This Rank is used when historical information is missing. This is sometimes the case with adopted children or those in foster care. Adult patients may, at times, be unable to reconstruct their own early histories.

No Risk (Likert Rank 1):
This Rank is used when a well documented history confirms an absence of adverse postnatal events.

IV. Diagnostic Categories

The 256 Diagnostic Codes can be logically grouped into 22 Diagnostic Categories

Category	Name
A	Fetal alcohol syndrome (alcohol exposed)
B	Fetal alcohol syndrome (alcohol exposure unknown)
C	Atypical fetal alcohol syndrome (alcohol exposed)
D	Fetal alcohol syndrome phenocopy (no alcohol exposure)
E	Sentinel physical findings / static encephalopathy (alcohol exposed)
F	Static encephalopathy (alcohol exposed)
G	Sentinel physical findings / neurobehavioral disorder (alcohol exposed)
H	Neurobehavioral disorder (alcohol exposed)
I	Sentinel physical findings (alcohol exposed)
J	No cognitive/behavioral or sentinel physical findings detected (alcohol exposed)
K	Sentinel physical findings / static encephalopathy (alcohol exposure unknown)
L	Static encephalopathy (alcohol exposure unknown)
M	Sentinel physical findings / neurobehavioral disorder (alcohol exposure unknown)
N	Neurobehavioral disorder (alcohol exposure unknown)
O	Sentinel physical findings (alcohol exposure unknown)
P	No cognitive/behavioral or sentinel physical findings detected (alcohol exposure unknown)
Q	Sentinel physical findings / static encephalopathy (no alcohol exposure)
R	Static encephalopathy (no alcohol exposure)
S	Sentinel physical findings / neurobehavioral disorder (no alcohol exposure)
T	Neurobehavioral disorder (no alcohol exposure)
U	Sentinel physical findings (no alcohol exposure)
V	No cognitive/behavioral or sentinel physical findings detected (no alcohol exposure)

V. 4-Digit Diagnostic Codes Within each Diagnostic Category

Category	Diagnostic Name and Codes
A	Fetal alcohol syndrome (alcohol exposed) 3433 4433 3434 4434 3443 4443 3444 4444
B	Fetal alcohol syndrome (alcohol exposure unknown) 3432 4432 3442 4442
C	Atypical fetal alcohol syndrome (alcohol exposed) 1443 1434 2434 3334 4334 4343 2443 1444 2444 3344 4344
D	Fetal alcohol syndrome phenocopy (no alcohol exposure) 3431 4341 4441 3441 4431
E	Sentinel physical findings / static encephalopathy (alcohol exposed) 1333 1433 2344 3143 3243 4133 4233 4333 1334 2333 2433 3144 3244 4134 4234 1343 2334 3133 3233 3333 4143 4243 1344 2343 3134 3234 3343 4144 4244
F	Static encephalopathy (alcohol exposed) 1133 1144 1243 2134 2233 2244 1134 1233 1244 2143 2234 1143 1234 2133 2144 2243
G	Sentinel physical findings / neurobehavioral disorder (alcohol exposed) 1323 2323 3123 3323 4123 4323 1324 2324 3124 3324 4124 4324 1423 2423 3223 3423 4223 4423 1424 2424 3224 3424 4224 4424

Category	Diagnostic Name and Codes
H	Neurobehavioral disorder (alcohol exposed) 1123 2123 1124 2124 1223 2223 1224 2224
I	Sentinel physical findings (alcohol exposed) 1313 2313 3113 3313 4113 4313 1314 2314 3114 3314 4114 4314 1413 2413 3213 3413 4213 4413 1414 2414 3214 3414 4214 4414
J	No cognitive/behavioral or sentinel physical findings detected (alcohol exposed) 1113 2113 1114 2114 1213 2213 1214 2214
K	Sentinel physical findings / static encephalopathy (alcohol exposure unknown) 1332 2332 3132 3332 4232 1342 2342 3142 3342 4242 1432 2432 3232 4132 4332 1442 2442 3242 4142 4342
L	Static encephalopathy (alcohol exposure unknown) 1132 1232 2132 2232 1142 1242 2142 2242
M	Sentinel physical findings / neurobehavioral disorder (alcohol exposure unknown) 1322 2322 3122 3322 4122 4322 1422 2422 3222 3422 4222 4422
N	Neurobehavioral disorder (alcohol exposure unknown) 1122 1222 2122 2222
O	Sentinel physical findings (alcohol exposure unknown) 1312 2312 3112 3312 4112 4312 1412 2412 3212 3412 4212 4412

Category	Diagnostic Name and Codes
P	No cogn./behavioral or sentinel physical findings detected (alcohol exposure unknown) 1112 2112 1212 2212
Q	Sentinel physical findings / static encephalopathy (no alcohol exposure) 1331 2341 3231 4141 1341 2431 3241 4231 1431 2441 3331 4241 1441 3131 3341 4331 2331 3141 4131
R	Static encephalopathy (no alcohol exposure) 1131 2131 1141 2141 1231 2231 1241 2241
S	Sentinel physical findings / neurobehavioral disorder (no alcohol exposure) 1321 3121 4121 1421 3221 4221 2321 3321 4321 2421 3421 4421
T	Neurobehavioral disorder (no alcohol exposure) 1121 2121 2221 1221
U	Sentinel physical findings (no alcohol exposure) 1311 3111 4111 1411 3211 4211 2311 3311 4311 2411 3411 4411
V	No cognitive/behavioral or sentinel physical findings detected (no alcohol exposure) 1111 2111 1211 2211

VI. 4-Digit Diagnostic Codes Sorted Numerically

Code	Category	Diagnostic Name
1111	V	No cognitive/behavioral or sentinel physical findings detected (no alcohol exposure)
1112	P	No cognitive/behavioral or sentinel physical findings detected (alcohol exposure unknown)
1113	J	No cognitive/behavioral or sentinel physical findings detected (alcohol exposed)
1114	J	No cognitive/behavioral or sentinel physical findings detected (alcohol exposed)
1121	T	Neurobehavioral disorder (no alcohol exposure)
1122	N	Neurobehavioral disorder (alcohol exposure unknown)
1123	H	Neurobehavioral disorder (alcohol exposed)
1124	H	Neurobehavioral disorder (alcohol exposed)
1131	R	Static encephalopathy (no alcohol exposure)
1132	L	Static encephalopathy (alcohol exposure unknown)
1133	F	Static encephalopathy (alcohol exposed)
1134	F	Static encephalopathy (alcohol exposed)
1141	R	Static encephalopathy (no alcohol exposure)
1142	L	Static encephalopathy (alcohol exposure unknown)
1143	F	Static encephalopathy (alcohol exposed)
1144	F	Static encephalopathy (alcohol exposed)
1211	V	No cognitive/behavioral or sentinel physical findings detected (no alcohol exposure)
1212	P	No cognitive/behavioral or sentinel physical findings detected (alcohol exposure unknown)
1213	J	No cognitive/behavioral or sentinel physical findings detected (alcohol exposed)
1214	J	No cognitive/behavioral or sentinel physical findings detected (alcohol exposed)
1221	T	Neurobehavioral disorder (no alcohol exposure)
1222	N	Neurobehavioral disorder (alcohol exposure unknown)
1223	H	Neurobehavioral disorder (alcohol exposed)
1224	H	Neurobehavioral disorder (alcohol exposed)
1231	R	Static encephalopathy (no alcohol exposure)
1232	L	Static encephalopathy (alcohol exposure unknown)
1233	F	Static encephalopathy (alcohol exposed)
1234	F	Static encephalopathy (alcohol exposed)
1241	R	Static encephalopathy (no alcohol exposure)
1242	L	Static encephalopathy (alcohol exposure unknown)
1243	F	Static encephalopathy (alcohol exposed)
1244	F	Static encephalopathy (alcohol exposed)
1311	U	Sentinel physical findings (no alcohol exposure)
1312	O	Sentinel physical findings (alcohol exposure unknown)
1313	I	Sentinel physical findings (alcohol exposed)
1314	I	Sentinel physical findings (alcohol exposed)
1321	S	Sentinel physical findings / neurobehavioral disorder (no alcohol exposure)
1322	M	Sentinel physical findings / neurobehavioral disorder (alcohol exposure unknown)
1323	G	Sentinel physical findings / neurobehavioral disorder (alcohol exposed)

Code	Category	Diagnostic Name
1324	G	Sentinel physical findings / neurobehavioral disorder (alcohol exposed)
1331	Q	Sentinel physical findings / static encephalopathy (no alcohol exposure)
1332	K	Sentinel physical findings / static encephalopathy (alcohol exposure unknown)
1333	E	Sentinel physical findings / static encephalopathy (alcohol exposed)
1334	E	Sentinel physical findings / static encephalopathy (alcohol exposed)
1341	Q	Sentinel physical findings / static encephalopathy (no alcohol exposure)
1342	K	Sentinel physical findings / static encephalopathy (alcohol exposure unknown)
1343	E	Sentinel physical findings / static encephalopathy (alcohol exposed)
1344	E	Sentinel physical findings / static encephalopathy (alcohol exposed)
1411	U	Sentinel physical findings (no alcohol exposure)
1412	O	Sentinel physical findings (alcohol exposure unknown)
1413	I	Sentinel physical findings (alcohol exposed)
1414	I	Sentinel physical findings (alcohol exposed)
1421	S	Sentinel physical findings / neurobehavioral disorder (no alcohol exposure)
1422	M	Sentinel physical findings / neurobehavioral disorder (alcohol exposure unknown)
1423	G	Sentinel physical findings / neurobehavioral disorder (alcohol exposed)
1424	G	Sentinel physical findings / neurobehavioral disorder (alcohol exposed)
1431	Q	Sentinel physical findings / static encephalopathy (no alcohol exposure)
1432	K	Sentinel physical findings / static encephalopathy (alcohol exposure unknown)
1433	E	Sentinel physical findings / static encephalopathy (alcohol exposed)
1434	C	Atypical fetal alcohol syndrome (alcohol exposed)
1441	Q	Sentinel physical findings / static encephalopathy (no alcohol exposure)
1442	K	Sentinel physical findings / static encephalopathy (alcohol exposure unknown)
1443	C	Atypical fetal alcohol syndrome (alcohol exposed)
1444	C	Atypical fetal alcohol syndrome (alcohol exposed)
2111	V	No cognitive/behavioral or sentinel physical findings detected (no alcohol exposure)
2112	P	No cognitive/behavioral or sentinel physical findings detected (alcohol exposure unknown)
2113	J	No cognitive/behavioral or sentinel physical findings detected (alcohol exposed)
2114	J	No cognitive/behavioral or sentinel physical findings detected (alcohol exposed)
2121	T	Neurobehavioral disorder (no alcohol exposure)
2122	N	Neurobehavioral disorder (alcohol exposure unknown)
2123	H	Neurobehavioral disorder (alcohol exposed)
2124	H	Neurobehavioral disorder (alcohol exposed)
2131	R	Static encephalopathy (no alcohol exposure)
2132	L	Static encephalopathy (alcohol exposure unknown)
2133	F	Static encephalopathy (alcohol exposed)
2134	F	Static encephalopathy (alcohol exposed)
2141	R	Static encephalopathy (no alcohol exposure)
2142	L	Static encephalopathy (alcohol exposure unknown)
2143	F	Static encephalopathy (alcohol exposed)
2144	F	Static encephalopathy (alcohol exposed)
2211	V	No cognitive/behavioral or sentinel physical findings detected (no alcohol exposure)
2212	P	No cognitive/behavioral or sentinel physical findings detected (alcohol exposure unknown)
2213	J	No cognitive/behavioral or sentinel physical findings detected (alcohol exposed)

Code	Category	Diagnostic Name
2214	J	No cognitive/behavioral or sentinel physical findings detected (alcohol exposed)
2221	T	Neurobehavioral disorder (no alcohol exposure)
2222	N	Neurobehavioral disorder (alcohol exposure unknown)
2223	H	Neurobehavioral disorder (alcohol exposed)
2224	H	Neurobehavioral disorder (alcohol exposed)
2231	R	Static encephalopathy (no alcohol exposure)
2232	L	Static encephalopathy (alcohol exposure unknown)
2233	F	Static encephalopathy (alcohol exposed)
2234	F	Static encephalopathy (alcohol exposed)
2241	R	Static encephalopathy (no alcohol exposure)
2242	L	Static encephalopathy (alcohol exposure unknown)
2243	F	Static encephalopathy (alcohol exposed)
2244	F	Static encephalopathy (alcohol exposed)
2311	U	Sentinel physical findings (no alcohol exposure)
2312	O	Sentinel physical findings (alcohol exposure unknown)
2313	I	Sentinel physical findings (alcohol exposed)
2314	I	Sentinel physical findings (alcohol exposed)
2321	S	Sentinel physical findings / neurobehavioral disorder (no alcohol exposure)
2322	M	Sentinel physical findings / neurobehavioral disorder (alcohol exposure unknown)
2323	G	Sentinel physical findings / neurobehavioral disorder (alcohol exposed)
2324	G	Sentinel physical findings / neurobehavioral disorder (alcohol exposed)
2331	Q	Sentinel physical findings / static encephalopathy (no alcohol exposure)
2332	K	Sentinel physical findings / static encephalopathy (alcohol exposure unknown)
2333	E	Sentinel physical findings / static encephalopathy (alcohol exposed)
2334	E	Sentinel physical findings / static encephalopathy (alcohol exposed)
2341	Q	Sentinel physical findings / static encephalopathy (no alcohol exposure)
2342	K	Sentinel physical findings / static encephalopathy (alcohol exposure unknown)
2343	E	Sentinel physical findings / static encephalopathy (alcohol exposed)
2344	E	Sentinel physical findings / static encephalopathy (alcohol exposed)
2411	U	Sentinel physical findings (no alcohol exposure)
2412	O	Sentinel physical findings (alcohol exposure unknown)
2413	I	Sentinel physical findings (alcohol exposed)
2414	I	Sentinel physical findings (alcohol exposed)
2421	S	Sentinel physical findings / neurobehavioral disorder (no alcohol exposure)
2422	M	Sentinel physical findings / neurobehavioral disorder (alcohol exposure unknown)
2423	G	Sentinel physical findings / neurobehavioral disorder (alcohol exposed)
2424	G	Sentinel physical findings / neurobehavioral disorder (alcohol exposed)
2431	Q	Sentinel physical findings / static encephalopathy (no alcohol exposure)
2432	K	Sentinel physical findings / static encephalopathy (alcohol exposure unknown)
2433	E	Sentinel physical findings / static encephalopathy (alcohol exposed)
2434	C	Atypical fetal alcohol syndrome (alcohol exposed)
2441	Q	Sentinel physical findings / static encephalopathy (no alcohol exposure)
2442	K	Sentinel physical findings / static encephalopathy (alcohol exposure unknown)
2443	C	Atypical fetal alcohol syndrome (alcohol exposed)

Code	Category	Diagnostic Name
2444	C	Atypical fetal alcohol syndrome (alcohol exposed)
3111	U	Sentinel physical findings (no alcohol exposure)
3112	O	Sentinel physical findings (alcohol exposure unknown)
3113	I	Sentinel physical findings (alcohol exposed)
3114	I	Sentinel physical findings (alcohol exposed)
3121	S	Sentinel physical findings / neurobehavioral disorder (no alcohol exposure)

VII. Clinical Summaries
For each of the 22 Diagnostic Categories

Clinical summaries for each of the 22 Diagnostic Categories are presented on the following pages listed alphabetically from A through V. A complete list of the 22 categories is presented in Section IV.

These summaries can be used as the first page of the final diagnostic report. They often require minor alterations or additions to conform to the specifics of an individual case.

A

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Fetal Alcohol Syndrome**
(2) Alcohol exposed

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of brain damage which occur in individuals exposed to alcohol during gestation. On the attached sheets are the specific findings in this patient's case that led to our conclusion that there was sufficient evidence to make the diagnosis of fetal alcohol syndrome.

Although we believe that the patient clearly has fetal alcohol syndrome, this does not mean that alcohol exposure during pregnancy is the only cause of the patient's current problems. A number of other factors could be contributing to the present situation, such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. Such factors may partly explain why there is so much variability in the kinds of specific difficulties that patients with FAS have.

Individuals with FAS have brain damage as a major component of their cognitive and behavioral problems and should be viewed individuals with disabilities. The fetal alcohol syndrome diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific concerns that have been identified that need attention.

C

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Atypical Fetal Alcohol Syndrome**
(2) Alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies and evidence of brain damage occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS. Indeed, many patients who have been exposed to alcohol show most, but not all, of the classic features of this syndrome. We use the term "atypical fetal alcohol syndrome" when a patient's characteristic features are very close to the classic features of FAS and the alcohol history strongly suggests that alcohol exposure during gestation was at high risk and likely to have played a role in the syndrome. Patients with atypical FAS either have the full set of facial anomalies found with FAS and evidence of brain damage, but do not have growth deficiency; or they have growth deficiency and evidence of brain damage, and most but not all of the FAS facial features. As you can see from the enclosed list of features found in this patient, the patient meets the criteria for atypical FAS. Patients diagnosed with atypical FAS must have confirmed exposure to high levels of alcohol during gestation.

In addition to gestational exposure to alcohol, a number of other factors could be contributing to the patient's current problems, such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. Such factors may partly explain why there is so much variability in the kinds of specific difficulties that patients with FAS experience.

Patients with atypical FAS have brain damage as a major component of their cognitive and behavioral problems and should be viewed as having a disability. The diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific concerns that have been identified that need attention.

Physician's Signature Date

D

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Fetal Alcohol Syndrome Phenocopy**
(2) No alcohol exposure

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies and evidence of brain damage occurring in patients exposed to alcohol during gestation. On the attached sheets are the specific findings in this patient's case that led to our conclusion that the patient has all of the features of FAS. However, there is good reason to believe this patient was not exposed to alcohol during gestation.

Most syndromes can occasionally arise from an alternate cause. Presumably, this is the situation here. A number of other factors could be contributing to the present situation, such as the patient's genetic background and other potential exposures or problems during pregnancy, and various experiences since birth.

Whatever the cause of this patient's syndrome, there is brain damage which is a major component of their cognitive and behavioral problems and the patient should be viewed as a person with a disability. The syndrome diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific concerns that have been identified that need attention.

E

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Static encephalopathy**
(2) Sentinel physical findings
(3) Alcohol exposed

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of brain damage in individuals exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, some but not all of the characteristic growth and facial features associated with FAS were present and there was evidence of brain damage as you will see noted on the attached pages. There was also a clear history of exposure to significant amounts of alcohol during gestation. In this situation, we use the terms "static encephalopathy" and "sentinel physical findings" to describe the patient's condition. Static encephalopathy literally means non-progressive brain dysfunction. The diagnoses of "static encephalopathy and sentinel physical findings" in the presence of alcohol exposure do not mean that alcohol is the only cause of the problem. A number of other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during gestation, and various experiences since birth. These kinds of differences may partly explain why there is so much variability in the kinds of specific difficulties that patients with static encephalopathy and alcohol exposure have.

The diagnoses made today are based on the information available at the time of this assessment. If this patient's alcohol exposure was considered "low risk" and new information is uncovered which documents higher exposures; or if the patient's facial features, growth, or neurobehavioral problems were judged "probable" and further growth or development suggest a "definite" problem is present, then reconsideration of the diagnosis of fetal alcohol syndrome would be appropriate. Alternately other birth defect syndromes not related to alcohol exposure may also need reconsideration.

Individuals with static encephalopathy have brain damage which is a major component of their cognitive and behavioral problems and they should be viewed as individuals with disabilities. The static encephalopathy diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

G

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Neurobehavioral disorder**
(2) Sentinel physical findings
(3) Alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies and evidence of brain damage occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS. On the attached sheets you will find our specific observations in this case. We found that some, but not all, of the characteristic physical findings seen in patients with FAS were present. There was not strong evidence that the patient's cognitive/behavioral problems were clearly due to brain damage, but there were suggestions that this was the case. In this situation we use the term "neurobehavioral disorder" to emphasize the possibility that the problems may not be entirely due to postnatal experiences. Certainly a number of other factors could be contributing to the patient's condition such as genetic background, other potential exposures or problems during pregnancy, and various experiences since birth.

The diagnoses made today are based on the information at hand. If further testing is done which makes the likelihood of brain damage of prenatal cause more likely, then an alternate diagnosis could be considered. Alternately other birth defect syndromes not related to alcohol exposure may also need consideration.

In any event, the diagnosis of neurobehavioral disorder means that issues of abnormal brain structure and brain impairment need to be considered with implications for educational planning, societal expectations, and health. On the attached sheet, you will find a list of specific problems that have been identified that need attention.

DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Sentinel physical findings**
(2) Alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies and evidence of brain damage occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS. Some individuals have the growth deficiency and/or facial characteristics, but do not have evidence of brain damage. We refer to this condition as "Sentinel physical findings / Alcohol exposed". On the attached sheets are the specific findings in this patient's case which indicate that the characteristic growth deficiencies and/or facial features are, to some extent, compatible with FAS, but at this time there is no clear evidence of cognitive or behavioral problems that strongly suggest brain damage. At such time in the future that brain damage is found through images of the brain, neurologic testing or cognitive behavioral assessment, then the diagnosis of fetal alcohol syndrome should be reconsidered. Other birth defect syndromes that are not related to alcohol exposure should also be considered as alternate explanations for the patient's problems.

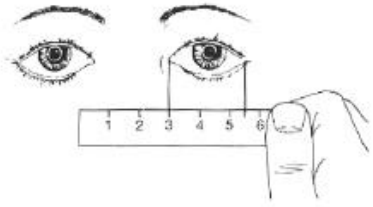
VIII. Reference Charts of Normal Growth

The attached charts should be used to record standardized measures of palpebral fissure length, inner canthal distance, head circumference, height, weight, and parental height adjustment on the FAS Diagnostic Evaluation Form.

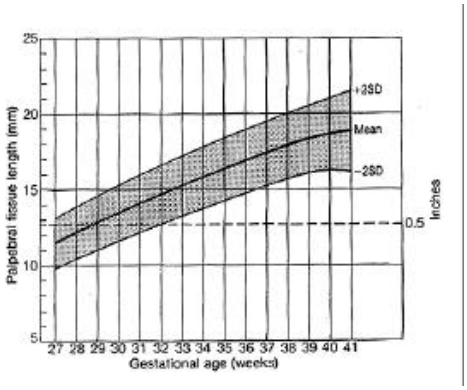
Palpebral Fissure Distance

(From Hall et. al., 1989, by permission)[18]

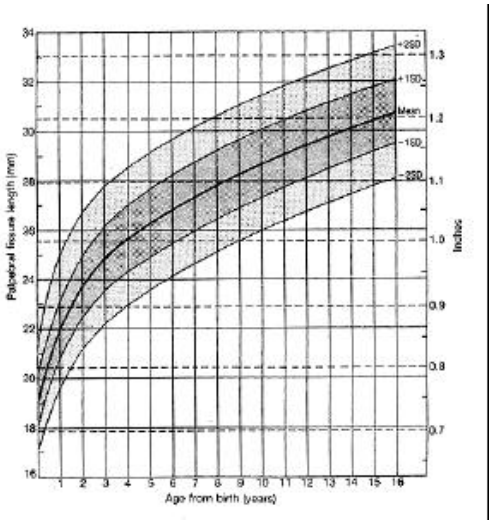


Measure from the inner to the outer canthi.

Have patient look up while holding head level to standardize and maximize fissure length.



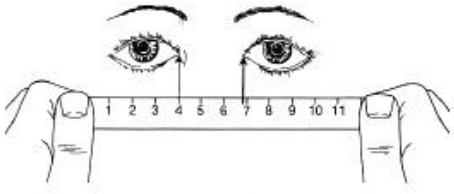
Palpebral fissure length, both sexes, at birth.



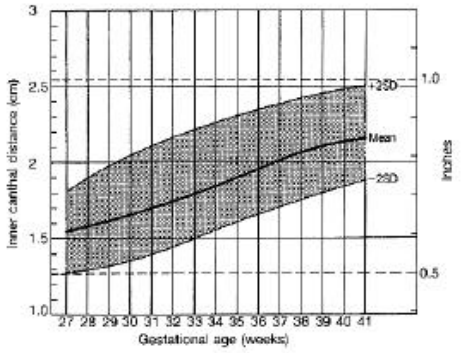
Palpebral fissure length, both sexes, birth to 16 years.

Inner Canthal Distance

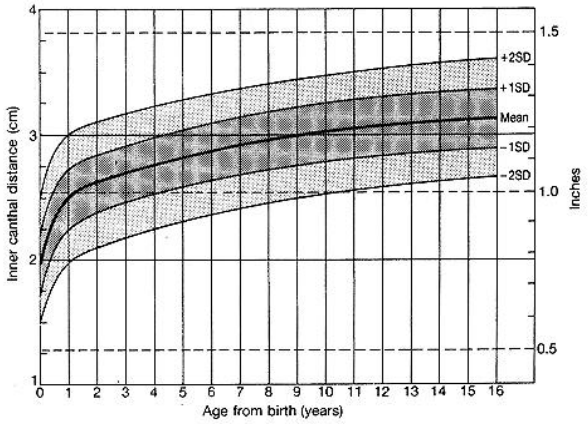
(From Hall et. al., 1989, by permission) [18]



Measure from the innermost corner of each eye, in a straight line avoiding the curvature of the nose.



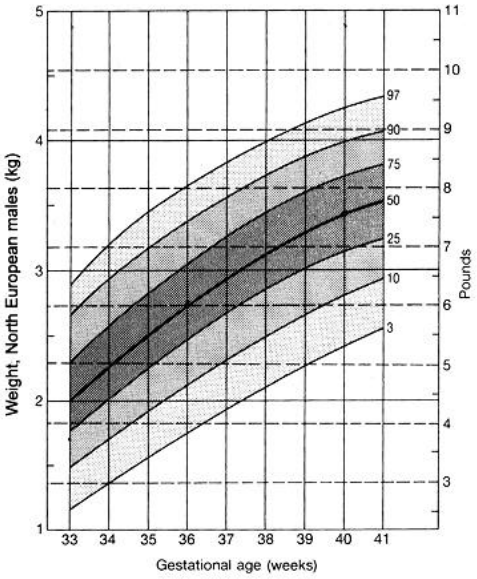
Inner canthal distance, both sexes, at birth.



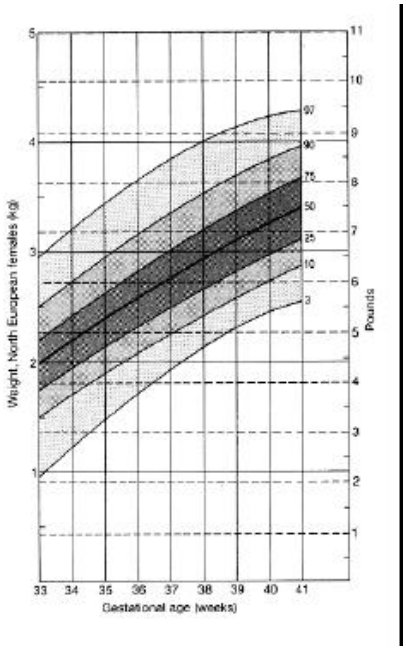
Inner canthal distance, both sexes, birth to 16 years.

Birth Weight

(Hall et. al., 1989, by permission) [18]



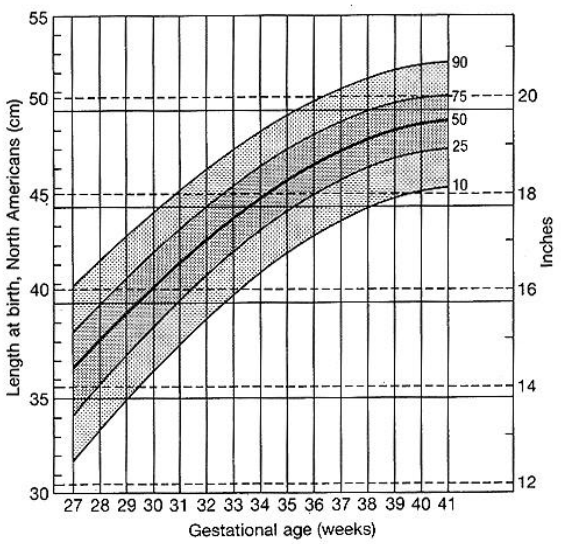
North European males at birth



North European females at birth

Birth Length

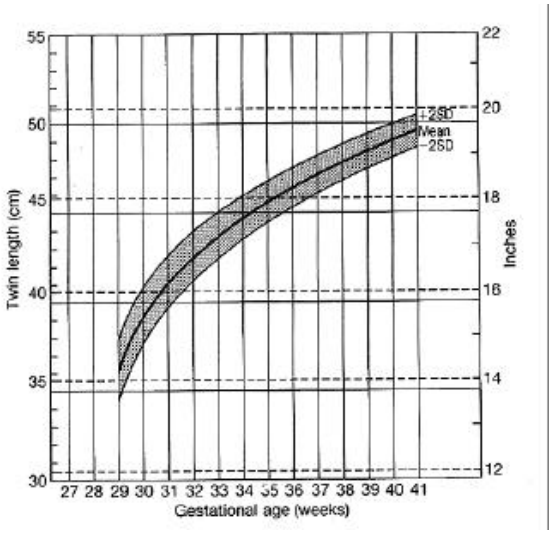
(Hall et. al., 1989, by permission) [18]



Length at birth, North Americans, both sexes.

Birth Length, Twin

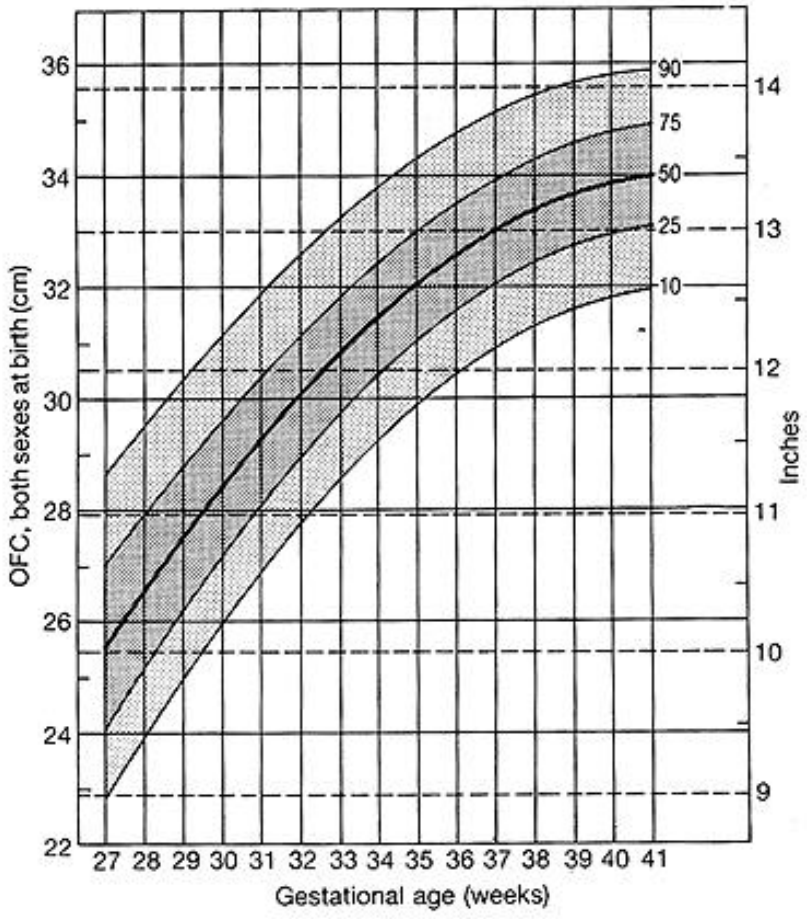
(Hall et. al., 1989, by permission) [18]



Twin length at birth, both sexes.

Head Circumference

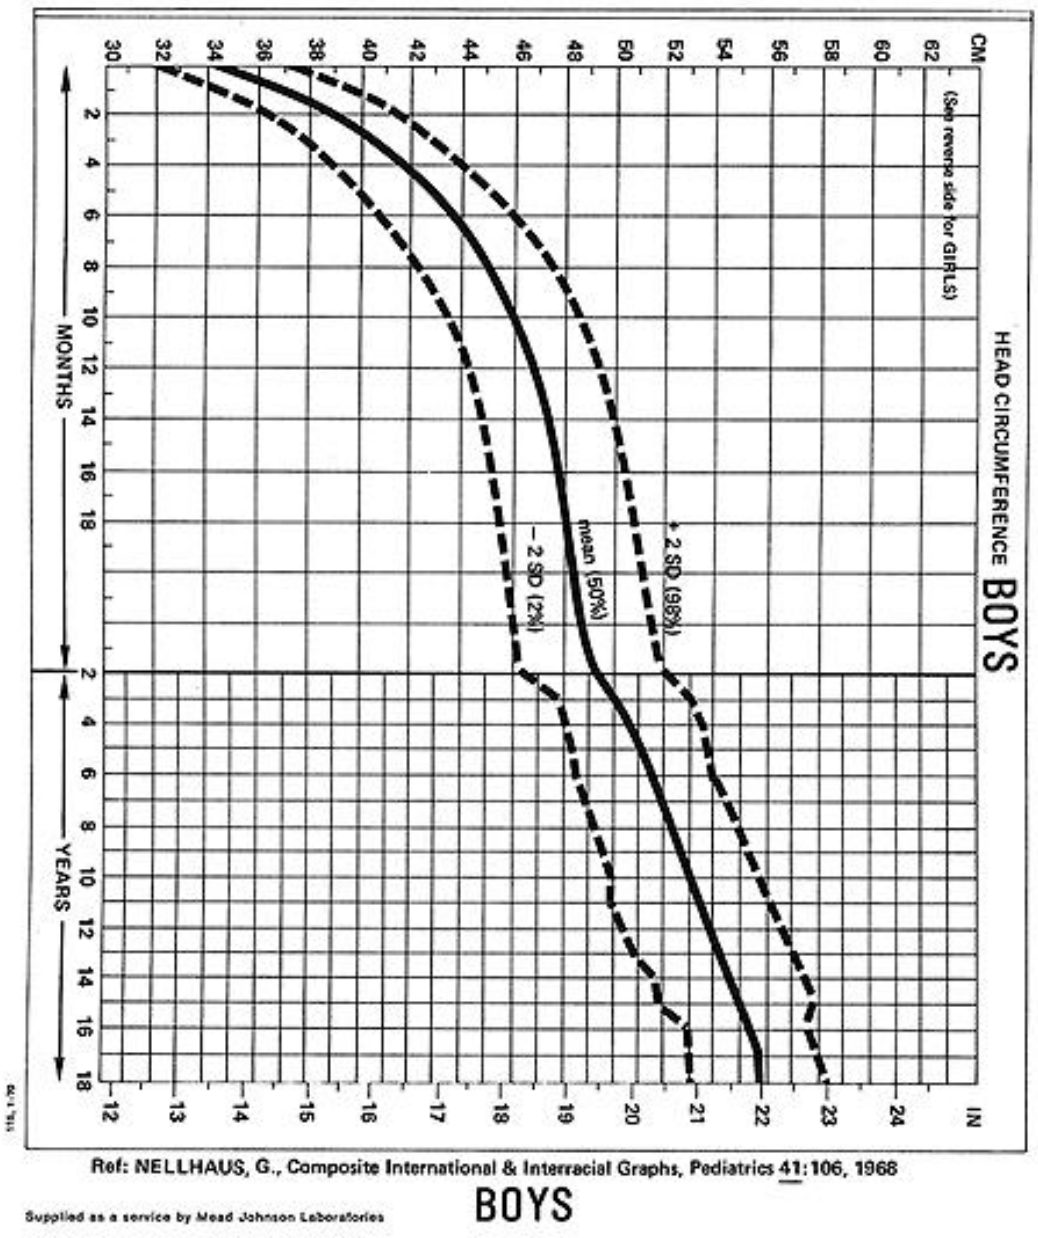
(Hall et. al., 1989, by permission) [18]



Head circumference, both sexes, at birth.

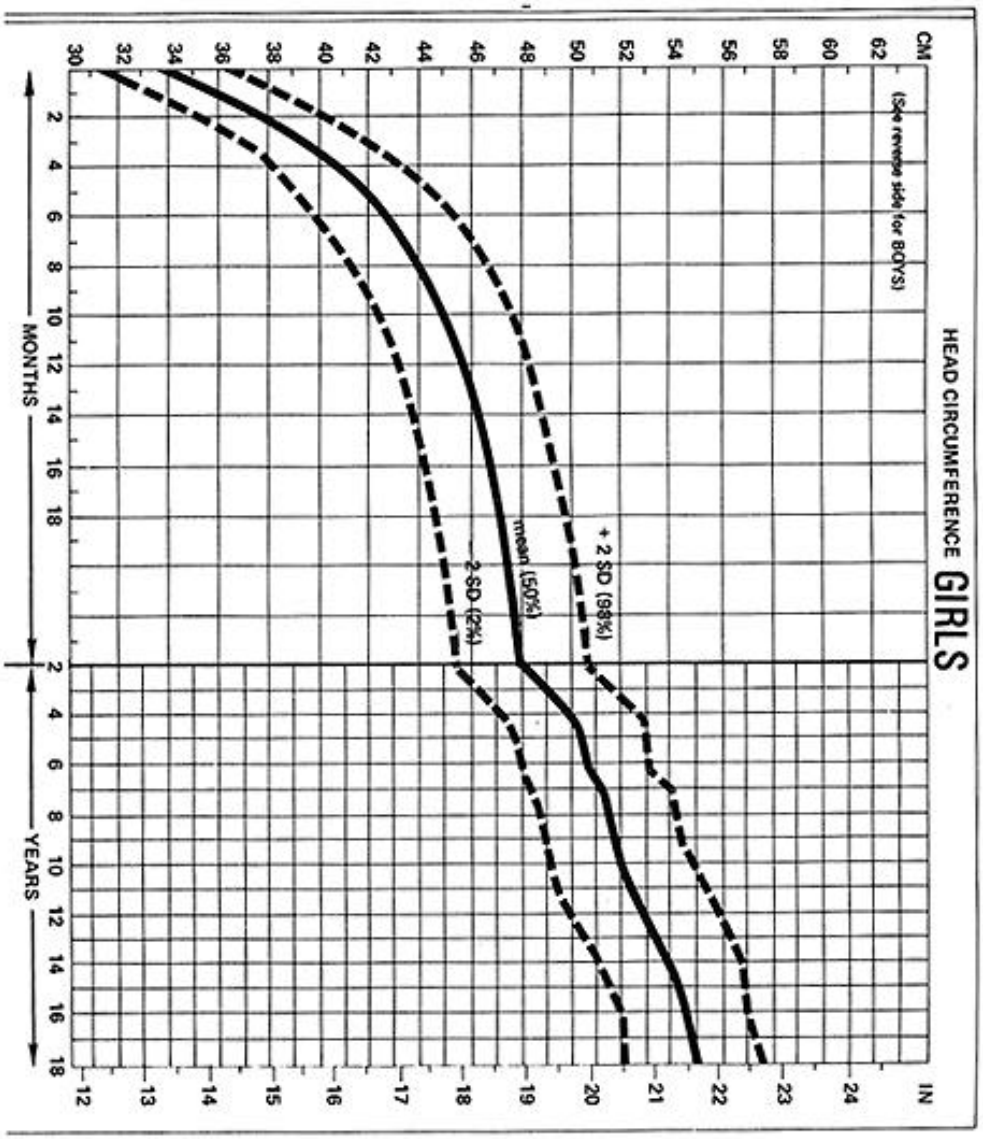
Head Circumference BOYS

(Mead Johnson Nutritionals by permission)[21]



Head Circumference GIRLS

(Mead Johnson Nutritionals by permission)[21]



Girls: Birth to 36 Months, Height and Weight, NCHS Percentiles

PARENT-SPECIFIC ADJUSTMENTS FOR EVALUATION OF LENGTH AND STATURE — BOYS

Recumbent length and stature (standing height) are affected by both genetic and nongenetic factors. The genetic component should be considered when concern arises that diet or disease may have retarded or accelerated growth. Adjustment of length or stature to take parental stature into account may help identify or explain the nature of a growth problem. Such adjustment may prompt diagnostic studies or suggest a genetic basis for the growth problem.

Parent-specific adjustment procedures have been developed for US children by Himes, Roche, and Thissen.[1,2] The accompanying tables of adjustments are adapted from their research. Parent-specific adjustments need not be done routinely but should be considered when a child has unusual length or stature. As a guideline for applying parent-specific adjustments, "unusual" may be defined as below the 5th percentile or above the 95th percentile in length or stature for age.

Occasionally, a child's length or stature may appear normal, but the parents (one or both) are very tall or very short. Under such circumstances, parent-specific adjustment also is appropriate. Rapid decrease or increase in a child's percentile for length or stature generally is not an indication for applying parent-specific adjustments because the cause is more likely to be nongenetic than genetic.

Parent Specific Adjustments for Evaluation of Length and Stature (continued)

Instructions

INSTRUCTIONS

1. Measure and record mother's stature.
2. Measure and record father's stature.
3. When one parent's stature cannot be measured, the measured parent's estimate of the other parent's stature (in cm) can be substituted for measured stature, and midparent stature can be calculated as in instruction 4. Alternatively, the measured parent's perception of the other parent's stature (short, medium, or tall) can be used to determine midparent stature directly from Table 4.

Table 4. Midparent Stature (cm) When Measured Parent Reports Other Parent's Stature as Short, Medium, or Tall

Measured Parent's Stature (cm)	Midparent Stature (cm)* When Mother Reports Father's Stature as Short†	Medium†	Tall†	When Father Reports Mother's Stature as Short‡	Medium‡	Tall‡

198	182	—	—	176	180	184

* All midparent statures are rounded to the nearest 2 cm to facilitate use of Tables 2 and 3.
† Values for father's stature used in calculations of midparent stature: short, 167.6 cm (5 ft 6 in.); medium, 176.3 cm (5 ft 9½ in.); tall, 185.4 cm (6 ft 1 in.).
‡ Values for mother's stature used in calculations of midparent stature: short, 154.9 cm (5 ft 1 in.); medium, 162.6 cm (5 ft 4 in.); tall, 170.7 cm (5 ft 7¼ in.).

4. Calculate midparent stature by adding the mother's stature and the father's stature in cm and dividing by two. Metric equivalents for stature are shown in Table 1.
5. Measure, record, and plot the boy's length (birth to 36 months) or stature (3 to 18 years) in cm on the appropriate growth chart that displays the National Center for Health Statistics (NCHS) percentiles. Metric equivalents for length and stature are shown in Table 1.
6. Calculate the boy's adjusted length or stature by using the parent-specific adjustments from Table 2 for length or from Table 3 for stature:
   a. Locate the age closest to that achieved by the boy.
   b. For that age, locate the horizontal row that includes the boy's length or stature.
   c. Locate the vertical column closest to the midparent stature for the boy's mother and father.
   d. The parent-specific adjustment (in cm) appears at the row-column intersection.
   e. Add the parent-specific adjustment to the boy's length or stature if the factor has no sign; subtract the adjustment if it has a minus sign.
7. Determine the boy's parent-specific adjusted percentile by plotting adjusted length or stature on the appropriate NCHS growth chart. Clearly label plotted measurements as being actual or adjusted values.

Interpretation: A boy at a low percentile for actual length or stature whose parents are short probably is genetically short. However, his shortness, particularly if it is extreme, may have additional contributing factors that should be considered.

If the boy's adjusted percentile is low, his growth probably has been slowed by nongenetic factors, and diagnostic studies should be considered. If the parents are tall, the boy's adjusted percentile will be lower than his actual percentile, and his shortness is more likely due to malnutrition or disease.

A boy at a high adjusted percentile for length or stature most often will be found to have accelerated maturation. Rarely, a specific disorder such as Marfan's syndrome or pituitary gigantism may be responsible for the boy's unusual length or stature.

Follow-Up: Counseling may be advisable when a boy is judged to be genetically short or tall. Additional contributing factors should be considered and growth monitored to confirm the relative stability of the boy's length or stature percentile.

Further investigation and modification of diet or specific therapy are indicated for a boy with unusual length or stature due to malnutrition or disease. Growth should be monitored to evaluate the effectiveness of dietary management or drug therapy.

Example #1. Boy aged 12 months, length 28 in., mother's stature 60½ in., and father's stature 65¼ in.

Son's actual length in cm is 71.1 (from Table 1).
Son's actual percentile is below the 5th (from NCHS growth chart).
Mother's stature in cm is 153.7 (from Table 1).
Father's stature in cm is 165.7 (from Table 1).
Midparent stature is $\frac{153.7 + 165.7}{2} = 159.7$ cm.
Adjustment is 2 cm (from Table 2).
Son's adjusted length is 71.1 cm + 2 cm = 73.1 cm.
Son's adjusted percentile is between the 10th and 25th (from NCHS growth chart).
Interpretation: Probably genetically short. Consider additional contributing factors.

Example #2. Boy aged 8 years, stature 47¼ in., mother's stature 68½ in., and father's stature reported as "tall."

Son's actual stature in cm is 120.0 (from Table 1).
Son's actual percentile is 10th (from NCHS growth chart).
Mother's stature in cm is 174.0 (from Table 1).
Midparent stature is 180.0 cm (from Table 4).
Adjustment is − 7 cm (from Table 3).
Son's adjusted stature is 120.0 cm − 7 cm = 113.0 cm.
Son's adjusted percentile is below the 5th (from NCHS growth chart).
Interpretation: Probably nongenetically short. Further investigation is indicated.

DIAGNOSING THE FULL SPECTRUM OF FETAL ALCOHOL EXPOSED INDIVIDUALS: INTRODUCING THE 4-DIGIT DIAGNOSTIC CODE

Susan J. Astley, Ph.D.[1,2] and Sterling K. Clarren, M.D.[2]

[1]Department of Epidemiology, School of Public Health and Community Medicine and [2]Department of Pediatrics, School of Medicine, University of Washington, Seattle, Washington, USA

(*Received* 18 *November* 1999*; in revised form* 24 *March* 2000*; accepted* 30 *March* 2000*)*

Abstract-The medical/research records of 1,014 patients diagnosed at the Washington State FAS Diagnostic and Prevention Network of clinics were used to develop a new, comprehensive, reproducible method for diagnosing the full spectrum of outcomes among patients with prenatal alcohol exposure. This new diagnostic method, called the 4-Digit Diagnostic Code, was compared to the standard gestalt method of diagnosis on the first 454 patients who had received a gestalt diagnosis of FAS, atypical FAS (AFAS) or possible fetal alcohol effect (PFAE) prior to the development of the 4-Digit Diagnostic Code. The outcomes of the patients were more accurately and comprehensively documented by the 4-Digit Diagnostic Code because of it's use of quantitative, objective measurement scales and specific case-definitions. The four digits in the Code reflect the magnitude of expression of the four key diagnostic features of FAS in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) central nervous system damage/dysfunction, and (4) gestational alcohol exposure. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong 'classic' presence of the FAS feature**.** The 4-Digit Diagnostic Code is being used effectively for diagnosis, screening and surveillance efforts in all Washington State FAS DPN clinics.

INTRODUCTION

The fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The definition of the FAS has changed little since the 1970's when the condition was first described and refined (Jones and Smith, 1973; Rosett, 1980; Clarren and Smith, 1978; Sokol and Clarren, 1989; Stratton *et al*., 1996). The syndrome has been broadly characterized by pre- and/or postnatal growth deficiency, a characteristic set of minor facial anomalies, central nervous system (CNS) dysfunction and prenatal alcohol exposure. The presentation of each individual feature of the syndrome may be variably expressed with age.

For trained clinicians, dysmorphologists, or clinical geneticists, there is likely to be full agreement on a diagnosis of FAS only when the anomalies in growth, face, and brain are all very extreme and the alcohol exposure is conclusive and substantial. But the features are not dichotomous, that is either normal or clearly abnormal. Rather, the features, and indeed the history of alcohol exposure, all range along separate continua from normal to clearly abnormal and distinctive.

In the absence of accurate, precise, and unbiased methods for measuring and recording the severity of exposure and outcome in individual patients, diagnoses will continue to vary widely from clinic to clinic (Chavez *et al*., 1988; Aase, 1994; Stratton *et al*., 1996). From a clinical perspective, diagnostic misclassification leads to inappropriate patient care, increased risk for secondary disabilities (Streissguth and Kanton, 1997) and missed opportunities for primary prevention. From a public health perspective, diagnostic misclassification leads to inaccurate estimates of incidence and prevalence (Stratton *et al*., 1996). Inaccurate estimates thwart efforts to allocate sufficient social, educational and health care services to this high-risk population and preclude accurate assessment of primary prevention intervention efforts. From a clinical research perspective, diagnostic misclassification reduces the power to identify clinically meaningful contrasts between groups. Non-standardized diagnostic methods prevent valid comparisons between studies.

The primary limitations in the current practice of diagnosing individuals with prenatal alcohol exposure include:

1. *While there are diagnostic guidelines that physicians and medical researchers are encouraged to follow, the guidelines are not sufficiently specific to assure diagnostic accuracy or precision.* While the diagnostic guidelines published by Sokol and Clarren (1989), which were a minor modification of the definition by the Fetal Alcohol Study Group of the Research Society for Alcoholism (Rosett, 1980) which, in turn, were derived from the work of Clarren and Smith (1978), do provide guidance, they are not sufficiently specific to assure diagnostic accuracy and precision. They reflect a more gestalt approach to diagnosis. The guidelines for CNS dysfunction do not address how many areas of deficit must be present, how severe the deficits must be or what level of documentation must exist to substantiate the presence of the deficit (i.e., parental history, psychometric testing or structural imaging). The guidelines for the facial phenotype are equally nonspecific. How many facial features must be present, how severe must the features be and what scale of measurement should be used to judge their severity? One need only read the clinical literature or review medical records, birth certificates, birth defect registries or ICD-9 codes to see how variably these criteria are interpreted, applied and reported (Cordero *et al*., 1994; CDC, 1995, 1995a; Ernhart *et al*., 1995; Stratton *et al*., 1996). Although the most recent guidelines published by the Institute of Medicine (Stratton *et al*., 1996) have not been out long enough to judge their impact on diagnostic accuracy and precision, the Institute guidelines present with the same limitations as previous guidelines.

2. There is a lack of objective, quantitative scales to measure and report the magnitude of expression of key diagnostic features. For example, although a thin upper lip and smooth philtrum are key diagnostic features (Jones and Smith, 1973; Clarren and Smith, 1978; Astley and Clarren, 1996, Stratton *et al*., 1996), quantitative measurement scales have never been used to measure thinness or smoothness and guidelines have never been established for how thin or smooth the features must be. Objective quantitative scales would not only improve accuracy and precision, they would also greatly increase the statistical power to detect clinically important exposure-outcome patterns (Polit and Hungler, 1995) by increasing the level of measurement from the current nominal scales (e.g., upper lip thin/not thin) to ordinal scales (e.g., 5-point Likert pictorial scale for lip thinness) or continuous scales (e.g., upper lip circularity: perimeter^2/area). Ordinal and continuous scales better reflect the true continuum of outcome and exposure in FAS. Objective, quantitative scales also establish a common descriptive language for communicating outcomes in medical records and in the medical literature (Polit and Hungler, 1995).

3. The term fetal alcohol effects (FAE) is broadly used and poorly defined. The term 'suspected fetal alcohol effects' was first introduced into the medical literature in 1978 and was defined as 'less complete partial expressions' of FAS in individuals with prenatal alcohol exposure (Clarren and Smith, 1978). Based on this definition, an individual whose mother drank a few glasses of wine intermittently throughout pregnancy and presented with attention deficit hyperactivity disorder would meet the criteria for FAE. So would an individual whose mother drank a fifth of vodka (757ml) daily throughout pregnancy and presented with microcephaly, severe mental retardation, growth deficiency and no facial anomalies. The broad use of this term and the reluctance to abandon it points to the clear need to develop diagnostic terms for individuals with prenatal alcohol exposure who present with physical anomalies and/or cognitive/behavioral disabilities, but do not meet the criteria for FAS.

4. Clinical terms like FAE, alcohol related birth defects (ARBD) and alcohol related neurodevelopmental disorder (ARND) (Stratton et al. 1996) inappropriately imply a causal link between exposure and outcome in a given individual. With the likely exception of the full facial phenotype, no other physical anomalies or cognitive/behavioral disabilities observed in an individual with prenatal alcohol exposure are necessarily specific to (caused only by) their prenatal alcohol exposure (Stratton *et al*., 1996). There have already been formal appeals by noted dysmorphologists in the field to discontinue the use of the term FAE (Aase *et al*., 1995; Sokol and Clarren, 1989). The diagnostic terms ARBD and ARND introduce the same limitations as FAE, namely, implying alcohol exposure caused the birth defect or neurodevelopmental disorder in an *individual* patient.

5. The terms FAS and FAE fail to convey the diversity of disability present in these individuals. No two individuals with FAS present with precisely the same constellation of anomalies and disabilities. Growth, facial phenotype, CNS dysfunction and alcohol exposure all vary along separate continua. The term FAS only conveys that the condition is permanent and was caused by prenatal alcohol exposure. The term does not convey what the individual's disabilities are. A nomenclature that not only conveys the diversity of outcomes among individuals with prenatal exposure, but also separates outcome from exposure would benefit both the patient and their medical/social/educational care network.

Each of these limitations have been largely overcome with the development of a comprehensive manual for the diagnosis of FAS entitled '*Diagnostic Guide for Fetal Alcohol Syndrome and Related Conditions*' (Astley and Clarren 1999) introducing a new quantitative approach to diagnosis, the '4-Digit Diagnostic Code'. The diagnostic method was developed through the combined expertise of the University of Washington FAS Diagnostic and Prevention Network (FAS DPN) multidisciplinary, clinical team and the comprehensive records of 1,014 FAS DPN patients (birth to 51 years of age) with reported prenatal alcohol exposure.

The creation of the 4-Digit Diagnostic Code was developed to assure accurate and precise diagnosis of individuals with prenatal alcohol exposure across all seven FAS Clinics in the Washington State FAS DPN (Clarren and Astley 1997). The FAS DPN (expanded from the CDC-sponsored FAS Clinic at the University of Washington) was mandated by the 1995 Washington State Legislature in response to the high, statewide demand for diagnostic services. The guide was developed to meet the needs of a broad range of professionals in an equally broad range of settings. A core team that includes a physician, a psychologist, a language pathologist, an occupational therapist staffs each clinic and a family advocate. Each core team has community-based links to alcohol treatment centers, genetics clinics, schools, and social and legal service agencies. The seven clinics have been established in the following settings: a children's hospital neurodevelopmental clinic, two public health clinics, an alcohol treatment clinic, a private psychological services clinic paired with an academic institution and a comprehensive children's medical/social services center. These six clinics are led by the FAS DPN core center at the Center for Human Development and Disability at the University of Washington.

The need to standardize the criteria for FAS was recognized early on by the Fetal Alcohol Study Group of the Research Society of Alcoholism, resulting in a published guidelines by Rosett (1980) followed by several efforts to hone, clarify and express concern about the guidelines (Sokol and Clarren, 1989; Aase e. al., 1995; Stratton *et al*., 1996). In the absence of specific case-definitions, the FAS DPN has responded to both a mandate by its State legislature and recommendations by the Institute of Medicine (Statton *et al*., 1996) to establish a diagnostic method which could be administered accurately and reproducibly.

Below are a brief description of the 4-Digit Diagnostic Code and a comparison of the gestalt (Sokol and Clarren, 1989) and 4-Digit Diagnostic code outcomes for 454 patients seen in the FAS DPN who received both diagnostic approaches. A more detailed description of the 4-Digit Code can be found in a 111 page manual distributed by the University of Washington in Seattle. The diagnostic guide includes a standardized FAS Diagnostic and Evaluation Form accompanied by instructions, case definitions, normal anthropometric charts, pictorial Likert scales for ranking lip thinness and philtrum smoothness, and a New Patient Information Form which is completed by the patient's family to document the patient's exposure and developmental history. The guide is accompanied by an instructional CD-ROM entitled 'Fetal Alcohol Syndrome Tutor

Medical Training Software' (Astley *et al*., 1999). We have used the 4-Digit Code to diagnose over 1,000 patients and have found the system to be very helpful in clinical and research areas. We describe it here and present preliminary assessments of its accuracy, precision and power so that others can consider and evaluate its use.

METHODS

The 4-Digit Diagnostic Code was developed through the expertise of the multidisciplinary FAS DPN clinical staff and use of the medical research records of 1,014 patients diagnosed in the FAS DPN. The purpose was not to redefine, but rather, more specifically case define the key diagnostic components of FAS as presented across several published FAS diagnostic guidelines (Clarren and Smith, 1978; Rosett, 1980; Sokol and Clarren, 1989; Stratton *et al*., 1996). The first working draft of the method completed in 1997 (Astley and Clarren, 1997), was pilot tested on all patients seen in the FAS DPN from 1997 – 1999 ($n \approx 400$) and was refined to its current form. Prior to the development of the 4-Digit Code, all 598 patients seen in the University of Washington FAS DPN Clinic (1993-97) were diagnosed using the 'gestalt' (Sokol and Clarren, 1989) method. In 1997, the FAS DPN clinics stopped using the gestalt method and started using the 4-Digit Diagnostic Code method. The charts of all patients who had previously been diagnosed with the gestalt method were retrofitted to the 4-Digit Diagnostic Code system for research purposes. The gestalt and 4-Digit Diagnostic Code outcomes are compared among the 454 patients who had received gestalt diagnoses of FAS, atypical FAS (AFAS) or possible fetal alcohol effect (PFAE). The University of Washington Human Subjects Review Board approved use of this data.

Preliminary assessments of precision, accuracy and power are presented to assist the reader in their evaluation of this new diagnostic method. The diagnostic evaluation forms of 20 patients were randomly selected from the 736 patients who received a 4-Digit Diagnostic Code one to four years ago at the University of Washington FAS DPN Clinic by SKC and SJA. The standardized diagnostic forms document the clinical and psychometric data that was available on the patient at the time of their diagnosis. The 4-Digit Codes were deleted from the forms by the research assistant and re-derived by SKC and SJA independently. Inter-rater reliability between SKC and SJA was assessed by comparing their re-derived 4-Digit Codes. Intra-rater reliability was assessed by comparing the re-derived codes to the original 4-Digit Codes. An additional assessment of inter-rater reliability was conducted on all 16 patients who had received 4-Digit Diagnostic Codes from one of the six FAS DPN clinics without consult by the FAS DPN Core team at the University of Washington. The level of agreement between the 4-Digit Diagnostic Codes derived by the Network and University of Washington clinical teams was assessed. The Kappa statistic was computed to test intra-and inter-rater agreement. Accuracy (the degree to which a measurement represents the true value of the attribute that is being measured) was assessed by comparing the 4-Digit Diagnostic outcomes to the gestalt diagnostic outcomes of the 454 patients who were diagnosed by both methods. Each of the diagnostic outcomes were also compared to the published diagnostic guidelines (Sokol and Clarren, 1989) available when the gestalt diagnoses were made. Power, the probability of detecting an effect in a study sample if an effect of a specified size or greater truly exists in the population was computed using SamplePower (SPSS Inc., 1997).

RESULTS

The 4-Digit Diagnostic Code

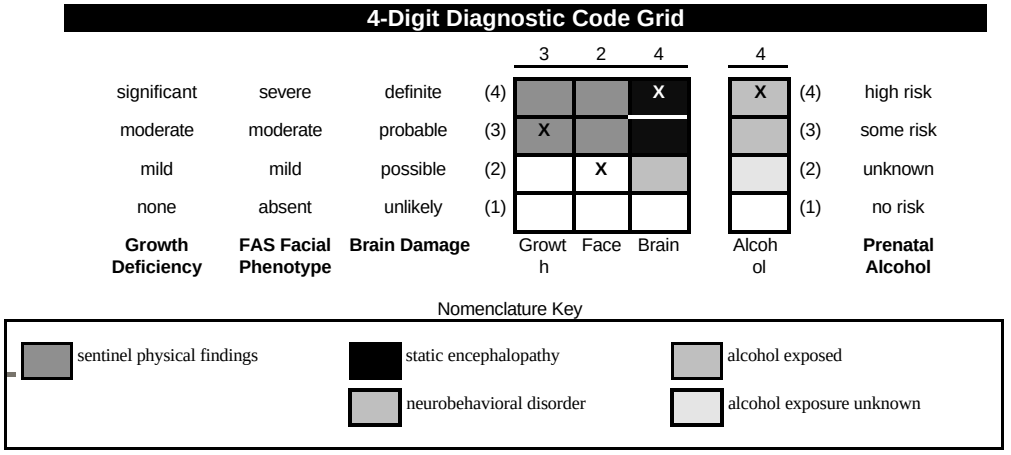
The four digits of the diagnostic code reflect the magnitude of expression of four key diagnostic features of FAS in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) brain damage/dysfunction, and (4) gestational alcohol exposure (Fig. 1). The 4-Digit Diagnostic Code is generated by first recording key clinical data on the standardized FAS Diagnostic Evaluation Form and following specific case-definitions to generate each digit.

The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong 'classic' presence of the FAS feature. Each Likert rank is specifically case-defined. The 4-Digit Diagnostic Code can be used to diagnose individuals of all ages.

Clinical Nomenclature

There are 256 possible 4-Digit Diagnostic Codes ranging from 1111 to 4444. Each 4-Digit Diagnostic Code falls into one of 22 unique Clinical Diagnostic Categories (labeled A through V) (Table 1). The 22 Diagnostic Categories are named to reflect the Likert ranking of each digit in the 4-Digit Diagnostic Code. The names are constructed sequentially from four terms: 'sentinel physical findings', 'neurobehavioral disorder', 'static encephalopathy' and 'alcohol exposure status' as presented in Figure 1 and Table 1. Note that the names for Diagnostic Categories E-J, K-P and Q-V only differ by alcohol exposure, thus there are essentially only nine unique diagnostic *outcome* categories ranging from 'no cognitive/behavioral or sentinel physical findings detected' to 'FAS'. This is in contrast to the five diagnostic outcome categories (FAS, Partial FAS, ARBD, ARND and FAE) currently in use across the various gestalt guidelines (Clarren and Smith, 1978; Sokol and Clarren, 1999; Stratton *et al*., 1996).

The first two diagnostic categories (A and B) meet the criteria for a clinical diagnosis of FAS and are named as such (Table 1). The term Atypical FAS (category C) is introduced for use with a relatively small group of patients who present with static encephalopathy, most, but not all of the sentinel physical findings of FAS, and were alcohol exposed. The term FAS Phenocopy (category D) applies to the patient who presents with all of the features of FAS, but has a confirmed *absence* of gestational ethanol exposure. We have not yet observed such a patient. The remaining 19 categories (E - V) do not meet the minimum criteria for FAS and are subsequently named to reflect the Likert ranking of each digit in the 4-Digit Diagnostic Code. For example, a code of 4342 is the Diagnostic Category called '*sentinel physical findings / static encephalopathy (alcohol exposure unknown)*'. Many of these patients might have previously been referred to variably as having possible ARBD), or alcohol related neurodevelopmental disorder ((ARND) (Stratton *et al*., 1996).



4-Digit Diagnostic Code Grid and Nomenclature
This grid is used to record the 4-Digit Diagnostic Code following the guidelines presented in the text. A code of 3 or 4 in the Growth or Face column is referred to as a 'sentinel physical finding'. A code of 2 in the Brain column is a 'neurobehavioral disorder'; a code of 3 or 4 is 'static encephalopathy'. A code of 3 or 4 in the alcohol column is 'alcohol exposed'. The code 3244 would receive the name 'sentinel physical findings, static encephalopathy, alcohol exposed'. A subset of 4-Digit Diagnostic Codes that fall within the category 'sentinel physical findings, static encephalopathy, alcohol exposed' are referred to as FAS when the four digits are sufficiently high to meet the criteria for FAS (see Table 1).

This new nomenclature replaces all of these terms. These terms are not used here because the inclusion of 'alcohol-related' or 'alcohol-effect' in the diagnostic name inappropriately implies a confirmed causal link between exposure and outcome in an individual. Diagnostic Categories E - I would have previously been referred to as 'fetal alcohol effects', 'alcohol related birth defects' or 'alcohol related neurobehavioral disorder'. Categories J - V are new categories that describe a large number of patient groups who have never been adequately classified or described in the past. The Likert ranks for the four digits of the code are case defined for consistent application. The case definitions are briefly presented below and are more fully presented in the Diagnostic Guide for FAS (Astley and Clarren, 1999).

Case Defining the Growth Component of the 4-Digit Diagnostic Code

Age- and gender- adjusted height- and weight-centiles are ranked by circling A, B or C in the ABC-Score table (Table 2A). The Height-Weight ABC Score recorded in Table 2A is converted to a 4-Digit Diagnostic Code Rank using Table 2B. The 4-Digit Code Rank is transferred to the 4-Digit Diagnostic Code Grid (Figure 1). Detailed instructions are provided in the Diagnostic Guide for FAS (Astley and Clarren, 1999) for ranking growth when growth measures are available at more than one time point.

Case Defining the Facial Phenotype Component of the 4-Digit Diagnostic Code

Three key diagnostic features characterize the FAS facial phenotype: small palpebral fissures, a smooth philtrum and thin upper lip (Clarren and Smith, 1978; Astley and Clarren, 1996). Palpebral fissure length z-scores are computed with adjustment for age and when possible, race (Hall *et al*., 1989). The thinness of the vermilion border of the upper lip and the smoothness of the philtrum are coded independently on 5-point pictorial Likert scales using Figure 2. Lips must be gently closed with no smile. The magnitude of palpebral fissure length deficiency, philtrum smoothness and upper lip thinness are ranked by circling A, B, or C in each column in the ABC-Score table (Table 3A). The ABC-Score is converted to the 4-Digit Diagnostic Code Rank for face using Table 3B.

Facial phenotype can be assessed directly or from digitized facial photographs (Astley and Clarren, 1996; Astley *et al*., 1999). It has been our experience that palpebral fissure length and upper lip thinness can be more accurately measured from digitized photographs using image analysis software (SigmaScan, 1996). A standardized, digital, facial photograph is taken of the patient with an internal measure of scale (2 cm sticker) placed on the forehead. The image is displayed on a computer monitor and PFL is measured by clicking the mouse on the endocanthion and exocanthion landmarks and comparing the distance between the landmarks relative to the size of the internal measure of scale. Upper lip thinness is measured by tracing the outline of the vermilion border with the mouse and computing circularity (perimeter^2/area). The thinner the lip the smaller the circularity. Circularity is used to guide the 5-point ranking of upper lip thinness as demonstrated in Figure 2. All patients seen in the FAS DPN clinic have their digital facial photographs analyzed during their diagnostic evaluation. The process takes approximately ten minutes and is described in detail in the FAS Tutor™ CD-ROM (Astley *et al*., 1999).

Table 1. Diagnostic Categories.

Category	Diagnostic Category Name and 4-Digit Codes within each Category
A	Fetal alcohol syndrome (alcohol exposed)
	3433 4433 3434 4434 3443 4443 3444 4444
B	Fetal alcohol syndrome (alcohol exposure unknown)
	3432 4432 3442 4442
C	Atypical fetal alcohol syndrome (alcohol exposed)
	1443 1434 2434 3334 4334 2443 1444 2444 3344 4344 4343
D	Fetal alcohol syndrome phenocopy (no alcohol exposure)
	3431 4341 4441 3441 4431
E	Sentinel physical findings / static encephalopathy (alcohol exposed)
	1333 1433 2344 3143 3243 4133 4233 4333 1334 2333 2433

	4411
V	No cognitive/behavioral or sentinel physical findings detected (no alcohol exposure)
	1111 2111 1211 2211

The 4-Digit Diagnostic Code reflects the magnitude of expression of four key diagnostic components of FAS in the order growth, facial phenotype, CNS damage/dysfunction and alcohol exposure. Each component is measured on a 4-point Likert scale, thus producing 256 possible combinations of 4-Digit Diagnostic Codes. These codes are collapsed into 22 Diagnostic Categories as presented above

Case-Defining the Brain Damage/Dysfunction Component of the 4-Digit Diagnostic Code

Brain damage/dysfunction is the most significant disability for individuals damaged by prenatal alcohol exposure. Ethanol alters the developing brain in a variety of ways from structural to gross anomalies of gray and/or white matter and/or to subtle alterations in neurochemical levels (West, 1986). Accurately quantifying and qualifying brain damage/dysfunction

Table 2. ABC score and case definitions for growth deficiency

A)

ABC Rank	Centile Range	Circle the ABC-Score for: Height	Weight
C	≤ 3rd	C	**C**
B	>3rd and ≤ 10th	**B**	B
A	>10th	A	A

B)

4-Digit Diagnostic Code Rank	Growth Deficiency Category	Height-Weight ABC-Score Combinations
4	Severe	CCC
3	**Moderate**	CB, **BC**
2	Mild	CA, BB, AC
1	None	BA, AB, AA

A) The first step in deriving the Likert rank for growth is to derive the ABC-Score for growth. If a patient's height centile was 8% and weight centile was 2%, an ABC-Score of **BC** would be assigned. B) The final step in deriving the Likert rank for growth is to convert the ABC-Score for Growth into a 4-Digit Diagnostic Code rank. A score of **BC** translates into a 4-Digit Diagnostic Code rank of **3.** This rank would serve as the first digit in the 4-Digit Diagnostic Code (Figure 1).

Lip-Philtrum Guide Likert Ranks	ABC-Score	Upper Lip Circularity
	C	178
	C	80
	B	65
	A	50
	A	35

Figure 2. Lip-Philtrum Guide

Pictorial examples of the 5-point Likert scale, upper lip circularity scale and the ABC-scale used to rank upper lip thinness and philtrum smoothness. Circularity (perimeter^2/area) is a continuous measure of upper lip thinness that can be used to facilitate the ranking of the upper lip. Circularity ranges from 12.8 for a circle to infinity as the circle is squashed into a line (or becomes thinner). Circularity is measured by outlining the vermilion border of the upper lip using image analysis software such as SigmaScan Pro (1996) (Astley and Clarren, 1996; Astley *et al*., 1999). It is important that the individual's lips are gently closed with no smile.

is important for both diagnosis and treatment planning. Brain damage can be defined in a large number of ways that are each associated with a broad spectrum of disability. The 4-point Brain Damage Likert Scale (Table 4) allows the clinician to separate patients with clear evidence of brain damage (Likert Rank 4) from patients with no evidence of brain damage (Likert Rank 1). The 4-Digit Rank for brain does not rank the severity of structural, neurologic or functional problems faced by the patient. Rather it ranks the strength of evidence supporting the presence of an organic cause for cerebral/cerebellar dysfunction.

A rank of 4 is reserved for patients who present with 'medical' evidence of structural or neurologic brain damage. Examples include any one of the following: microcephaly, structural alterations on brain imaging studies, hard neurologic findings like a primary seizure disorder or cerebral palsy or an intelligence quotient that is clearly below the normal distribution (FSIQ<60).

A rank of 3 is reserved for patients who present with 'psychometric' evidence of brain damage. Clearly, there are patients who have organic brain damage at a level not detectable by the current technology that allows us to derive a Rank 4. In the absence of advanced technology, we feel it is important to identify patients who present with cognitive/behavioral dysfunction as measured on standardized psychometric tests. At this time we case define Rank 3 to mean that a patient has had an age appropriate battery of tests in the areas of intelligence, adaptation, academic achievement, language and neuropsychology. The pattern of abnormality on the test battery, when taken as a whole, must be clinically interpreted by the assessing team to strongly support abnormal brain function. Patients who do not meet the

Table 3. ABC score and case definitions for facial phenotype

A)

5-Point Likert Scale for Philtrum & Lip	Z-score for largest Palpebral Fissure Length	Palpebral Fissure	Circle the ABC-Scores for: Philtrum	Upper Lip
4 or 5	≤ -2 SD	C	C	C
3	>-2 SD and ≤ -1 SD	B	B	B
1 or 2	> -1 SD	A	A	A

B)

4-Digit Diagnostic Code Rank*	Level of Expression of FAS Facial Phenotype	Palpebral Fissure - Philtrum - Lip ABC-Score Combinations
4	Severe	CCC
3	Moderate	CCB, CBC, BCC
2	**Mild**	CCA, CAC, CBB, CBA, **CAB**, CAA BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	Absent	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

A) The first step in deriving the Likert rank for facial phenotype is to derive the ABC-Score for facial phenotype. If a patient's palpebral fissure lengths were > 2 SD below the norm and their philtrum and upper lip received Likert scores of 2 and 3 respectively (Figure 2), the facial phenotype would receive an ABC-Score of **CAB**. B) The final step in deriving the Likert rank for facial phenotype is to convert the ABC-Score for Facial Phenotype to a 4-Digit Diagnostic Code Rank. A **CAB** score translates into a 4-Digit Diagnostic Code rank of **2**. This rank would serve as the second digit in the 4-Digit Code (Figure 1).

Table 4. Case Definitions for Brain Damage.

4-Digit Diagnostic Code Rank	Brain Damage Scale	Confirmatory Findings
4	**Definite** *referred to as static encephalopathy*	● **Microcephaly, OFC ≤ -2 S. D.** *and / or* ● Abnormalities on brain images diagnostic of prenatal alteration *and / or* ● Evidence of persistent neurologic findings likely to be of prenatal origin *and / or* ● I.Q. score ≤ 60
3	**Probable** *referred to as static encephalopathy*	● Substantial deficiencies or discrepancies across multiple areas of brain performance such as cognition, achievement, adaptation, neurologic 'soft' signs, and language. Three or more areas should be found aberrant.
2	**Possible** *referred to as neurobehavioral disorder*	● Historical information / personal observations strongly suggest that the possibility of brain damage, but data to this point does not permit a Rank 3 or 4 classification.
1	**Absent**	● No problems likely to reflect brain damage are presented.

A patient presenting with a head circumference below the second centile would receive a 4-Digit Diagnostic Code rank of **4**. This rank would serve as the third digit in the 4-Digit Code (Figure 1).

criteria for a Rank 4, yet have psychometric test outcomes that document abnormal brain function (greater than 2 standard deviations below the mean) across three or more areas listed above receive a Rank 3. Although there are no scientific data to support that a criterion of three or more failures is more reflective of brain damage than a criterion of one or two failures, our experience with over 1,000 patients has demonstrated that the criteria we have selected have good face validity (e.g., the team is more likely to clinically interpret the battery as a whole as strongly supporting abnormal brain function when there are three or more failures). We anticipate that further clinical research coupled with rapidly advancing technology will likely provide more objective scientific data from which to judge the validity of these criteria. It is important to note that it is possible for a patient to meet the criteria for both a Rank 3 and Rank 4 since these are not mutually exclusive categories. If this occurs, the higher rank (Rank 4) is inserted into the 4-Digit Code because, for diagnostic purposes, it reflects the strongest clinical evidence of brain damage. The psychometric outcomes, whether normal or abnormal, facilitate the development of the treatment plan for all patients.

Likert Rank 2 is given to two subgroups of patients. All patients in Rank 2 should have histories of behavioral and/or cognitive problems that strongly suggest underlying brain dysfunction. One group of patients has not yet had the types of testing that would move them into Ranks 3 or 4, if positive. The reason for

Table 5. Case Definitions for Prenatal Alcohol Exposure.

4-Digit Diagnostic Code Rank	Prenatal Alcohol Exposure Category	Description
4	**High Risk**	● Alcohol use during pregnancy CONFIRMED *and* ● Exposure pattern is consistent with the medical literature placing the fetus at 'high risk' (generally high peak blood alcohol concentrations delivered at least weekly in early pregnancy).
3	Some Risk	● Alcohol use during pregnancy CONFIRMED *and* ● Drinking occurred in gestation in frequencies and volumes less than in Rank 4 or exact amounts unknown.
2	Unknown Risk	● Gestational exposure is simply not known or information is of questionable reliability.
1	No Risk	● Alcohol use during pregnancy is CONFIRMED to be completely ABSENT.

The case-definitions used to derive the 4-Digit Diagnostic Code rank for alcohol exposure. If a birth mother reported drinking a fifth of liquor several times a week throughout pregnancy, alcohol exposure would receive a 4-Digit Diagnostic Code rank of **4**. This rank would serve as the fourth digit in the 4-Digit Code (Figure 1).

this lack of testing is usually because the patients are too young to be reliably or conclusively tested (i.e., less than six years of age). The other group of patients is those who have had testing that did not reveal compelling evidence for Rank 3 or 4 classification, and yet, in the clinician's judgment, a strong possibility of brain damage can not be wholly dismissed. Alternative testing and/or follow-up testing should usually be considered. If adequately sensitive and appropriate testing has been carried out without clear evidence of brain dysfunction, it is unlikely a Rank 2 classification would be given.

Patients are classified as Rank 1 when no structural, neurological or cognitive/behavioral problems measured by clinical/psychometric assessment or caregiver interview are discerned.

Case Defining the Gestational Alcohol Exposure Component of the 4-Digit Diagnostic Code

Alcohol exposure is ranked according to the quantity, timing, frequency and certainty of exposure during pregnancy (Table 5). The case-definitions address the facts that exposure information is often unavailable and/or inaccurate and a clear consensus is not available concerning the amount of alcohol that can actually be toxic to each individual fetus (Stratton *et al.*, 1996). The case-definitions differentiate four clinically meaningful exposure groups (4. confirmed high exposure, 3. confirmed exposure, but level is low or unknown, 2. unknown exposure, and 1. confirmed absence of exposure).

High exposure is defined generally to be a blood alcohol concentration of greater than 100 mg/dL (a level that typically can be reached by a 55-kg woman consuming six to eight beers) weekly, early in pregnancy. In the absence of a clear consensus on the amount of alcohol that can actually be toxic to the fetus, this general definition should only serve as a guide, not a threshold. One example of a 'rank 4' exposure is birth mother reported drinking to intoxication weekly throughout pregnancy. Two examples of 'rank 3' exposures include: a) birth mother was observed to be drinking during pregnancy, but the amount is unknown, b) birth mother reported drinking one glass of wine once a week, but stopped drinking as soon as she learned she was pregnant. A few examples of when alcohol exposure is ultimately unknown and thus coded as a 'rank 2' include: a) the child is adopted and the records are closed, b) birth father reports birth mother drank while pregnant, but birth mother

Table 6. Cross-tabulation of Gestalt and 4-Digit Diagnostic Outcomes.

4-Digit Diagnostic Categories		Gestalt Diagnostic Categories FAS n = 69	AFAS n = 41	PFAE n = 344	Total n = 454
A	FAS (AE)	8	2	0	10
B	FAS (AE Unknown)	1	0	0	1
C	Atypical FAS (AE)	12	2	2	16
E	Sentinel physical findings/static encephalopathy (AE)	10	10	17	37
F	Static encephalopathy (AE)	8	8	69	73
G	Sentinel physical findings/neurobehavioral disorder (AE)	15	11	15	41
H	Neurobehavioral disorder (AE)	11	7	179	197
I	Sentinel physical findings (AE)	0	1	6	7
J	No cognitive/behavioral or sentinel physical findings (AE)	0	1	18	19
K	Sentinel physical findings /static encephalopathy (AE unknown)	1	0	2	3
L	Static encephalopathy (AE unknown)	0	1	5	6
M	Sentinel physical findings /neurobehavioral disorder (AE unknown)	2	0	5	7
N	Neurobehavioral disorder (AE unknown)	1	0	25	26
P	No cognitive/behavioral or sentinel physical findings (AE unknown)	0	0	1	1

Cross-tabulation of the Gestalt and 4-Digit diagnostic outcomes for 454 patients diagnosed by both methods in the Washington State FAS DPN clinics.
AE, alcohol exposure during gestation confirmed; AE unknown, alcohol exposure during gestation unknown; FAS, fetal alcohol syndrome; AFAS, atypical fetal alcohol syndrome; PFAE, possible fetal alcohol effects.

Table 7. Comparison of Gestalt and 4-Digit Diagnostic Outcomes.

4-Digit Ranks for Key	Diagnostic Outcomes						
	FAS		AFAS		PFAE		All Other
Diagnostic Features	Gestalt	4-Digit[1]	Gestalt	4-Digit[2]	Gestalt	4-Digit[3]	4-Digit[4]
	n = 69	n = 11	n = 41	n = 16	n = 344	n = 365	n = 62
Growth Deficiency[5] (n)

3. Some risk	26	5	17	2	160	188	8
4. High risk	38	5	23	14	146	177	11

Magnitude of expression of key FAS diagnostic features compared between the gestalt (Sokol and Clarren, 1989) and 4-Digit (Astley and Clarren 1999) diagnostic outcomes of 454 patients diagnosed by both methods in the Washington State FAS DPN clinics

FAS: fetal alcohol syndrome; AFAS: atypical fetal alcohol syndrome; PFAE: possible fetal alcohol effects; (1) 4-Digit Diagnostic categories A and B; (2) 4-Digit Diagnostic Category C; (3) 4-Digit Diagnostic Categories E-I; (4) All other 4-Digit Diagnostic Categories D, J-V; (5) Defined in Tables 2A, 2B; (6) Defined in Tables 3A and 3B; (7) Defined in Table 4; (8) Defined in Table 5.

reports she did not drink, c) birth mother started drinking at the age of 13 yrs, was never known to have a prolonged period of sobriety, thus the family assumed she drank during pregnancy.

Other Prenatal and Postnatal Exposures/Experiences

A comprehensive diagnostic process must take into consideration the risks associated with prenatal and postnatal exposures and experiences other than prenatal alcohol exposure. Most of the features associated with FAS are not specific to prenatal alcohol exposure. A variety of prenatal (poor prenatal care, prenatal complications, familial genetics and exposure to other potentially teratogenic agents, etc.) and/or postnatal (physical/sexual abuse, disrupted placement histories, head injuries, chronic substance abuse by the patient, etc.) events could explain all or some of the symptoms presented by the patient. The 4-Digit Diagnostic method requires the clinician to record pertinent prenatal and postnatal exposures and events on the standardized FAS Diagnostic Evaluation Form, rank their severity using case-defined 4-point Likert scales and report them in the standardized medical summary template provided in the Diagnostic Guide for FAS (Astley and Clarren, 1999).

Comparison of the Gestalt and 4-Digit Diagnostic Methods

The gestalt (Sokol and Clarren, 1989) and 4-Digit Diagnostic Code outcomes for 454 patients who initially received gestalt diagnostic evaluations at the University of Washington FAS DPN clinic are compared in Tables 6 and 7. Table 6 presents a cross-tabulation of the gestalt and 4-Digit diagnostic outcomes. Table 7 illustrates the variable magnitude of expression of the key diagnostic features of FAS (growth, face, brain and alcohol) for the three gestalt diagnostic outcomes (FAS, PFAS and PFAE) and for the equivalent 4-Digit diagnostic categories (Categories A and B are equivalent to the gestalt FAS; Category C is equivalent to the gestalt PFAS; and Categories E - I would be equivalent to the gestalt category of PFAE). The study population was 57.7% male, ranged in age from birth to 51 years old with a mean of 10.1 ± 7.0 years and had the following racial distribution: Caucasian (57.5%), African American (9.0%), Native American/Alaskan (14.1%), other (19.4%). Race, age and gender were equally distributed across the 4-Digit and gestalt diagnostic categories.

Of the 69 patients who received a gestalt diagnosis of FAS, only nine met the 4-Digit criteria for FAS (Categories A and B) (Table 6). In the absence of specific case-definitions, quantitative measurement scales and only three diagnostic choices (FAS, PFAS, or PFAE), the gestalt method for diagnosing FAS produced a very heterogeneous population, more heterogeneous than would be supported by the gestalt guidelines (Sokol and Clarren, 1989). For example, 37 of the 69 patients had no evidence of growth deficiency, 27 had only one of the three facial features, 29 had no psychometric or structural evidence of brain damage and five had unknown exposure to
alcohol (Table 7). Of the 344 patients who received a gestalt diagnosis of PFAE, the outcomes of these patients are also remarkably variable. These patients fall into 13 different 4-Digit

Diagnostic Categories (Table 6) and present with every combination of diagnostic features (Table 7). The term PFAE clearly fails to convey the diversity of outcomes within this group. Some patients received a diagnosis of PFAE based solely on alcohol exposure (n = 18) while other patients received a diagnosis of PFAE based on outcomes that fell just short of the full syndrome (n = 2). Research studies that treat this diverse group of patients as one 'homogeneous' group are at great risk of failing to identify clinically meaningful outcomes.

Precision: Inter- and Intra-rater Reliability

The 4-Digit Diagnostic Codes of 20 randomly selected patient files were rederived by SKC and SJA independently while masked to the original 4-Digit code that had been derived one to four years ago by the University of Washington Clinical team. The codes re-derived by SKC and SJA matched the original 4-Digit Codes across all four digits for all 20 subjects (inter- and intra-rater reliability was 100%, (Kappa = 1.0, p = 0.000). The 4-Digit Codes for the 20 randomly selected patients spanned the entire spectrum of normal to AFAS (1124 to 1444). Inter-rater reliability between the six FAS DPN regional clinics and the University of Washington FAS DPN Core clinic resulted in an exact match across all four digits on 15 of 16 (94%) patients (Kappa = 0.93, p = 0.000) and an exact match on Diagnostic Category on all 16 (100%) of the patients (Kappa = 1.0, p = 0.000). The one 4-Digit code that did not match was coded by the regional FAS DPN clinic as 1223 and the University FAS DPN clinic as 1123. The mismatch in the facial score was due to the network physician not pulling the epicanthal fold back before measuring the palpebral fissure length resulting in an underestimate of the length.

POWER

To demonstrate the statistical power of the 4-Digit Code over the gestalt method of diagnosis, the hypothesis that the full-scale intelligence quotient (FSIQ) decreases with increasing magnitude of expression of the FAS facial phenotype was tested among 216 patients who had been diagnosed by both the gestalt and 4-Digit diagnostic systems. Of the 216 patients, 31 received a gestalt diagnosis of FAS. The difference in the mean FSIQ between the patients with and without the gestalt FAS facial phenotype (82.3 and 85.0 respectively) was not statistically significant (t = -1.56, p = 0.13). In contrast, when the same 216 patients were classified by their 4-point Likert rank reflecting the magnitude of expression of the FAS facial phenotype, a statistically significant, inverse, linear association was revealed. The mean FSIQ among the patients with Likert facial ranks of 4, 3, 2, and 1 were 78.5, 83.8, 84.8 and 87.7 respectively (f = 4.1, p = 0.04). The power of the t-test to detect a contrast in facial phenotype between the two gestalt groups was only 23%, whereas the power of the ANOVA to detect the linear trend was 85%. By convention, the minimum power of a clinical research study is set at 80% (Hulley and Cummings, 1988). Thus, a clinically important linear association between face and brain that was detected by the 4-Digit Code failed to be detected by the gestalt method of diagnosis.

DISCUSSION

The 4-Digit Diagnostic Code method has been used in all seven FAS DPN clinics in Washington State for over three years, demonstrating that it can be taught to a broad array of social and health care professionals in an equally broad array of clinical settings. Some of our FAS DPN colleagues were hesitant to make diagnoses in patients with prenatal alcohol exposure prior to using this system precisely because the old nomenclature was too simplistic and did not offer consistent or helpful diagnostic outcomes. After three years of field testing this method, both prospectively and retrospectively on over 1,000 patients, it continues to uniformly reflect clinical judgement (a measure of face validity) and provide tremendous power to identify clinically meaningful patterns of outcome.

The 4-Digit Diagnostic Code presents with many strengths. It offers an intuitively logical digital approach to reporting outcomes and exposure that reflects the true diversity and continuum of disability associated with prenatal alcohol exposure. Preliminary assessments of precision, accuracy and power appear to be greatly increased over the 'gestalt' method of diagnosis. This can be attributed, in large part, to the use of objective, ordinal and continuous measurement scales, specific, comprehensive case-definitions (Polit and Hungler, 1995) and the use of a multidisciplinary clinical team approach. This study as well as others (Abel, 1990; Hannigan *et al*., 1992) have demonstrated that the current gestalt approach to diagnosis can often lead to diagnoses of FAS made solely on exposure, made in the absence of CNS dysfunction or made when only a single facial anomaly is present. The 4-Digit Code prevents this from occurring. Outcomes and exposures are reported independently so as not to imply that an *individual's* disabilities and/or anomalies are confirmed to be caused by their prenatal alcohol exposure. The 4-Digit Code serves as a standardized, descriptive language that will allow clinicians and researchers to clearly and objectively communicate the exposures and outcomes of their patients. Although the FAS DPN has gone one step further and clinically categorized and labeled the codes, use of the 4-Digit code is independent of this step, much like measuring and reporting birth weight in grams and centiles is independent of defining the cut-off for 'low birth weight'. Failure to reach consensus on the categorization and labeling of the codes need not prevent the use of the 4-Digit Codes. The 4-Digit diagnostic method is fully comprehensive. It can be used to diagnose individuals of all ages and races who present across the full spectrum of exposure and outcomes. This is achieved by directing the clinician to age-, gender- and race - adjusted anthropometric and psychometric measures when available and appropriate. The availability and reliability of outcome and exposure information varies across patients. The derivation of the 4-Digit Code addresses this reality by encoding both the presence and absence of outcome and exposure information. This method can be taught to a wide array of health care and social service providers, thus greatly expanding the availability of diagnostic services. Multidisciplinary clinical teams from six States in the U.S. and three Canadian Provinces have been trained to use the 4-Digit Code to date.

Although the 4-Digit diagnostic method was developed for prospective use in a fully staffed, multidisciplinary clinic, it can also be used in active and passive screening and surveillance efforts. Surveillance generally uses methods distinguished by their practicality, uniformity, and frequently their rapidity, rather

than by complete accuracy (Last, 1988). A key feature of the 4-Digit Diagnostic Code is that it not only documents exposure and outcome, but also documents how much data was available (or not available) to support the diagnostic outcome. The standardized FAS Diagnostic Evaluation Form served as an efficient tool for conducting the retrospective chart review on the 736 patients whose gestalt diagnoses were upgraded to 4-Digit Diagnostic Codes. The method provides an efficient and reproducible method for conducting retrospective chart reviews, a process that is the very essence of passive surveillance. The computerized facial analysis component of the 4-Digit Code also serves as an efficient and highly effective photographic method for screening for FAS (Astley *et al*., 1999). This method is currently being used to screen all children entering foster care in one county in WA State.

Meaningful progress in the areas of screening, diagnosis, intervention, surveillance and primary prevention all hinge on development of an accurate, precise, valid and efficient method for identification of individuals damaged by prenatal alcohol exposure. The 4-Digit Diagnostic Code was developed to achieve that goal in Washington State.

Acknowledgements - We wish to acknowledge our clinical colleagues Diane Bailey, R.N., Sharon Beck, M.Ed., Heather Carmichael Olson, Ph.D., Sandra G. B. Clarren, Ph.D., Truman Coggins, Ph.D., Tracy Jirikowic, M.S., OTR/L, Robin LaDue, Ph.D., Christina Talbot, M.S.W. and the clinical teams at the FAS DPN clinics who have helped us to sharpen this diagnostic system. We also wish to thank Kathleen Tharp, Julie Gelo, Kathryn Briggs-Jones, Heather Grigg, B.A., Heather Wicklein Sanchez B.S. and Cliff Astley, M.S. who readily offered their assistance when needed. Finally, a very special thanks is extended to all of our patients and their families who have contributed a wealth of knowledge and information to the development of this methodology. The development of this 4-Digit Diagnostic Code was supported in part by the following agencies and contributors: Centers for Disease Control and Prevention; Center for Human Development and Disability at the University of Washington, Seattle, Washington; Division of Alcohol and Substance Abuse, Washington State Department of Social and Health Services; March of Dimes Birth Defects Foundation and the John B. Chavez FAS Memorial Fund.

I wish to acknowledge my colleague and co-author on the 1st and 2nd Editions of this Guide, Sterling K. Clarren, M.D., who retired from the FAS Diagnostic & Prevention Network in 2001. His invaluable contributions to the field of FASD for over 25 years are reflected throughout the Guide and in the interdisciplinary approach to the diagnosis of FASD.

I would also like to acknowledge the University of Washington FAS Diagnostic & Prevention Network (FAS DPN) clinical team members over the years who have used this Guide weekly and have helped hone the material on an ongoing basis: Diane Bailey, R.N., M.S.N., Pediatric Nurse Practitioner; Sharon Beck, M.Ed., Educational Counselor; Julia Bledsoe, M.D., Pediatrician; Allison Brooks, Ph.D., Educational Psychologist; Heather Carmichael Olson, Ph.D., Psychologist; Sandra G. Bernstein Clarren, Ph.D., Educational Psychologist; Truman Coggins, Ph.D., Speech Language Pathologist; Julian Davies, M.D., Pediatrician; Susan Dorn, M.Ed, Educational Psychologist; Julie Gelo, Family Advocate/Resource Advisor; Beth Gendler, M.S.W., Social Worker; Tracy Jirikowic, Ph.D., OTR/L Occupational Therapist; Paul Kraegel, M.S.W., Social Worker, and Tina Talbot, M.S.W., Social Worker. The interdisciplinary teams at the Everett, Federal Way, Pullman, Spokane, Tacoma and Yakima FAS DPN clinics across Washington State have also contributed greatly to the advancement of this Guide. Their thoughtful insights have been invaluable. I also wish to thank Kathy Briggs-Jones, Kristen Daniels, M.L.I.S; Heather Grigg B.A.; Joshua Hunter, B.S.; Deborah Raymond; Kathleen Tharp and Heather Wicklein Sanchez B.S., who readily offered their assistance over the years. Finally, a special thanks is extended to all of our patients and their families who have contributed a wealth of knowledge and information to the development of this Guide.

Preface

What's New in this Third Edition?

The first and second editions of the Diagnostic Guide were printed in 1997 and 1999 (Astley and Clarren, 1997, 1999). The key updates in this third edition are presented below. These updates are based on our use of the 4-Digit Code for the past seven years on over 2,000 patients, advancements in medical research, U.S. and Canadian efforts to establish National Diagnostic Guidelines, and feedback from over 70 clinical teams trained to use the 4-Digit Diagnostic Code. We will continue to make modifications that enhance accuracy, improve clarity, and increase ease of use. We hope you will find this comprehensive approach to the diagnosis of individuals with prenatal alcohol exposure helpful and broadly applicable.

Key updates in this 3rd edition include:

1. Re-Classification of Nineteen 4-Digit Codes across Seven Diagnostic Categories. Based on current efforts in the U.S. and Canada to establish National Diagnostic Guidelines, and our own experience using the 4-Digit Code, we have reclassified 19 of the 246 4-Digit Codes. Most of these reclassifications reflect the widespread consensus to relax the growth criteria. A detailed presentation of which codes were reclassified, why they were reclassified, and the impact the reclassification has on the prevalence of each diagnostic category can be found on the FAS DPN website (http://depts.washington.edu/fasdpn).
2. Modification of the growth deficiency case-definitions to harmonize with the U.S. and Canadian Diagnostic case-definitions for growth deficiency. This modification allows one to document and differentiate growth deficiency at both the 3rd and 10th percentiles.
3. Updated FASD Diagnostic Form with a new Functional Domains page. The FASD Diagnostic Form has been updated to provide a more comprehensive format. An additional page has been added to allow one to document "Domains of Brain Dysfunction". Documentation of impaired domains (e.g., cognition, memory, executive function, etc.) is a key component of the Canadian and U.S. National Diagnostic Guidelines and has always been required to derive/support a CNS Rank 3 classification when using the 4-Digit Code.
4. Updated Growth Charts. The most recent 2000 CDC growth charts are included with reference to their website for computerized charting of growth.
5. New Caucasian and African American Lip-Philtrum Guides, 2004. A new Caucasian Lip-Philtrum Guide was printed that uses higher-resolution, higher quality photographs. The magnitude of lip thinness and philtrum smoothness remain unchanged from the 1999 Caucasian Lip-Philtrum Guide. A new African American Lip-Philtrum Guide has also been created. The cut-off values for each of the five ranks in the African American Guide were set to be comparable to the percentile cutoffs used in the Caucasian Lip-Philtrum Guide. Both Guides require a Rank 4 or 5 lip and philtrum to meet the criteria for the FAS facial phenotype. The 2004 modified growth table is printed on the backside of each Lip-Philtrum Guide.

I. Introduction

A. What are Fetal Alcohol Syndrome (FAS) and Fetal Alcohol Spectrum Disorders (FASD)

FAS is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The definition of the FAS has changed little since the 1970's when the condition was first described and refined (Jones and Smith, 1973; Rosett, 1980; Clarren and Smith, 1978; Sokol and Clarren, 1989; Stratton *et al*., 1996). The condition has been broadly characterized by prenatal and/or postnatal growth deficiency, a unique cluster of minor facial anomalies, and central nervous system (CNS) abnormalities. FAS is the leading known cause of mental retardation/developmental disabilities in the Western World (Abel & Sokol, 1987) and is entirely preventable. The prevalence of FAS is estimated to be 1 to 3 per 1,000 live births (Stratton et al., 1996) in the general population, but has been documented to be as high as 10 to 15 per 1,000 in some high-risk populations (Astley et al., 2002).

The physical, cognitive, and behavioral deficits observed among individuals with prenatal alcohol exposure are not dichotomous, that is either normal or clearly abnormal. Rather, the outcomes, and the prenatal alcohol exposure, all range along separate continua from normal to clearly abnormal and distinctive. This full range of outcomes observed among individuals with prenatal alcohol exposure has come to be called Fetal Alcohol Spectrum Disorders (FASD). The term FASD is not intended for use as a clinical diagnosis. A patient would not receive a diagnosis of FASD, for the term is too broadly defined to be of clinical value. FAS, on the other hand, is a clinical diagnosis and is one of several alcohol-related diagnoses that fall under the umbrella of FASD.

Although reference to the harmful effects of prenatal alcohol exposure on infant outcome dates back to the biblical literature, it was not until 1968 when the first reference was published in the medical literature by Lemoine and colleagues from France (Lemoine et al., 1968). Ulleland and colleagues from the United States published similar research findings in 1970 and 1972 (Ulleland et al., 1970; Ulleland, 1972). Using today's terminology, one could say Lemoine and Ulleland were the first to describe FASD in the medical literature. In 1973, Jones and Smith coined the term FAS (Jones & Smith, 1973) to describe a subset of alcohol-exposed children, obtained from Dr. Ulleland's study and their own clinical records, who shared a common pattern of malformation (Jones et al., 1973).

B. The Diagnostic Challenge

FASD can present a daunting, but not insurmountable challenge for diagnosis. Individuals with prenatal alcohol exposure present with a wide range of outcomes, most of which are not specific to prenatal alcohol exposure and often manifest differently across the lifespan. Professionals from multiple disciplines (medicine, psychology, speech-language pathology, occupational therapy, etc.) are needed to accurately assess and interpret the broad array of outcomes that define the diagnoses. The pattern and severity of outcome is dependent on the timing, frequency, and quantity of alcohol exposure (which is rarely known with any level of accuracy), and is frequently confounded by other adverse prenatal and postnatal exposures and events.

In the absence of accurate, precise, and unbiased methods for measuring and recording the severity of exposures and outcomes in individual patients, diagnoses have varied widely from clinic to clinic

(Aase, 1994; Astley & Clarren 2000; Chavez et al., 1988; Stratton et al., 1996). From a clinical perspective, diagnostic misclassification leads to inappropriate patient care, increased risk for secondary disabilities (Streissguth & Kanton, 1997) and missed opportunities for primary prevention. From a public health perspective, diagnostic misclassification leads to inaccurate estimates of incidence and prevalence (Stratton et al., 1996). Inaccurate estimates thwart efforts to allocate sufficient social, educational, and health care services to this high-risk population, and preclude accurate assessment of primary prevention intervention efforts. From a clinical research perspective, diagnostic misclassification reduces the power to identify clinically meaningful contrasts between FAS and control groups (Astley & Clarren, 2001). Non-standardized diagnostic methods prevent valid comparisons between studies.

The 4-Digit Diagnostic Code was originally created in 1997 to address the following limitations in the conventional gestalt approach to diagnosing individuals with prenatal alcohol exposure.

1. *There have been no standardized operational definitions for FAS or for any of the other diagnoses that fall under the umbrella of FASD. Rather, there have been diagnostic guidelines that physicians have been encouraged to follow, but the guidelines have not been sufficiently specific to assure diagnostic accuracy or precision.*

   For example, according to the diagnostic guidelines published by Sokol and Clarren (1989), which were a minor modification of the 1980 definition of FAS by the Fetal Alcohol Study Group of the Research Society for Alcoholism (Rosett, 1980), which, in turn, were derived from the work of Clarren and Smith (1978): "The diagnosis of FAS can only be made when the patient has signs of abnormality in each of the three categories: 1) Prenatal and/or postnatal growth retardation [weight and/or length below the 10^{th} percentile when corrected for gestational age], 2) central nervous system involvement (including neurological abnormality, developmental delay, behavioral dysfunction or deficit, intellectual impairment, and/or structural abnormalities, such as microcephaly [head circumference below the 3^{rd} percentile or brain malformations found on imaging studies or autopsy] and 3) a characteristic face, currently qualitatively described as including short palpebral fissures, an elongated midface, a long and flattened philtrum, thin upper lip, and flattened maxilla."

   The 1996 guidelines for the diagnosis of FAS proposed by the Institute of Medicine (Stratton et al., 1996) took a similar approach. The diagnosis of FAS can be made when the patient presents with: "1) Evidence of growth retardation, as in at least one of the following: a) low birth weight for gestational age; b) decelerating weight over time not due to nutrition; or c) disproportional low weight to height; 2) Evidence of a characteristic pattern of facial anomalies that includes features such as short palpebral fissures and abnormalities in the premaxillary zone (e.g., flat upper lip, flattened philtrum, and flat midface); and 3) Evidence of CNS neurodevelopmental abnormalities, as in at least one of the following: a) decreased cranial size at birth; b) structural brain abnormalities (e.g., microcephaly, partial or complete agenesis of the corpus callosum, cerebellar hypoplasia);c) neurological hard or soft signs (as age appropriate), such as impaired fine motor skills, neurosensory hearing loss, poor tandem gait, poor eye-hand coordination."

   Although these descriptions do provide guidance, they are not sufficiently specific to assure diagnostic accuracy and precision. They reflect a more "gestalt" approach to diagnosis. The guidelines for CNS abnormalities do not address how many areas of deficit must be present, how

severe the deficits must be, or what level of documentation must exist to substantiate the presence of the deficit. The guidelines for the facial phenotype are equally nonspecific. How many facial features must be present, how severe must the features be, and what scale of measurement should be used to judge the severity? One need only read the clinical literature or review medical records, birth certificates, birth defect registries or ICD-9 codes to see how variably these criteria are interpreted, applied and reported (CDC, 1995, 1995a; Cordero et al., 1994; Ernhart et al., 1995; Stratton et al., 1996).

New U. S. diagnostic guidelines for FAS (Bertrand et al., 2004) and Canadian diagnostic guidelines for FASD (Chudley et al., 2004) offer more standardized, case-defined criteria than those published in previous guidelines (Sokol and Clarren, 1989, Stratton et al., 1996). Both are slated for release in 2004.

2. *There has been a lack of objective, quantitative scales to measure and report the magnitude of expression of key diagnostic features*

   For example, although a thin upper lip and smooth philtrum are key diagnostic features (Astley & Clarren, 1996; Clarren & Smith, 1978; Jones & Smith, 1973; Smith, 1979; Stratton et al., 1996), quantitative measurement scales were never used to measure thinness or smoothness, and guidelines had never been established for how thin or smooth the features must be. Objective quantitative scales not only improve accuracy and precision, but also establish a common numeric language for communicating outcomes in medical records and in the medical literature.

3. *The term fetal alcohol effects (FAE) was broadly used and poorly defined.*

   The term 'suspected fetal alcohol effects' was first introduced into the medical literature in 1978 and was defined as 'less complete partial expressions' of FAS in individuals with prenatal alcohol exposure (Clarren & Smith, 1978). Based on this definition, an individual whose mother drank a few glasses of wine intermittently throughout pregnancy and presented with attention deficit hyperactivity disorder would meet the criteria for FAE. So would an individual whose mother drank a fifth of vodka daily throughout pregnancy and presented with microcephaly, severe mental retardation, growth deficiency and no facial anomalies. The broad use of this term and the reluctance to abandon it points to the clear need to develop diagnostic terms for individuals with prenatal alcohol exposure who present with physical anomalies and/or cognitive/behavioral disabilities, but do not meet the criteria for FAS. New diagnostic terms that more finely differentiate the variable exposures and outcomes of individual patients, without implying alcohol as the sole causal agent, are needed.

4. *Clinical terms like FAE* (Aase et al., 1995), *alcohol-related birth defects (ARBD) (Stratton et al., 1996) and alcohol-related neurodevelopmental disorder (ARND) (Stratton et al., 1996) imply a causal link between alcohol exposure and outcome in a given individual that, to date, cannot be medically confirmed. Leading dysmorphologists in the field of FAS diagnosis have formally requested that the term FAE no longer be used for this reason (Aase et al., 1995; Sokol & Clarren, 1989).*

   With the likely exception of the full facial phenotype, no other physical anomalies or cognitive/behavioral disabilities observed in an individual with prenatal alcohol exposure are necessarily specific to (caused only by) their prenatal alcohol exposure (Stratton et al., 1996). Features

such as microcephaly, neurological abnormalities, attention deficit, mental retardation, and growth deficiency frequently occur in individuals with prenatal alcohol exposure, and frequently occur in individuals with no prenatal alcohol exposure. The diagnostic terms ARBD and ARND introduce the same limitation as does FAE, namely, implying alcohol exposure caused the birth defect or neurobehavioral disorder in an individual patient. The 4-Digit Code avoids this problem by using a nomenclature that reports the patient was *exposed* to prenatal alcohol rather than reporting the patient's outcomes are *alcohol effects* or *alcohol-related outcomes*. The 4-Digit Code also requires that all other adverse prenatal and postnatal exposures and events be documented for they too serve as important risk factors that must be taken into consideration when deriving a diagnosis and intervention plan.

5. *Too often diagnoses depicting FASD are reported in the medical records and medical literature with no documentation of the method used to derive the diagnosis and little or no documentation of the data used to support the diagnosis.*

   Failure to report this information can limit the patient's ability to qualify for and receive appropriate intervention services from subsequent health care, social service, and educational providers. For example, simply reporting that an individual has FAS does little to convey the individual's strengths and disabilities. Some individuals with FAS have low IQs, some have normal IQs, some have attention deficits, some do not, some have problems with memory, while others have language deficits. From a public health perspective, failure to report these data also prevents surveillance efforts from accurately tracking the prevalence of FASD diagnoses in the population. The supportive data are needed to validate the diagnoses. Accurate surveillance is vital for setting public health policy and assessing the effectiveness of primary prevention efforts. The 4-Digit Code requires that data be collected not just to support the diagnosis, but to derive the diagnosis. The 4-Digit Code provides a comprehensive FASD Diagnostic Form for recording all supportive data and provides a numeric classification scheme that is readily incorporated into clinical, research, and surveillance databases.

C. Meeting the Diagnostic Challenge

Each of the above limitations has been largely overcome with the development of the "*4-Digit Diagnostic Code*". The four digits reflect the magnitude of expression of four key diagnostic features of FASD in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) CNS abnormalities, and (4) prenatal alcohol exposure. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic" presence of the FAS feature. Thus, the 4-Digit Code 4444 reflects the most severe expression of FAS (significant growth deficiency, all three FAS facial features, structural/neurological evidence of CNS damage, and confirmed prenatal exposure to high levels of alcohol). At the opposite end of the scale is the 4-Digit Code 1111 reflecting normal growth, none of the three FAS facial features, no evidence of CNS abnormalities, and confirmed absence of prenatal alcohol exposure. Every combination of 4-Digit Code has been observed in the Washington State FAS Diagnostic & Prevention Network.

This diagnostic method was developed through the combined expertise of the University of Washington FAS Diagnostic and Prevention Network (FAS DPN) interdisciplinary clinical team

(Clarren & Astley, 1997; Clarren et al., 2000) and the comprehensive records of over 2,000 patients (birth to 53 years of age) diagnosed through the FAS DPN.

D. Benefits of the 4-Digit Diagnostic Code

The 4-Digit Diagnostic Code:

1. Greatly increases diagnostic precision and accuracy through the use of objective, quantitative measurement scales, image analysis software, and specific case definitions.
2. Diagnoses the full spectrum of outcomes (FASD) observed in individuals of all ages with prenatal alcohol exposure.
3. Offers an intuitively logical numeric approach to reporting outcomes and exposure that reflects the true diversity and continuum of disability associated with prenatal alcohol exposure.
4. Documents the presence of prenatal alcohol exposure without judging its causal role.
5. Documents all other prenatal and postnatal adverse exposures and events that can also impact outcome.
6. Provides a quantitative measurement and reporting system that can be used independent of diagnostic nomenclature.
7. Can be taught to a wide array of health care and social service providers, thus greatly expanding the availability of diagnostic services. (Appendix 1)

The 4-Digit Code currently serves as the cornerstone of a fully integrated and highly successful screening, diagnostic, prevention and surveillance program in Washington State (Astley et al., 2002; Astley, 2004).

While this document might at first appear overly complex and perhaps daunting, one will find that this diagnostic approach is logical and easy to use, and will greatly facilitate the proper description and classification of patients presenting with all possible combinations of outcomes and exposures.

E. Other Syndromes

The methods of diagnosing fetal alcohol syndrome arise from the larger fields of teratology and dysmorphology (clinical genetics). It is essential to remember that many birth defect syndromes share *isolated* features, but each is differentiated by a unique *constellation* of features. A few examples of conditions that share some, but not all, of the features of FAS include fetal hydantoin syndrome, maternal PKU fetal effects, and fetal valproate syndrome. Although this guide is "FASD-specific", this in no way should imply that the diagnostician need not consider alternate or co-existing syndromic, medical or psychiatric conditions at all times. A differential diagnosis is essential in making an accurate diagnosis.

II. FASD Diagnostic Form

The FASD Diagnostic Form guides the interdisciplinary clinical team in the collection, recording, and interpretation of all key information used to derive accurate and precise diagnoses across the full spectrum of outcomes. Comprehensive assessments lead to accurate diagnoses and informed intervention plans. Although space has been provided to record a full complement of data, we are not implying that all of these assessments must be conducted to derive a diagnosis. It is the responsibility of the clinical team to select the most appropriate assessment battery for each patient.

The form also serves as a centralized data repository for efficient generation of the final medical report and is designed to facilitate data entry into a database.

Where is the Information for the Diagnostic Form Obtained?

The information recorded in the FASD Diagnostic Form is obtained from four primary sources:

1. The New Patient Information Form completed by the caregivers prior to the diagnostic evaluation (Appendix 2).

2. Medical/psychological/educational assessments conducted prior to the diagnostic evaluation.

3. Assessments administered by the clinical team at the time of the diagnostic evaluation.

4. The caregiver/patient interview conducted at the time of the diagnostic evaluation

When is the Form Completed and by Who?

Diagnosis of fetal alcohol spectrum disorders by a multidisciplinary team of professionals (physician, psychologist, speech-language pathologist, occupation therapist, etc.) will result in the most accurate assessment and interpretation of the broad array of outcomes (growth deficiency, facial anomalies, and structural/neurological/functional CNS abnormalities) that define the diagnoses. The FASD Diagnostic Form is completed by the clinical team before and during the patient's clinic visit. Typically, the physician completes the sections pertaining to growth, structural and neurological measures of the CNS, facial features and other physical findings. The occupational therapist, psychologist, speech language pathologist, and/or other team members complete the sections pertaining to psychometric measures of CNS function. All team members participate in the derivation of the 4-Digit Code and intervention plan.

Diagnostic Form, Section II Diagnostic Guide for FASD

MATERNAL ALCOHOL USE

Alcohol Consumption of the Birth Mother

Before Pregnancy	**average number of drinks** per drinking occasion:					
	maximum number of drinks per occasion:					
	average number of **drinking days per week**:					
	Type(s) of alcohol	wine	beer	liquor	unknown	Other (specify)

During Pregnancy	**average number of drinks** per drinking occasion:					
	maximum number of drinks per occasion:					
	average number of **drinking days per week**:					
	Type(s) of alcohol	wine	beer	liquor	unknown	Other (specify)

Trimester(s) in which alcohol was consumed	1st	2nd	3rd	unknown	none
Was the birth mother ever reported to have a **problem** with alcohol?	yes	suspected	no	unknown	
Was the birth mother ever **diagnosed** with alcoholism?	yes	suspected	no	unknown	
Did the birth mother ever **receive treatment** for alcohol addiction?	yes	suspected	no	unknown	
Was alcohol use during this pregnancy **positively confirmed**?	yes	no			
If yes, **source** of confirmation:					
Reported use of alcohol during this pregnancy is:	Reliable	Somewhat reliable		Unk. reliability	
Other information about alcohol use **during** this pregnancy					

4-DIGIT RANK for Alcohol Exposure

4-Digit Diagnostic Rank	Prenatal Alcohol Exposure Category	Description
4	High Risk	● Alcohol use during pregnancy is CONFIRMED. *and* ● Exposure pattern is consistent with the medical literature placing the fetus at "high risk" (generally high peak blood alcohol concentrations delivered at least weekly in early pregnancy).
3	Some Risk	● Alcohol use during pregnancy is CONFIRMED. *and* ● Level of alcohol use is less than in Rank (4) or level is unknown.
2	Unknown Risk	● Alcohol use during pregnancy is UNKNOWN.
1	No Risk	● Alcohol use during pregnancy is CONFIRMED to be completely ABSENT from conception to birth.

Circle the 4-Digit Diagnostic Rank in the table above that best reflects the patient's Prenatal Alcohol Exposure

OTHER PRENATAL AND POSTNATAL EXPOSURES / EVENTS

III. Instructions for Deriving the 4-Digit Code

A. The 4-Digit Diagnostic Code

What are the 4 Digits?

The four digits reflect the magnitude of expression of the four key diagnostic features of FASD in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) CNS abnormalities, and (4) prenatal alcohol exposure. The 4-Digit Diagnostic Code is generated at the completion of the diagnostic evaluation using information recorded on the FASD Diagnostic Form. The code is derived following the directions in Sections III. B. 1 through B. 4.

4-Digit Diagnostic Code Grid

				3	4	4		4		
Severe	Severe	Definite	(4)		X	X		X	(4)	High risk
Moderate	Moderate	Probable	(3)	X					(3)	Some risk
Mild	Mild	Possible	(2)						(2)	Unknown
None	None	Unlikely	(1)						(1)	No Risk
Growth Deficiency	**FAS Facial Features**	**CNS Damage**		Growth	Face	CNS		Alcohol		**Prenatal Alcohol**

The 4-Digit Diagnostic Code 3444 inserted in the grid is one of twelve 4-Digit Codes that meet the diagnostic criteria for FAS.

How are the 4 Digits Ranked?

The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic" presence of the FAS feature. Specific guidelines for ranking the magnitude of each of the FAS features are presented in Section III.B.

How Many 4-Digit Diagnostic Codes are There?

There are 256 possible 4-Digit Diagnostic Codes ranging from 1111 to 4444. The 256 codes and their corresponding clinical names are listed in numerical order in Section VI.

How Many Different Clinical Diagnostic Categories are There?

Each 4-Digit Diagnostic Code falls into one of 22 unique Clinical Diagnostic Categories (labeled A through V). A list of the 22 Diagnostic Categories is presented in Section IV. A list of the 4-Digit Diagnostic Codes, which fall within each Clinical Diagnostic Category, is presented in Section V.

What are the Names of the Clinical Diagnostic Categories?

The following terms are used in varying combinations to name the 22 diagnostic categories. They include:

- **Sentinel Physical findings:**
  The term "S*entinel Physical Findings*" is used in this diagnostic system when the patient presents with growth deficiency at the Rank 3 or 4 level and/or presents with the FAS facial phenotype at the Rank 3 or 4 level. The adjective *"sentinel"* refers to physical findings that are key diagnostic features of FAS. These include a unique cluster of minor facial anomalies (short palpebral fissures, thin upper lip, and a smooth philtrum) and growth deficiency. Other physical findings (major or minor anomalies) may be detected instead of or in addition to these sentinel findings that may suggest alternate or additional conditions. There are places on the Diagnostic Form to record and interpret other physical findings.

- **Static Encephalopathy:**
  The term *"encephalopathy"* refers to "any significant abnormal condition of the structure or function of brain tissues" (Anderson, 2002). The term *"static"* means that the abnormality in the brain is unchanging; neither progressing nor regressing. The term *"Static Encephalopathy"* is used in this diagnostic system when the patient presents with significant structural, neurological, and/or functional abnormalities that strongly support the presence of underlying CNS damage at the Rank 3 and/or Rank 4 levels. The term does not define or suggest any specific pattern of structural, neurological, or functional abnormality.

- **Neurobehavioral Disorder:**
  The term *"Neurobehavioral Disorder"* is used in this diagnostic system when the patient presents with cognitive/behavioral dysfunction at the Rank 2 level and no evidence of structural, neurological or functional abnormalities at the Rank 3 or Rank 4 levels.

- **Alcohol (Exposed, Not Exposed, Exposure Unknown):**
  These terms are used to reflect prenatal alcohol exposure and its potential risk to the unborn child. Alcohol exposure is reported <u>independently</u> of outcome(s) and does not imply that a causal association exists between the exposure and the outcome(s).

- **Fetal Alcohol Syndrome (alcohol exposed)**
  The term FAS is used to refer to patients who present with one of twelve 4-Digit Diagnostic Code combinations reflecting growth deficiency; the full FAS facial phenotype; significant structural, neurological, and/or functional CNS abnormalities; and confirmed prenatal alcohol exposure. These 12 Codes are presented in Section V.

- **Fetal Alcohol Syndrome (alcohol exposure unknown)**
  A diagnosis of FAS can be rendered when prenatal alcohol exposure is "unknown" but only when the outcomes (growth, face, and CNS) are at the severe end of the spectrum to maintain the specificity of these outcomes to prenatal alcohol exposure. (Astley et al., 2001) Six 4-Digit Codes fall under this category (Section V).

- **Partial Fetal Alcohol Syndrome (alcohol exposed):**
  This term is used for patients who present with static encephalopathy, most (but not all) of the growth and/or facial features of FAS, and have a confirmed history of prenatal alcohol exposure. Given the fact that variable presentation is the rule rather than the exception after teratogenic exposures, we felt it was appropriate to establish this diagnostic category. Twenty 4-Digit Codes fall under this category (Section V).

- **Fetal Alcohol Syndrome Phenocopy (no alcohol exposure):**
  This term is used for patients who meet the growth, face and CNS criteria for FAS, but have a confirmed absence of alcohol exposure during gestation. We have never seen such a case (or phenocopy), but we may some day.

The names assigned to each diagnostic category reflect the patient's clinical outcome and alcohol exposure. The names are listed in Sections IV and V. The first three categories (A through C) meet the criteria for a clinical diagnosis of FAS and are named as such. The fourth category (D) applies to the patient who presents with all of the features of FAS, but has a confirmed *absence* of prenatal alcohol exposure from conception to birth. This category is referred to as a FAS Phenocopy and has yet to be observed. The remaining 19 categories (E through V) do not meet the minimum criteria for FAS or partial FAS. These are subsequently named to reflect the Likert ranking of each digit in the 4-Digit Diagnostic Code. For example, a code of 3243 is the Diagnostic Category called "*Sentinel physical finding(s) / static encephalopathy (alcohol exposed)*".

Which Diagnostic Categories are Comparable to PFAE, ARND and ARBD?

Many 4-Digit Codes within Diagnostic Categories E through I would previously have been referred to as "possible fetal alcohol effects" (PFAE), "alcohol-related birth defects" (ARND) or "alcohol-related neurodevelopmental disorder" (ARBD). (Sokol & Clarren, 1989; Stratton et al., 1996) A report that translates which 4-Digit Codes meet the criteria for ARND and ARBD can be found on the FAS DPN website http://depts.washington.edu/fasdpn. Categories J through V are categories that describe a large number of patient groups who have never been adequately classified or described by previous FASD diagnostic guidelines.

Ultimately, establishing terms that are both clinically accurate, broadly applicable, and facilitate access to services remains a challenge. It is important to remember that the 4-Digit Code provides a numeric measurement and reporting system for exposures and outcomes that can be used independently of the proposed diagnostic nomenclature.

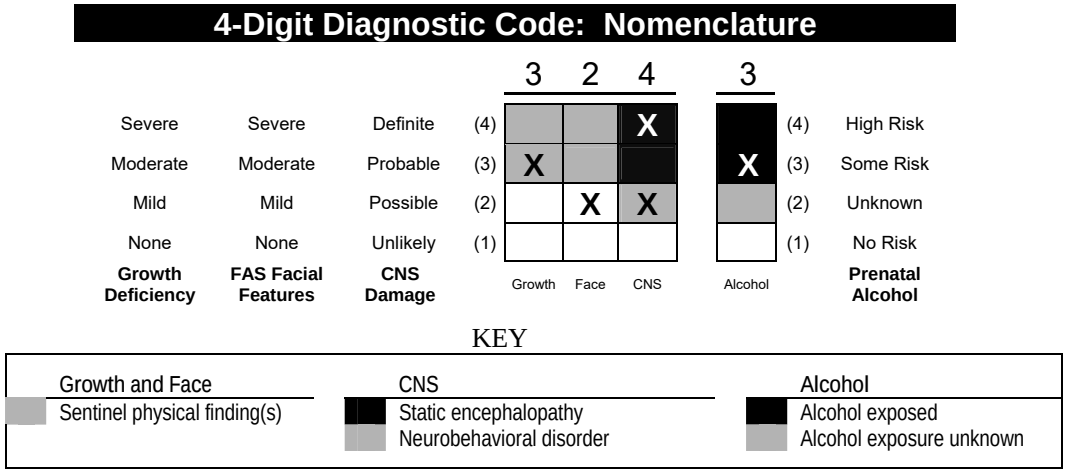
How are the Names of the Clinical Diagnostic Category Constructed?

- Growth deficiency and facial features are physical features. When either feature receives a rank of 3 or 4, *Sentinel physical finding(s)* is placed at the beginning of the name.

- When CNS receives only a Rank 2, the term *Neurobehavioral Disorder* is included in the name. When CNS receives a Rank 3 or 4, the term *Static Encephalopathy* is included in the name.

- When alcohol exposure receives a Rank 3 or 4, (*alcohol exposed*) is placed at the end of the name. When alcohol exposure receives a Rank 2, (*alcohol exposure unknown*) is placed at the end of the name.

- When the criteria for FAS or PFAS are met, those clinical terms are used in place of the more generic terms. For example the term FAS is used rather than *Sentinel physical finding(s / static encephalopathy (alcohol exposed).*



The 4-Digit Code 3243 would receive the clinical name *Sentinel physical finding(s) / static encephalopathy (alcohol exposed).* Note that the CNS received both Rank 4 and Rank 2. The higher Rank is used to derive the 4-Digit Code and construct the name. A code of 1222 would receive the clinical name *Neurobehavioral disorder (alcohol exposure unknown).*

How Do You Explain the Diagnosis to the Patient?

Generic summaries of each of the 22 Clinical Diagnostic Categories are presented in Section VII. These summaries can be used as the first page of the patient's final Medical Summary Note. Subsequent pages in the Medical Summary Note should document the findings and recommendations specific to the patient. We recommend the growth, face, CNS, and exposure data, used to generate the 4-Digit Code, be reported in the Medical Summary Note to provide essential information to subsequent medical professionals and facilitate records-based public health surveillance efforts.

III. Instructions for Deriving the 4-Digit Code

B.1. Ranking Growth

What Type of Growth Deficiency Are We Looking For?

We are looking for growth deficiency characteristic of a teratogenic insult, not characteristic of postnatal environmental factors such as nutritional deprivation or chronic or acute illness. We want to answer the question *'What is the patient's growth potential after controlling for parental height and postnatal environmental influences?'* Growth deficiency of teratogenic origin is likely to present as a relatively consistent impairment over a period of time (i.e., the patient's growth follows the normal curve, but is below genetic expectation for family background). In contrast, growth deficiency due to postnatal environmental influences is likely to present as periodic fluctuations in the curve. Separating the two growth patterns requires astute clinical judgment.

The method described below allows one to rank a patient's overall growth pattern on a single 4-point Likert scale with 1 equal to 'normal' and 4 equal to significantly deficient. Not all patients will have complete growth curves available, therefore, a guide is provided below for prioritizing the ranking of the patient's growth over a lifetime

How to Measure and Rank Growth: The 1st Digit of the 4-Digit Diagnostic Code

A. The height percentile should be age and gender adjusted. Because there is a significant genetic component in attained stature, adjustment for mid-parent stature is also recommended when both parents' heights are known. Himes et. al., (1985) provide charts for mid-parent adjustment of recumbent length (birth to 3 years) and stature (3 to 18 years) of US children relative to National Center for Health Statistics growth charts.

B. The weight percentile should be age and gender adjusted. Weight is not adjusted for height.

   CDC 2000 Growth Charts are provided in Section VIII. Other valid growth charts may be used. We recommend electronic computation of percentiles for increased accuracy. CDC offers a free software program called Epi Info that will compute percentiles and plot data on the CDC Growth Charts. This software can be obtained from the CDC website www.cdc.gov/epiinfo.

C. For ranking purposes, the growth record is separated into two parts:
   1. Prenatal growth (birth measures)
   2. Postnatal growth (all measures collected after birth)

   Select the part of the growth record with the greatest deficiency in the height percentile.

   If the prenatal height percentile is lower than all postnatal height percentiles, proceed to section D for instructions on how to rank prenatal growth.

If any of the postnatal height percentiles are lower than the prenatal height percentile, select the point or consecutive points in the growth record that reflect the lowest height percentiles that cannot be attributed to postnatal environmental influences such as nutritional deprivation or chronic illness. If the height deficiency is reflected in a series of points in the growth record, as opposed to a single point, rank the level of deficiency based on the percentile range where the majority of the points fall. Proceed to section D for instructions.

D. Rank the level of deficiency of the height and weight percentiles, for the part of the growth record with greatest deficiency in the height percentile by circling A, B, or C in the ABC-Score table at the bottom of page 1 of the FASD Diagnostic Form. This ABC-Score table is duplicated below as Table 1. The height and weight percentiles selected for ranking should be matched sets. For example, if the height at 10 years of age is selected for ranking, the corresponding weight percentile at 10 years of age should also be selected for ranking. One does not rank the height at one age and the weight at another age to generate an ABC-Score.

Table 1: Deriving the ABC-Score for Growth

	Circle the ABC-Scores for:	
Percentile Range	Height	Weight
$\leq 3^{rd}$	C	C
$>3^{rd}$ and $\leq 10^{th}$	B	B
$>10^{th}$	A	A

E. Next, refer to Table 2 to determine the *4-Digit Diagnostic Rank* of the Height-Weight ABC-Score recorded in Table 1. Transfer the resulting 4-Digit Diagnostic Rank for growth to the 4-Digit Diagnostic Code Grid at the top of page 1 of the FASD Diagnostic Form.

Table 2: Converting the Growth ABC-Score to a 4-Digit Diagnostic Rank for Growth

4-Digit Diagnostic Rank	Growth Deficiency Category	Height-Weight ABC-Score Combinations
4	Severe	CC
3	Moderate	CB, BC, CA, AC
2	Mild	BA, BB, AB
1	None	AA

Example for Scoring Growth Deficiency

Patient's Growth Record:

	Age (years)	Height Percentile	Weight Percentile
birth	0.0	8 %	1 %
	1.5	14 %	16 %
	5.0	12 %	15 %
	7.0	12 %	15 %
	15.5	15 %	15 %

Assume the clinical records rule-out any environmental influence on postnatal measures and mid-parental height is unknown.

Ranking:

- Priority would be placed on ranking the birth length and weight because the birth length percentile is lower than all postnatal height percentiles recorded.
- Birth length (8 %) would receive an **ABC-Score = B** (> 3rd and ≤ 10th percentile) (Table 1).
- Birth weight (1 %) would receive an **ABC-Score = C** (≤ 3rd percentile) (Table 1).
- The Height-Weight ABC-Score combination would be **BC** (Table 1).

Table 1: Deriving the ABC Score for Growth

	Circle the ABC-Scores for:	
Percentile Range	Height	Weight
≤ 3rd	C	**C**
>3rd and ≤ 10th	**B**	B
>10th	A	A

- The Height-Weight ABC-Score of **BC** reflects **Moderate** growth deficiency (Table 2)
- **Moderate** growth deficiency would receive a **Rank 3** in the 4-Digit Diagnostic Code (Table 2).

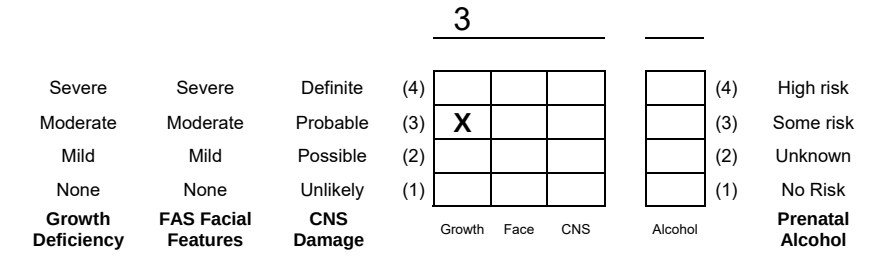
Table 2: Converting the Growth ABC-Score to a 4-Digit Diagnostic Rank for Growth

4-Digit Diagnostic Rank	Growth Deficiency Category	Height-Weight ABC-Score Combinations
4	Severe	CC
3	**Moderate**	CB, **BC**, CA, AC
2	Mild	BA, BB, AB
1	None	AA

- **Rank 3** would be transferred to the 4-Digit Diagnostic Code Grid on page 1 of the FASD Diagnostic Form (as duplicated below).

Result:

4-Digit Diagnostic Code Grid



III. Instructions for Deriving the 4-Digit Code

B.2. Ranking the Facial Phenotype

The FAS Facial Phenotype

The face of FAS is distinguished by the simultaneous expression of three facial features:

1. Small palpebral fissure lengths (2 or more standard deviations below the mean) (Figure 2)
2. Smooth Philtrum (Rank 4 or 5 on the Lip-Philtrum Guide) (Figure 3).
3. Thin upper lip (Rank 4 or 5 on the Lip-Philtrum Guide) (Figure 3).

David Smith, M.D., who coined the term FAS in 1973, identified these features as the *key* diagnostic facial features in 1979 (Smith, 1979). A series of analytic studies conducted 20 years later confirmed the sensitivity and specificity of these features to FAS, and served to case-define the magnitude of expression required to maximize sensitivity (100%) and specificity (99%) (Astley & Clarren, 1996, 2000, 2001). Relaxation of these criteria substantially reduces sensitivity and specificity. The clinical validity of these features has been confirmed through population-based screening and surveillance studies (Astley et al., 2002; Astley, 2004) and empirical studies documenting remarkably strong correlations between these midline facial anomalies and underlying brain damage/dysfunction (Astley & Clarren, 2001). As the FAS facial phenotype increases in severity of expression from Rank 1 to Rank 2 to Rank 3 to Rank 4, the prevalence of underlying brain damage/dysfunction also increases linearly. The FAS facial phenotype, including partial expressions of the phenotype, serves as a sensitive marker of brain damage/dysfunction.

How to Measure and Rank the Face: The 2nd Digit of the 4-Digit Diagnostic Code

There are two methods for measuring the facial features: 1) direct measurement and 2) computerized analysis of a digital facial photograph using the FAS Facial Photographic Analysis Software. The latter is the most accurate and is described in detail in Astley & Clarren (2001). The facial analysis software can be obtained from the FAS Diagnostic & Prevention Network website [http://depts.washington.edu/fasdpn]. The computerized method for analyzing facial features was designed to use a *standard* digital camera to maximize clinical access to this technology, while maintaining the highest level of accuracy. An instructional CD-ROM called FAS TUTOR ™ demonstrates how to accurately measure the facial features. It too can be obtained from the FAS DPN website.

A. Palpebral Fissure Length (PFL)

Direct measurement: The PFLs are measured to the nearest mm with a clear plastic, 15-cm ruler, held as close as possible to the eye without touching the eye or eye-lashes (Figures 1A, 1B). We choose not to use calipers because we find our patients are often too young and active to cooperate safely. The patient is asked to open their eyes fully to allow accurate identification of the endocanthion and exocanthion landmarks (Astley et al., 1999; Farkas, 1994). Epicanthal folds should be gently pulled to the midline to expose the endocanthion. It is difficult to obtain accurate measures of the PFL by direct measure. The physician should confirm the accuracy of their measurement technique against a gold standard (perhaps by measuring a colleague's PFL with a ruler that was previously measured with calipers). See the FAS-TUTOR CD for instructional animations (Astley et al.1999).

Computer measurement: A digital photo of the face is taken with a ¾ inch paper sticker placed between the eyebrows to serve as an internal measure of scale (Astley & Clarren, 2001). The photo is analyzed using the FAS Facial Photographic Analysis Software (Astley, 2003). The PFL is measured by clicking the mouse on the endocanthion and exocanthion landmarks of the right and left eyes. The length of each palpebral fissure and its z-score (number of standard deviations above or below the norm) are computed automatically based on formulas and normal charts embedded in the software. More detailed instructions are provided with the software.

Ranking*:* The PFL is ranked according to its z-score (or how many standard deviations above or below the mean it is on a normal anthropometric chart). If the eyes are substantially different in size, (more than 2 mm different) rank the larger PFL. If the eyes are comparable in size, rank the mean of the right and left PFL. Normal palpebral fissure length charts for Caucasians are provided in Section VIII (Hall et al., 1989). Normal PFL charts adjusted for race should be used if available and confirmed valid. There is general agreement among medical professionals that new more accurate and valid norms for palpebral fissure charts are needed. Until new charts are available, we have chosen to use the Hall Caucasian Charts for they reflect a composite of several published Caucasian charts and best reflect the rate of growth from birth to 16 years of age that we have observed among normally developing Caucasian children.

B. Upper Lip Thinness and Philtrum Smoothness

Direct measurement: Upper lip thinness (the red or vermilion portion of the upper lip) and philtrum smoothness are measured independent of one another using the 5-point pictorial Likert scale presented on the Lip-Philtrum Guides (Figure 3). Two Guides are available, one for Caucasians and one for African Americans. The Guide that best matches the phenotypic profile of the patient's race should be used. The physician holds the Lip-Philtrum Guide next to the patient's face and identifies the picture that best matches the patient's upper lip and identifies the picture that best matches the patient's philtrum. Lips must be *gently closed* with *no* smile to obtain accurate measures (Figure 4) (Astley et al., 1999). The physician's eyes must be in the patient's frankfort horizontal plane (represented by a line drawn from the external auditory canal through the lowest border of the bony orbital rim [orbitale]) to obtain accurate, standardized measures of upper lip thinness (Figure 5). This alignment is readily achieved with a handheld Guide. Stereotaxic equipment is not required.

Computer measurement: A digital photograph of the face is taken with the camera lens aligned in the patient's frankfort horizontal plane. The image is imported into the FAS Facial Photographic Analysis Software. The red (or vermilion) portion of the upper lip is outlined with the mouse to compute circularity (perimeter^2/area) (Figure 1). The thinner the upper lip, the greater the circularity (Figure 3). Circularity is not influenced by the size of the photograph. Each Rank on the Lip-Philtrum Guide is defined by a range of circularities (Figure 3). The software automatically ranks lip thinness using the circularity measure. The philtrum is measured by selecting the picture on the Lip-Philtrum Guide that best matches the patient's philtrum. More detailed instructions are provided with the software.

Figure 1. An example of the upper lip outlined to compute circularity. The circularity of this lip is 44.2, which is equivalent to Rank 2 on Lip-Philtrum Guide 1.

C. Deriving the Facial ABC-Score

Rank palpebral fissure length, philtrum smoothness, and upper lip thinness by circling A, B, or C in each column in the ABC-Score table at the bottom of page 2 of the FASD Diagnostic Form. This table is duplicated below as Table 3. The three facial features must be measured at the same age. In other words, one would NOT rank PFL at 10 years of age and philtrum and lip at 15 years of age. If facial measures are available at more than one age, rank the age when the FAS phenotype is expressed the most. If FAS features are never expressed, score the face between the ages of 3 and 10 years, or at any age if this age range is not available.

Table 3: Deriving the ABC-Score for Facial Phenotype

5-Point Likert Rank for Philtrum & Lip	Z-score* for Palpebral Fissure Length	Circle the ABC-Scores for: Palpebral Fissure	Philtrum	Upper Lip
4 or 5	≤ -2 SD	C	C	C
3	>-2 SD and ≤ -1 SD	B	B	B
1 or 2	> -1 SD	A	A	A

* Z-Score = (patient's PFL - mean PFL for normal population) / (standard deviation of mean PFL for normal population)

The z-score reflects how many standard deviations above or below the mean the patient's PFL is.

D. Deriving the 4-Digit Rank for Face

Next, refer to Table 4 to determine the *4-Digit Diagnostic Rank* based on the ABC-Score derived from Table 3. Transfer the resulting 4-Digit Diagnostic Rank for face to the 4-Digit Diagnostic Code Grid on page 1 of the FASD Diagnostic Form.

Table 4: Converting the Facial ABC-Score to a 4-Digit Diagnostic Rank for Face

4-Digit Diagnostic Rank	Level of Expression of FAS Facial Features	Palpebral Fissure - Philtrum - Lip ABC-Score Combinations
4	Severe	CCC
3	Moderate	CCB, CBC, BCC
2	Mild	CCA, CAC, CBB, CBA, CAB, CAA BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	None	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

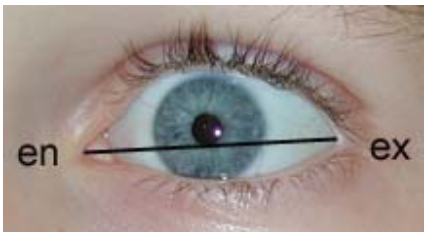


Figure 2A. Palpebral Fissure Length (PFL). Distance from endocanthion to exocanthion.

Figure 2B. PFL measured with a small ruler while patient looks up to fully expose exocanthion.

Lip-Philtrum Guide 1: Caucasian			ABC Scores		Lip-Philtrum Guide 2: African American		
	Upper Lip Circularity		Philtrum	Upper Lip	Upper Lip Circularity		
Rank	Range	Lip Pictured	Smoothness	Thinness	Lip Pictured	Range	Rank
5	≥ 131.5	178	C	C	80	≥ 62.1	5
4	131.4 to 75.5	85	C	C	57	62.0 to 52.1	4
3	75.4 to 57.5	65	B	B	39	52.0 to 30.1	3
2	57.4 to 42.5	50	A	A	29	30.0 to 27.5	2
1	≤ 42.4	35	A	A	25	≤ 27.4	1
Lip-Philtrum Guide 1							Lip-Philtrum Guide 2

Figure 3. Lip-Philtrum Guides 1 and 2. Pictorial examples of the 5-point Likert scales and the ABC-Scale used to rank upper lip thinness and philtrum smoothness in Caucasians and African Americans. Circularity is perimeter^2/area and is measured using the FAS Facial Photographic Analysis software. Laminated Lip-Philtrum Guides with the Growth and Face Tables printed on the backside are available at http://depts.washington.edu/fasdpn.

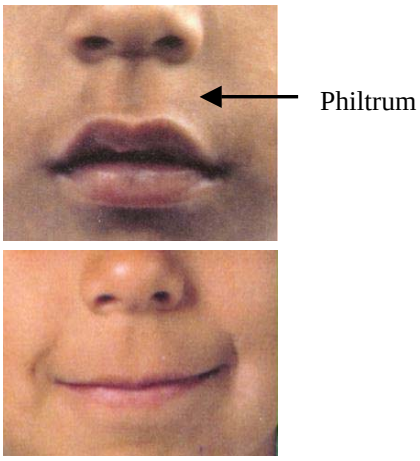

Figure 4. It is important that the patient have a relaxed facial expression (no smile). A smile can alter lip thinness and philtrum smoothness. This is the same person with and without a smile. Note that without the smile, the lip and philtrum would both receive a correct Likert rank of # 1 on the Caucasian Lip-Philtrum Guide 1. With a smile, the lip and philtrum would both receive an *incorrect* Likert rank of # 4.

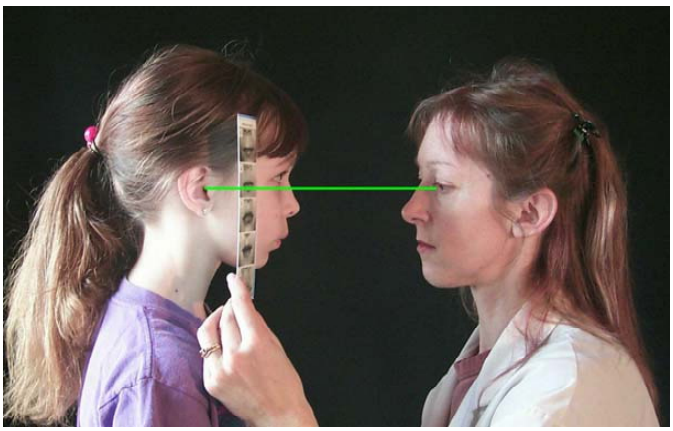

Figure 5. Illustration of a physician aligned in the patient's frankfort horizontal plane while using the Lip-Philtrum Guide to rank upper lip thinness and philtrum smoothness. The frankfort horizontal plane is defined by a line that passes through the patient's external auditory canal and the lowest border of the bony orbital rim (orbitale). The physician's eyes (or camera lens) should be directly in line with this plane. If the physician stood above this plane looking down on the patient, the patient's upper lip could appear thinner than it truly is.

Example: Ranking the Facial Phenotype

Patient Measurements at 10 Years of Age (Caucasian):

- Left PFL = 25.2 mm. Right PFL = 24.8 mm. Mean PFL = 25.0 mm
  Z-score = **-2.7** using Hall's PFL normal charts. (This means the PFL is 2.7 SDs below the norm)
  - Z-score = (25.0 – 28.7)/1.35 = -2.7.
  - Mean PFL for 10 years of age using Hall's Normal PFL chart = 28.7 mm.
  - 1 standard deviation on Hall's PFL normal chart = 1.35 mm.
  - The z-score is automatically computed by the FAS Facial Photographic Analysis Software.

- Philtrum smoothness received a **Rank 5** on the Caucasian Lip-Philtrum Guide (Figure 3).

- The circularity of the upper lip was 65.5. Thus, upper lip thinness received a **Rank 3** on the Caucasian Lip-Philtrum Guide (Figure 3). The circularity range for Rank 3 is 57.5 to 74.9.

Ranking

- The mean PFL z-score of -2.7 would receive an **ABC-Score = C** (≤ -2 SD) (Table 3).

- The Rank 5 philtrum would receive an **ABC-Score = C** (Table 3).

- The Rank 3 upper lip would receive an **ABC-Score = B** (Table 3).

- The ABC-Score combination for Palpebral Fissure - Philtrum - Lip would be **CCB** (Table 3).

Table 3: Deriving the ABC-Score for Facial Phenotype

5-Point Likert Rank for Philtrum & Lip	Z-score for Palpebral Fissure Length	Circle the ABC-Scores for: Palpebral Fissure	Philtrum	Upper Lip
4 or 5	≤ -2 SD	**C**	**C**	C
3	>-2 SD and ≤ -1 SD	B	B	**B**
1 or 2	> -1 SD	A	A	A

- The Facial ABC-Score of **CCB** reflects a **Moderate** level of expression of the FAS facial phenotype (Table 4).

- A **Moderate** expression of the FAS facial phenotype would receive a **Rank 3** in the 4-Digit Diagnostic (Table 4).

Table 4: Converting the Facial ABC-Score to a 4-Digit Diagnostic Rank

4-Digit Diagnostic Rank	Level of Expression of FAS Facial Features	Palpebral Fissure - Philtrum - Lip ABC-Score Combinations
4	Severe	CCC
3	**Moderate**	**CCB**, CBC, BCC
2	Mild	CCA, CAC, CBB, CBA, CAB, CAA, BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	None	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

- **Rank 3** would be transferred to the 4-Digit Diagnostic Code Grid on page 1 of the FASD Diagnostic Form (as duplicated below).

Result:

4-Digit Diagnostic Code Grid

3 ____

Growth Deficiency	FAS Facial Features	CNS Damage		Growth	Face	CNS	Alcohol		Prenatal Alcohol
Severe	Severe	Definite	(4)					(4)	High risk
Moderate	Moderate	Probable	(3)		X			(3)	Some risk
Mild	Mild	Possible	(2)					(2)	Unknown
None	None	Unlikely	(1)					(1)	No Risk

III. Instructions for Deriving the 4-Digit Code

B.3. Ranking CNS

Alcohol's Impact on the Developing Brain

Alcohol is a teratogen that can alter the developing brain in a variety of ways from gross structural anomalies to subtle alterations in neurochemical levels (Stratton et al., 1996; West, 1986). Alterations in brain structure and/or chemistry can lead to altered brain function. Our ability to detect structural, neurological, and functional CNS abnormalities is dependent on the sensitivity of today's measurement tools, which will continue to improve over time. Not all structural or neurological abnormalities result in *measurable* dysfunction and not all functional abnormalities are due to underlying brain damage. Some functional abnormalities result from adverse postnatal environmental factors and are transient in nature if the environment is improved.

How to Rank CNS: The 3rd Digit of the 4-Digit Diagnostic Code

The 4-point Likert Scale for CNS documents: 1) that individuals with prenatal alcohol exposure can present with structural, neurological and/or functional CNS abnormalities; 2) that these CNS abnormalities occur along a continuum of severity; and 3) that not all functional abnormalities are due to underlying brain damage.

An important point to keep in mind is that the CNS scale performs as two scales in one. In its first use, the full scale (from 1 to 4) documents increasing "probability" of underlying CNS damage based on structural, neurological, and/or functional evidence. *The higher the Rank from 1 to 4, the stronger the evidence or higher the probability that there is underlying CNS damage*. In its second use, the scale (from 1 to 3) also documents increasing severity of brain dysfunction. *The higher the Rank from 1 to 3, the more severe and global the dysfunction.*

The descriptive labels assigned to Ranks 1 through 4 reflect the increasing probability that underlying CNS damage exists. Rank 4 is labeled "definite" because structural/neurological abnormalities are definitive evidence of CNS damage. Ranks 1, 2, and 3 are labeled "unlikely", "possible", and "probable" evidence of CNS damage, respectively, because measures of dysfunction are not definitive evidence of CNS damage, but the probability of underlying CNS damage increases with increasing severity of dysfunction. Data from the University of Washington FAS DPN show this to be true. Among the first 1,500 patients diagnosed, those presenting with Rank 2 or Rank 3-level dysfunction had a 5.8-fold and 10.8-fold increased risk of having structural/neurological damage, respectively, relative to patients with no evidence of dysfunction (Rank 1). As stated in the Institute of Medicine report (Stratton et al., 1996) "FAS can be characterized by behavioral or cognitive problems that are thought to result from *organic brain damage*, are not easily related to genetic background or environmental influences, and are resistant to improvement with traditionally effective intervention techniques".

All patients receive a Rank 1, 2 or 3 to document their level of brain dysfunction. Patients who present with significant structural and/or neurological evidence of CNS damage will also receive a Rank 4. Thus, all patients with structural/neurological evidence of CNS damage will have two CNS Ranks, one documenting their structural/neurological damage (Rank 4) and one documenting their level of dysfunction (Rank 1, 2 or 3). More specifically, they will receive either: (a) Ranks 4 and 3 (structural/neurological damage with Rank 3 level dysfunction); (b) Ranks 4 and 2 (structural/neurological damage with Rank 2 level delay/dysfunction); or (c) Ranks 4 and 1 (structural/neurological damage with no current evidence of delay/dysfunction). When two CNS Ranks are applicable, the 4-Digit Code and Diagnostic Category are based on the *highest* CNS rank received, for it reflects the highest level of certainty there is underlying CNS damage. Both CNS ranks would be marked by an '**X**' in the CNS Column of the Diagnostic Grid, but only the number of the highest rank would be inserted into the 4-Digit Code (See 4-Digit Diagnostic Code Grid below).

4-Digit Diagnostic Code Grid

						4				
Severe	Severe	Definite	(4)			X		(4)	High risk
Moderate	Moderate	Probable	(3)			X		(3)	Some risk
Mild	Mild	Possible	(2)					(2)	Unknown
None	None	Unlikely	(1)					(1)	No Risk
Growth Deficiency	**FAS Facial Features**	**CNS Damage**		Growth	Face	CNS	Alcohol		**Prenatal Alcohol**

Definitions of CNS Ranks 1 through 4.

CNS Rank 4: (Structural/Neurological Abnormalities)
"Definite" Evidence of CNS Damage.

Rank 4 Description: This rank is selected when the evidence for CNS damage is defined through a traditional medical approach. It is our impression that "brain damage" or static encephalopathy is readily diagnosed by physicians when 'significant' structural abnormalities of the brain are detected or when neurological findings of presumed prenatal origin are found.

Structural evidence of CNS damage may include, but is not limited to:

1. Microcephaly, defined as an occipital frontal circumference (OFC) 2 or more standard deviations below the mean. It is important to take race/ethnicity into consideration when assessing OFC. Head circumference 2 or more standard deviations below the mean has been associated with mental deficiency in the literature (Dolk, 1991; Pryor & Thelander, 1968).

2. Significant brain abnormalities of presumed prenatal origin observable through imaging techniques. Abnormalities may include, but are not limited to hydrocephaly, heterotopias, and change in shape and/or size of brain regions. These abnormalities should be determined by appropriately trained medical professionals.

Neurological evidence of CNS damage may include, but is not limited:

1. Seizures not due to a postnatal insult or other postnatal process.
2. Other hard neurological signs of presumed prenatal origin.

Rank 4 Criteria: At least one "significant" structural or neurological finding is required for a classification of CNS Rank 4 (Table 5). A significant finding is one that is 2 or more standard deviations below the norm if measured on a standardized scale or deemed "clinically significant" when assessed by an appropriate trained professional like a clinical radiologist or neurologist. Findings deemed significant should receive a Severity Score = 3 (see below).

Documenting the Evidence that Supports a Rank 4 Classification: Structural and neurological findings are recorded under the STRUCTURAL and NEUROLOGICAL headings of the CNS section (page 3) of the FASD Diagnostic Form. A 'Severity Score' is provided along the left margin of the Form to allow the clinical team to rank the severity of all structural and neurological findings. Only structural and/or neurological findings that receive a Severity Score = 3 (Significant) can contribute toward a CNS Rank 4 classification. For example, a seizure disorder not due to a postnatal insult would receive a Severity Score = 3. Often this type of seizure would warrant medical treatment. A seizure that occurred just once during a high fever would receive a Severity Score = 2. Absence of any seizure-like activity would receive a Severity Score = 1. An OFC $\leq$ -2 SDs ($\leq 2.5^{th}$ percentile) would receive a Severity Score = 3. An OFC > 2.5^{th} percentile and $\leq 10^{th}$ percentile would receive a Severity Score = 2. An OFC > 10^{th} percentile would receive a Severity Score = 1. This Severity Score allows one to rapidly scan the FASD Diagnostic Form and identify significant findings that support a Rank 4 classification.

CNS Rank 3: (Significant Dysfunction)
"Probable" Evidence of CNS Damage.

Rank 3 Description: Through our experience with hundreds of patients who have been exposed to potentially teratogenic doses of alcohol, we have found that many would not qualify as having static encephalopathy using the definition above, but neither could the possibility that they have static encephalopathy be dismissed out of hand. These patients typically have problems across multiple domains that may include, but are not limited to, executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention or activity level. These patients have problems that seem likely due to underlying brain damage rather than to adverse postnatal environmental experiences.

Rank 3 is selected based on evidence generated by standardized, validated psychometric assessments (e.g., WISC-III, WIAT-II, TOLD, PLS3, D-KEFS, VMI-II, etc), that are administered directly to the affected individual, or obtained from reliable informants, and interpreted by qualified professionals (e.g., psychologists, psychiatrists, occupational therapists, speech-language pathologists, etc). Rank 3 is assigned when this testing evidence documents "significant" impairment in three or more domains of brain function. "Significant" impairment is generally defined as performance 2 or more standard deviations below the mean (or its equivalent) on a standardized test. Developmental instruments, such as the Bayley Scales of Infant Development-II

would typically not be used as a source of psychometric data to support a classification of "static encephalopathy", for developmental delay is not always predictive of brain damage/dysfunction. The one exception to this rule would be developmental scores that are so low (e.g., Bayley Scales of Infant Development-II standard scores: MDI < 50, PDI < 50) that relevant literature finds these scores highly predictive of significant brain damage/dysfunction.

Rank 3 Criteria: "Significant" impairment across three or more domains of brain function is required for a classification of CNS Rank 3 (Table 5). Global delay, in which multiple domains are (by definition) affected, can comprise evidence for a Rank 3. Domains of brain function may include, but are not limited to: executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention or activity level. The "domains" of interest, in each diagnostic evaluation, are determined by the experienced clinical professionals involved in assessing the affected individual. Evidence to support a Rank 3 classification must come from standardized psychometric tests. "Significant" impairment is generally defined as performance 2 or more standard deviations below the norm on a standardized psychometric test.

Documenting the Evidence that Supports a Rank 3 Classification: The clinical team records which functional domains are delayed/impaired and which tests/scores support their decisions on the Functional Domains page (page 7) of the FASD Diagnostic Form. Evidence to support a Rank 3 classification must come from standardized psychometric tests. The outcomes of these psychometric tests are recorded on pages 3-5 of the FASD Diagnostic Form. A 'Severity Score' is provided along the left margin of the Functional Domains page (page 7) to allow the clinical team to rank the severity of delay/impairment for each assessed domain. A functional domain must receive a Severity Score = 3 (Significant) to contribute toward a Rank 3 classification. The Severity Score is described more fully below.

CNS Rank 2 (Mild to Moderate Delay/Dysfunction).
"Possible" Evidence of CNS Damage.

Rank 2 Description: This Rank should be given to two groups of patients, all of whom should have histories of behavioral, cognitive, and/or developmental problems. One group of patients is those who have not yet had the types of testing that would move them into Rank 3, if positive. The reason for lack of testing is usually because the patients are too young to be tested (typically less than 6 years of age). Children in this group should be re-assessed, when old enough, to rule out whether testing evidence meets criteria for CNS Rank 3. *Note that the term "neurobehavioral disorder" is assigned to CNS Rank 2. When this Rank is being assigned to young children based primarily on developmental data, the clinical team may decide to forego the use of the term "neurobehavioral disorder".* The other group of patients is those whose testing did not reveal compelling evidence for Rank 3 classification, but for whom, in the clinical team's judgment, the possibility of CNS damage cannot be wholly dismissed. In these cases, the behaviors of the patient cannot be conceptualized as, for example, normal variants or transient emotional responses to environmental problems. Alternative testing or alternative diagnostic assessment procedures should usually be considered. But if adequately sensitive and appropriate testing has been carried out without clear evidence of dysfunction or developmental delay, it is unlikely a Rank 2 classification would be given.

Rank 2 Criteria: Rank 2 reflects a range of delay and/or dysfunction that suggests the possibility of CNS damage. At the mild end of the Rank 2 range are those who present with developmental delay that, by clinical judgment, precludes a Rank 1 classification. At the severe end of the Rank 2 range are those who present with clear evidence of dysfunction, but the dysfunction is not sufficiently severe and wide-ranging to meet the criteria for Rank 3 (Table 5). A Rank 2, by definition, is assigned to all who fall between Ranks 1 and 3. Evidence to support a Rank 2 classification can come from standardized psychometric tests, observational data, and/or caregiver interview. Deficiencies (or definite differences from normative expectations) recorded in the FUNCTIONAL section (pages 3-7) of the FASD Diagnostic Form serve to support a Rank 2 classification.

Documenting the Evidence that Supports a Rank 2 Classification: The clinical team records which functional domains are delayed or impaired and which tests/scores support their decisions on the Functional Domains page (page 7) of the FASD Diagnostic Form. Evidence to support a Rank 2 classification can come from standardized psychometric tests, observational data, and/or caregiver interview. These data are recorded on pages 3-6 of the FASD Diagnostic Form. A 'Severity Score' is provided along the left margin of the Functional Domains page (page 7) to allow the clinical team to rank the severity of delay or impairment for each assessed domain. Typically a patient who meets the criteria for Rank 2 will have at least one domain with a Severity Score = 2 (mild to moderate delay or impairment), but less than three domains with a Severity Score = 3 (significant impairment). The Severity Score is described more fully below.

CNS Rank 1 (No Current Evidence of Delay/Dysfunction)
"No" Current Evidence of CNS Damage.

A Rank 1 classification is assigned when no functional or developmental problems are discerned that are likely to reflect CNS damage. Evidence to support a Rank 1 can come from standardized psychometric tests, observational data, and/or caregiver interview. While this classification is typically quite rare in an FASD Diagnostic Clinic, it might help to think of this outcome in the context of a well-child assessment conducted in a general pediatric clinic where most children would be classified as Rank 1.

Completing the CNS Section of the FASD Diagnostic Form

The CNS section appears on pages 3 through 7 of the FASD Diagnostic Form. These pages serve as a place to record pertinent structural, neurological, psychometric, and caregiver interview data available on the patient. Although space has been provided to record a full complement of assessments, we are not implying that all of these assessments must be conducted to derive a diagnosis. It is the responsibility of the clinical team to select the most appropriate assessment battery for an individual patient. Recording data for the structural, neurological, and psychometric sections is self-explanatory. The Caregiver Interview section, however, warrants further explanation.

An important aspect of the FASD evaluation is an in depth interview of the caregivers of the patient. This interview takes approximately one hour and is conducted by a qualified member(s) of the clinical team. At the University of Washington FAS DPN clinic, this interview is conducted jointly by the physician and psychologist while the patient is being formally assessed by the other clinical

team members. As in any diagnostic situation, once records are reviewed and there is a preliminary case formulation, the diagnostic interview will address several questions, such as: What are the problems that led to the diagnostic referral? What do the caregivers hope to gain from the assessment? What are the caregivers' views of the patient's overall strengths and weaknesses? What is the child's social and medical history, pertinent to this diagnostic evaluation? In an FASD diagnostic evaluation, we have found it very useful to also methodically ask questions that review age-appropriate functional abilities in areas that, according to the literature, are commonly problematic for alcohol-exposed individuals. These areas (planning/temporal skills, behavioral regulation/sensory motor integration, abstract thinking/judgment, memory/learning/information processing, spatial skills/spatial memory, social skills/adaptive behavior, and motor/oral motor control) are presented on the FASD Diagnostic Form (page 6). Routinely inquiring about the patient's capabilities in these areas serves several purposes. First, the caregivers' answers to these questions give insight into their interpretation of the patient's behaviors and about their general relationship with the patient. Second, it is often helpful to compare this subjective assessment to the psychometric profile. This can reveal information about the pattern of neurodevelopmental and neurobehavioral difficulties that standardized testing may miss, or provide evidence that is supportive of test results. The data recorded on page 6 of the Diagnostic Form are non-standardized observational measures.

Severity Score [0, 1, 2, 3]

Along the left margin of each CNS page is a Severity Score. This Severity Score serves two purposes. 1) It allows one to rapidly scan the left margin of the CNS pages to see what structural, neurological, and functional areas are most impacted. 2) The Severity Scores in the Structural/Neurological Sections and the Functional Domains page also serve to document what evidence was present to meet the criteria for CNS Ranks 2, 3, and 4, as described above. For example, at least one area in the Structural or Neurological Sections should have a Severity Score = 3 to meet criteria for a CNS Rank 4. At least three domains on the Functional Domains page should a Severity Score = 3 to meet criteria for a CNS Rank 3.

The clinical team ranks the level of impairment/abnormality as follows:

0	Unknown, Not Assessed
1	Within Normal Limits
2	Mild to Moderate
3	Significant

For outcomes measured on standardized scales, in general, outcomes two or more standard deviations below the norm would be judged significant, whereas outcomes between one and two standard deviations below the norm could be judged mild to moderate.

A comprehensive assessment will identify domains of strength, as well as domains with mild or significant impairment. Documenting the outcomes of all assessed domains, not just those with significant impairment, is important for treatment planning.

Table 5: Criteria for CNS Ranks 1 through 4

4-Digit Diagnostic Rank*	Probability of CNS Damage	Confirmatory Findings
4	Definite **Structural and/or Neurological Abnormalities** *Static Encephalopathy*	● Microcephaly: OFC 2 or more SDs below the norm. *and / or* ● Significant abnormalities in brain structure of presumed prenatal origin. *and / or* ● Evidence of hard neurological findings likely to be of prenatal origin.
3	Probable **Significant Dysfunction** *Static Encephalopathy*	● Significant impairment in three or more domains of brain function such as, but not limited to: cognition, achievement, memory, executive function, motor, language, attention, activity level, neurological 'soft' signs.
2	Possible **Mild to Moderate Delay or Dysfunction** *Neurobehavioral Disorder*	● Evidence of delay or dysfunction that suggest the possibility of CNS damage, but data to this point do not permit a Rank 3 classification.
1	Unlikely	● No current evidence of delay or dysfunction likely to reflect CNS damage.

* Transfer the resulting 4-Digit Diagnostic Rank for CNS to the 4-Digit Diagnostic Code Grid on page 1 of the FASD Diagnostic Form.

III. Instructions for Deriving the 4-Digit Code

B.4. Ranking Alcohol Exposure

Method for Ranking Alcohol: The 4th Digit of the 4-Digit Diagnostic Code

Alcohol exposure is ranked according to the quantity, timing, frequency, and certainty of exposure during pregnancy (Table 6). The case-definitions for the four Ranks address two important issues: 1) that exposure information in a clinical setting can be of limited availability or of unknown accuracy and 2) a clear consensus is not available concerning the amount of alcohol that can actually be toxic to each individual fetus (Stratton et al., 1996).

The case-definitions for prenatal alcohol exposure differentiate four clinically meaningful groups (Rank 4: confirmed exposure to high levels of alcohol; Rank 3: confirmed exposure, but the level is less than Rank 4 or the level is unknown; Rank 2: unknown exposure (neither confirmed absent nor confirmed present); and Rank 1: confirmed absence of exposure from conception to birth). High exposure is defined generally to be a blood alcohol concentration of greater than 100 mg/dL (a level that typically can be reached by a 55-kg woman consuming six to eight beers) weekly, early in pregnancy. In the absence of a clear consensus on the amount of alcohol that can actually be toxic to the fetus, this general definition should only serve as a guide, not a threshold.

One example of a 'Rank 4' exposure is the birth mother reported drinking to the point of intoxication weekly throughout pregnancy. Two examples of 'Rank 3' exposures include: 1) birth mother was observed to be drinking during pregnancy, but the amount is unknown, 2) birth mother reported drinking a glass of wine weekly, but stopped drinking as soon as she learned she was pregnant at 3 months. Two examples of when alcohol exposure is ultimately unknown and thus coded as Rank 2 include: 1) the child is adopted and the records are closed, and 2) the birth mother is known to have a problem with drinking, but there are no records or direct observation of her drinking during the index pregnancy. A Rank 1 classification (confirmed absence of drinking from conception to birth) is relatively rare in the general population since it is unlikely to occur unless a pregnancy is either planned or the woman never drinks.

Table 6: Criteria for Prenatal Alcohol Exposure Ranks 1 through 4

4-Digit Diagnostic Rank	Prenatal Alcohol Exposure Category	Description of Alcohol Use During Pregnancy
4	High Risk	● Alcohol use during pregnancy is CONFIRMED. *and* ● Exposure pattern is consistent with the medical literature placing the fetus at "high risk" (generally high peak blood alcohol concentrations delivered at least weekly in early pregnancy).
3	Some Risk	● Alcohol use during pregnancy is CONFIRMED. *and* ● Level of alcohol use is less than in Rank (4) or level is unknown.
2	Unknown Risk	● Alcohol use during pregnancy is UNKNOWN.
1	No Risk	● Alcohol use during pregnancy is CONFIRMED to be completely ABSENT from conception to birth.

Transfer the resulting 4-Digit Diagnostic Rank for Alcohol Exposure to the 4-Digit Diagnostic Code Grid on page 1 of the FASD Diagnostic Form.

III. Instructions for Deriving the 4-Digit

B.5. Ranking Other Pre- and Postnatal Exposures/Events

The Importance of Documenting Other Risk Factors

A comprehensive diagnostic process must take into consideration all other adverse prenatal and postnatal exposures and events, not just prenatal alcohol exposure. Many of the outcomes observed in individuals with prenatal alcohol exposure are not specific to (caused only by) prenatal alcohol exposure. A variety of other prenatal (poor prenatal care, prenatal complications, familial genetics, and exposure to other potentially teratogenic agents, etc.), and/or postnatal (physical/sexual abuse, disrupted placement histories, head injuries, chronic substance abuse by the patient, etc.) exposures and events could also contribute to the outcomes presented by the patient. The 4-Digit Diagnostic method requires the clinical team to record all pertinent prenatal and postnatal exposures and events on the standardized FASD Diagnostic Form, rank their severity using case-defined 4-point Likert scales, report them in the medical summary, and take them into consideration when deriving a diagnosis and intervention plan. It is important to note that the presence of other risk factors does not reduce the teratogenic potential of alcohol. When multiple risk factors are present, including prenatal alcohol exposure, each risk factor has the potential of being fully responsible, partially responsible, or not responsible at all for any particular outcome. The medical technology to determine which risk factor is responsible for which outcome simply does not exist at this point in time.

A. Prenatal Rank Definitions

Rank 4: High Risk

This Rank is reserved for alternate genetic conditions (e.g., Fragile X, velocardiofacial syndrome, down syndrome, etc.) or exposure to known teratogens (e.g., dilantin, valproic acid, etc.) that have been clearly shown to produce physical abnormalities.

Rank 3: Some Risk

This category is used for potential genetic conditions, exposures or prenatal conditions that have been associated with physical or neurodevelopmental problems in a less well-established way, when compared to those falling in Prenatal Rank 4. Examples of conditions that would be placed in this category would include poor prenatal care; patients whose parents have mild mental retardation, attention deficit disorders, significant learning disabilities or learning problems thought to be due to a non-specific (and non-teratogenic) source; prenatal exposure to drugs like marijuana or heroin, in otherwise non-specified frequencies and quantities; and cigarette smoking during pregnancy.

Rank 2: Unknown Risk

This category is used when the details of the family background and gestation are unknown – generally in the circumstance of a closed adoption.

Rank 1: No Known Risk

On occasion, the genetic, teratogenic, and prenatal histories are well documented and no factors can be identified that would explain the abnormalities found in the patient.

B. Postnatal Rank Definitions

Rank 4: High Risk

This Rank is used to note postnatal circumstances that have been shown to have a significant adverse effect on development in most instances. Examples would include clear physical and sexual abuse, multiple disrupted placements with clear impact on the child, neglect resulting in failure to thrive, serious head injury, or medical conditions which lead to brain damage (i.e. kernicterus or persistent neonatal apnea).

Rank 3: Some Risk

This Rank is used to note conditions akin to those in Rank 4, but the circumstances are less severe and so less likely to be a definite factor in the patient's present condition. Obviously, clinical judgment is needed in judging the magnitude of a postnatal problem and interpreting this information into a Rank 3 or 4 placement.

Rank 2: Unknown Risk

This Rank is used when historical information is missing. This is sometimes the case with adopted children or those in foster care. Adult patients may, at times, be unable to reconstruct their own early histories.

Rank 1: No Known Risk

This Rank is used when a well-documented history confirms an absence of adverse postnatal exposures/events.

IV. Diagnostic Categories

The 256 Diagnostic Codes can be logically grouped into 22 Diagnostic Categories

Category	Name
A	Fetal alcohol syndrome (alcohol exposed)
B	Fetal alcohol syndrome (alcohol exposure unknown)
C	Partial fetal alcohol syndrome (alcohol exposed)
D	Fetal alcohol syndrome phenocopy (no alcohol exposure)
E	Sentinel physical finding(s) / static encephalopathy (alcohol exposed)
F	Static encephalopathy (alcohol exposed)
G	Sentinel physical finding(s) / neurobehavioral disorder (alcohol exposed)
H	Neurobehavioral disorder (alcohol exposed)
I	Sentinel physical finding(s) (alcohol exposed)
J	No sentinel physical findings or CNS abnormalities detected (alcohol exposed)
K	Sentinel physical finding(s) / static encephalopathy (alcohol exposure unknown)
L	Static encephalopathy (alcohol exposure unknown)
M	Sentinel physical finding(s) / neurobehavioral disorder (alcohol exposure unknown)
N	Neurobehavioral disorder (alcohol exposure unknown)
O	Sentinel physical finding(s) (alcohol exposure unknown)
P	No sentinel physical findings or CNS abnormalities detected (alcohol exposure unknown)
Q	Sentinel physical finding(s) / static encephalopathy (no alcohol exposure)
R	Static encephalopathy (no alcohol exposure)
S	Sentinel physical finding(s) / neurobehavioral disorder (no alcohol exposure)
T	Neurobehavioral disorder (no alcohol exposure)
U	Sentinel physical finding(s) (no alcohol exposure)
V	No sentinel physical findings or CNS abnormalities detected (no alcohol exposure)

V. 4-Digit Diagnostic Codes
Within each Diagnostic Category

Category	Diagnostic Name and Codes
A	Fetal alcohol syndrome (alcohol exposed) 2433 3433 4433 2434 3434 4434 2443 3443 4443 2444 3444 4444
B	Fetal alcohol syndrome (alcohol exposure unknown) 2432 3432 4432 2442 3442 4442
C	Partial fetal alcohol syndrome (alcohol exposed) 1333 1433 2333 3333 4333 1334 1434 2334 3334 4334 1343 1443 2343 3343 4343 1344 1444 2344 3344 4344
D	Fetal alcohol syndrome phenocopy (no alcohol exposure) 3431 4431 3441 4441
E	Sentinel physical finding(s) / static encephalopathy (alcohol exposed) 3133 3233 4133 4233 3134 3234 4134 4234 3143 3243 4143 4243 3144 3244 4144 4244
F	Static encephalopathy (alcohol exposed) 1133 1233 2133 2233 1134 1234 2134 2234 1143 1243 2143 2243 1144 1244 2144 2244
G	Sentinel physical finding(s) / neurobehavioral disorder (alcohol exposed) 1323 2323 3123 3323 4123 4323 1324 2324 3124 3324 4124 4324 1423 2423 3223 3423 4223 4423 1424 2424 3224 3424 4224 4424

Category	Diagnostic Name and Codes
H	Neurobehavioral disorder (alcohol exposed) 1123 1223 2123 2223 1124 1224 2124 2224
I	Sentinel physical finding(s) (alcohol exposed) 1313 2313 3113 3313 4113 4313 1314 2314 3114 3314 4114 4314 1413 2413 3213 3413 4213 4413 1414 2414 3214 3414 4214 4414
J	No physical findings or CNS abnormalities detected (alcohol exposed) 1113 1213 2113 2213 1114 1214 2114 2214
K	Sentinel physical finding(s) / static encephalopathy (alcohol exposure unknown) 1332 2332 3132 3332 4232 1342 2342 3142 3342 4242 1432 3232 4132 4332 1442 3242 4142 4342
L	Static encephalopathy (alcohol exposure unknown) 1132 1232 2132 2232 1142 1242 2142 2242
M	Sentinel physical finding(s) / neurobehavioral disorder (alcohol exposure unknown) 1322 2322 3122 3322 4122 4322 1422 2422 3222 3422 4222 4422
N	Neurobehavioral disorder (alcohol exposure unknown) 1122 1222 2122 2222
O	Sentinel physical finding(s) (alcohol exposure unknown) 1312 2312 3112 3312 4112 4312 1412 2412 3212 3412 4212 4412

Category	Diagnostic Name and Codes
P	No physical findings or CNS abnormalities detected (alcohol exposure unknown) 1112 2112 1212 2212
Q	Sentinel physical finding(s) / static encephalopathy (no alcohol exposure) 1331 2331 3131 4131 1341 2341 3141 4141 1431 2431 3231 4231 1441 2441 3241 4241 3331 4331 3341 4341
R	Static encephalopathy (no alcohol exposure) 1131 1231 2131 2231 1141 1241 2141 2241
S	Sentinel physical finding(s) / neurobehavioral disorder (no alcohol exposure) 1321 2321 3121 3321 4121 4321 1421 2421 3221 3421 4221 4421
T	Neurobehavioral disorder (no alcohol exposure) 1121 2121 2221 1221
U	Sentinel physical finding(s) (no alcohol exposure) 1311 2311 3111 3311 4111 4311 1411 2411 3211 3411 4211 4411
V	No physical findings or CNS abnormalities detected (no alcohol exposure) 1111 2111 1211 2211

VI. 4-Digit Diagnostic Codes Sorted Numerically

Code	Category	Diagnostic Name
1111	V	No sentinel physical findings or CNS abnormalities detected (no alcohol exposure)
1112	P	No sentinel physical findings or CNS abnormalities detected (alcohol exposure unk.)
1113	J	No sentinel physical findings or CNS abnormalities detected (alcohol exposed)
1114	J	No sentinel physical findings or CNS abnormalities detected (alcohol exposed)
1121	T	Neurobehavioral disorder (no alcohol exposure)
1122	N	Neurobehavioral disorder (alcohol exposure unknown)
1123	H	Neurobehavioral disorder (alcohol exposed)

VII. Clinical Summaries
For each of the 22 Diagnostic Categories

Clinical summaries for each of the 22 Diagnostic Categories are presented on the following pages listed alphabetically from A through V. A complete list of the 22 categories is presented in Section IV.

These summaries can be used as the first page of the final diagnostic report. They often require minor alterations or additions to conform to the specifics of an individual case.

A

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Fetal Alcohol Syndrome**
(2) Alcohol exposed

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant central nervous system (CNS) damage/dysfunction that occur in individuals exposed to alcohol during gestation. On the attached sheets are the specific findings in this patient's case that led to our conclusion that there was sufficient evidence to make the diagnosis of fetal alcohol syndrome.

Although we believe that the patient clearly has fetal alcohol syndrome, this does not mean that alcohol exposure during pregnancy is the only cause of the patient's current problems. A number of other factors could be contributing to the present situation, such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. Such factors may partly explain why there is so much variability in the kinds of specific difficulties that patients with FAS have.

Individuals with FAS have significant CNS damage/dysfunction and should be viewed as individuals with disabilities. The fetal alcohol syndrome diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific concerns that have been identified that need attention.

B

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Fetal Alcohol Syndrome**
(2) Alcohol exposure unknown

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of central nervous system (CNS) damage/dysfunction occurring in patients exposed to alcohol during gestation. On the attached sheets are the specific findings in this patient's case that led to our conclusion that there was sufficient evidence in this case to make a diagnosis of fetal alcohol syndrome even though the history of exposure to alcohol during gestation could not be confirmed.

Although we believe that the patient clearly has fetal alcohol syndrome, this does not mean that alcohol exposure during pregnancy is the only cause of the patient's current problems. A number of other factors could be contributing to the present issues, such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. Such factors may partly explain why there is so much variability in the kinds of specific difficulties that patients with FAS have.

Individuals with FAS have significant CNS damage/dysfunction and should be viewed as individuals with disabilities. The fetal alcohol syndrome diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific concerns that have been identified that need attention.

C

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Partial FAS**
(2) Alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of central nervous system (CNS) damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS. Indeed, many patients who have been exposed to alcohol show most, but not all, of the classic features of this syndrome. We use the term "Partial FAS" when a patient's characteristic features are very close to the classic features of FAS and the alcohol history strongly suggests that alcohol exposure during gestation was at high risk and likely to have played a role in the syndrome. Patients with Partial FAS either have the full set of facial anomalies found with FAS and evidence of CNS damage/dysfunction, but do not have growth deficiency; or they have growth deficiency and evidence of CNS damage/dysfunction, and most, but not all of the FAS facial features. The severity of CNS damage/dysfunction is comparable between FAS and PFAS. As you can see from the enclosed list of features found in this patient, the patient meets the criteria for Partial FAS. Patients diagnosed with Partial FAS must have confirmed exposure to alcohol during gestation.

In addition to prenatal exposure to alcohol, a number of other factors could be contributing to the patient's current problems, such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. Such factors may partly explain why there is so much variability in the kinds of specific difficulties patients with Partial FAS experience.

Patients with Partial FAS have significant CNS damage/dysfunction and should be viewed as having a disability. The diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific concerns that have been identified that need attention.

D

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Fetal Alcohol Syndrome Phenocopy**
(2) No alcohol exposure

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of central nervous system (CNS) damage/dysfunction occurring in patients exposed to alcohol during gestation. On the attached sheets are the specific findings in this patient's case that led to our conclusion that the patient has all of the features of FAS. However, there is good reason to believe this patient was not exposed to alcohol during gestation.

Most syndromes can occasionally arise from an alternate cause. Presumably, this is the situation here. A number of other factors could be contributing to the present situation, such as the patient's genetic background and other potential exposures or problems during pregnancy, and various experiences since birth.

Whatever the cause of this patient's syndrome, he/she has structural, neurological and/or cognitive/behavioral problems and should be viewed as a person with a disability. This diagnosis has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific concerns that have been identified that need attention.

E

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Sentinel physical finding(s)**
(2) Static encephalopathy
(3) Alcohol exposed

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of central nervous system (CNS) damage/dysfunction in individuals exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, some but not all of the characteristic growth and facial features associated with FAS were present and there was evidence of CNS damage and/or dysfunction as you will see noted on the attached pages. There was also a clear history of exposure to significant amounts of alcohol during gestation. In this situation, we use the terms "static encephalopathy" and "Sentinel physical finding(s)" to describe the patient's condition. The patient's CNS abnormalities may include structural, neurological and/or functional problems. The diagnoses of "Static encephalopathy and Sentinel physical finding(s)" in the presence of alcohol exposure do not mean that alcohol is the only cause of the problem. A number of other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during gestation, and various experiences since birth. These kinds of differences may partly explain why there is so much variability in the kinds of specific difficulties that patients with static encephalopathy and alcohol exposure have.

The diagnoses made today are based on the information available at the time of this assessment. If this patient's alcohol exposure was considered "low risk" and new information is uncovered which documents higher exposures; or if the patient's facial features, growth, or neurobehavioral problems were judged "probable" and further growth or development suggest a "definite" problem is present, then reconsideration of the diagnosis of fetal alcohol syndrome would be appropriate. Alternately other birth defect syndromes or conditions not related to alcohol exposure may also need reconsideration.

Individuals with significant CNS abnormalities have structural, neurological, and/or cognitive/behavioral problems and should be viewed as individuals with disabilities. The diagnosis of static encephalopathy has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

F

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Static encephalopathy**
(2) Alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of central nervous system (CNS) damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, no growth deficiency or characteristic set of facial features were found so the patient does not have FAS, but there was evidence of significant CNS damage/dysfunction as you will see noted on the attached pages. There was also a clear history of exposure to significant amounts of alcohol during gestation. In this situation, we use the term "static encephalopathy" to describe the patient's condition. On the attached sheets are the specific findings in this patient's case that led us to this conclusion. The diagnosis of static encephalopathy does not mean that alcohol is the only cause of the problem. A number of other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. These kinds of differences may partly explain why there is so much variability in the kinds of specific difficulties that patients with static encephalopathy face.

Individuals with significant CNS abnormalities have structural, neurological, and/or cognitive/behavioral evidence of CNS damage/dysfunction, and should be viewed as individuals with disabilities. The diagnosis of static encephalopathy has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

G

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Sentinel physical finding(s)**
(2) Neurobehavioral disorder
(3) Alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant central nervous system (CNS) damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS. On the attached sheets you will find our specific observations in this case. We found that some, but not all, of the characteristic physical findings seen in patients with FAS were present. There was not strong evidence that the patient's cognitive/behavioral problems were clearly due to CNS damage, but there were suggestions that this was the case. In this situation we use the term "neurobehavioral disorder" to emphasize the possibility that the problems may not be entirely due to postnatal experiences. Certainly a number of other factors could be contributing to the patient's condition such as genetic background, other potential exposures or problems during pregnancy, and various experiences since birth.

The diagnoses made today are based on the information at hand. If further testing is done which makes the likelihood of significant CNS damage/dysfunction of prenatal cause more likely, then an alternate diagnosis could be considered. Alternately other birth defect syndromes or conditions not related to alcohol exposure may also need consideration.

In any event, the diagnosis of neurobehavioral disorder has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Neurobehavioral disorder**
(2) Alcohol exposed

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of significant central nervous system (CNS) damage/dysfunction in individuals exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

On the attached sheets you will find our specific observations in this case. There was not strong evidence that the patient's cognitive/behavioral problems were clearly due to CNS damage, but there were suggestions that this was the case. In this situation we use the term "neurobehavioral disorder" to emphasize the possibility that the problems may not be entirely due to postnatal experiences. Certainly a number of other factors could be contributing to the patient's condition such as genetic background, other potential exposures or problems during gestation, and various experiences since birth.

The diagnosis made today is based on the information available at the time of this assessment. If this patient's alcohol exposure was considered "low risk" and new information is uncovered which documents higher exposure, or if the patient's facial features or growth become more abnormal or if further testing finds further evidence of significant CNS damage/dysfunction, then further diagnostic consideration would be appropriate.

Whatever the cause, the diagnosis of neurobehavioral disorder has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Sentinel physical finding(s)**
(2) Alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant central nervous system (CNS) damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS. Some individuals have the growth deficiency and/or facial characteristics, but do not have evidence of CNS damage/dysfunction. We refer to this condition as "Sentinel physical finding(s) / Alcohol exposed". On the attached sheets are the specific findings in this patient's case which indicate that the characteristic growth deficiencies and/or facial features are, to some extent, compatible with FAS, but at this time there is no clear evidence of cognitive or behavioral problems that strongly suggest CNS damage. At such time in the future that CNS damage/dysfunction is found through images of the brain, neurological testing or cognitive behavioral assessment, then the diagnosis of fetal alcohol syndrome should be reconsidered. Other birth defect syndromes that are not related to alcohol exposure should also be considered as alternate explanations for the patient's problems.

J

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis **(1) No sentinel physical findings or CNS abnormalities detected**
(2) Alcohol exposed

In this current assessment, we conclude that this patient was exposed to alcohol during gestation, but no specific cognitive, behavioral, or characteristic physical findings were detected in our examination.

No alcohol-related diagnoses are offered at this time. Re-evaluation would be appropriate in the future if problems arise that strongly suggest central nervous system (CNS) damage/dysfunction, growth deficiency, or facial dysmorphology.

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis
(1) Sentinel physical finding(s)
(2) Static encephalopathy
(3) Alcohol exposure unknown

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of significant central nervous system (CNS) damage/dysfunction in individuals exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, some but not all of the characteristic growth and facial features associated with FAS were present, and there was evidence of significant CNS damage/dysfunction as you will see noted on the attached pages. In this situation, we use the terms "Static encephalopathy" and "Sentinel physical finding(s)" to describe the patient's condition. Although it is unknown whether this patient was exposed to alcohol during gestation, a number of other factors could be contributing to the patient's current cognitive/behavioral problems such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. These kinds of differences may partly explain why there is so much variability in the kinds of specific difficulties that patients with CNS abnormalities have.

The diagnosis made today is based on the information available at the time of this assessment. In the event that a confirmed history of alcohol exposure is obtained, or if the patient's facial features or growth become more abnormal, then further diagnostic consideration would be appropriate. Alternately other birth defect syndromes or conditions not related to alcohol exposure may also need reconsideration.

Individuals with significant static encephalopathy have evidence of CNS damage/dysfunction and should be viewed as a person with a disability. The diagnosis of static encephalopathy has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

THE FETAL ALCOHOL SYNDROME CLINIC
DIAGNOSTIC SUMMARY

Final Diagnosis: **(1) Sentinel physical finding(s)**
(2) Neurobehavioral disorder
(3) Alcohol exposure unknown

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant central nervous system (CNS) damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS. On the attached sheets you will find our specific observations in this case. We found that some, but not all, of the characteristic physical findings seen in patients with FAS were present and a confirmed history of alcohol exposure during gestation was not available. There was not strong evidence that the patient's cognitive/behavioral problems were clearly due to CNS damage, but there were suggestions that this was the case. In this situation we use the term "neurobehavioral disorder" to emphasize the possibility that the problems may not be entirely due to postnatal experiences. Certainly a number of other factors could be contributing to the patient's condition such as genetic background, other potential exposures or problems during pregnancy, and various experiences since birth.

The diagnoses made today are based on the information at hand. If further testing is done which makes the likelihood of significant CNS damage/dysfunction of prenatal cause more likely, then an alternate diagnosis would be considered. Alternately other birth defect syndromes or conditions not related to alcohol exposure may also need reconsideration.

In any event, the diagnosis of neurobehavioral disorder has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

X. Appendices

1. FAS DPN WEBSITE http://depts.washington.edu/fasdpn

The University of Washington FAS DPN website provides a comprehensive overview of all clinical, research, and training activities conducted by the FAS DPN. Included are all publications, order forms for diagnostic tools, and registration forms for the training programs.

A. Frequently Asked Questions, Updates and Sample Forms.
Posted on the FAS DPN website are answers to frequently asked questions regarding the 4-Digit Code. Also posted are updates, support information and pdf versions of the FASD Diagnostic Form and NPIF. Examples of completed FASD Diagnostic Forms for selected 4-Digit Codes are also posted to further illustrate how to use the 4-Digit Code.

B. TRAINING PROGRAMS AND COURSES

i. Two-Day Interdisciplinary Clinical Training Program. This training program is offered twice a year at the University of Washington. Interdisciplinary clinical teams are taught how to use the 4-Digit Diagnostic Code in an interdisciplinary clinical setting.

ii. Online Training Course. This accredited course will provide healthcare, educational, and social service professionals with detailed instruction on the use of the 4-Digit Diagnostic Code in an interdisciplinary clinical setting.

iii. One-Day Clinical Observational Training Program. This training provides healthcare, social service, and educational professionals with insight into their role in the community for screening, referral, diagnosis, prevention, and intervention of FASD.

C. DIAGNOSTIC TOOLS AND SOFTWARE

i. FAS Facial Photographic Analysis Software (2003). This software is intended for use by healthcare and research professionals. The software allows one to measure the magnitude of expression of the key facial features of FAS from a digital facial photograph using the method derived by Astley & Clarren, (2001).

ii. FAS TUTOR ™ CD (1999). A compact disk entitled Fetal Alcohol Syndrome Tutor™ has been created by the University of Washington FAS DPN to instruct healthcare professionals, through video, computer animation, and photographic examples, on how to screen and diagnose FASD.

iii. Diagnostic Guide and Lip-Philtrum Guides (2004) Additional copies of the "*Diagnostic Guide for Fetal Alcohol Spectrum Disorders: The 4-Digit Diagnostic Code, 2004*" and the laminated, *Lip-Philtrum Guides* can be ordered from the FAS DPN website.

2. NEW PATIENT INFORMATION FORM (See form below).
This form is sent to families requesting a diagnostic evaluation at the University of Washington FAS DPN clinic. The form allows the family to share with the clinic why they are seeking a diagnostic evaluation, what they hope to gain from the evaluation and what they currently know about the patient's exposure(s) and outcomes. This form serves as a clinical intake form.

Name _____

Relationship to patient: ❑ birth, ❑ adoptive, or ❑ foster parent ❑ other (specify _____)

Address _____

City _____ County _____ State _____ zip code _____

Telephone Home ( ) _____ Work ( ) _____

Please complete this form to the best of your ability. We realize you will not have the answers to all questions. All information requested in this form is important in allowing us to provide you with the most accurate diagnosis and most appropriate referrals for care. Thank you for taking the time to complete it.

Reasons for Evaluation What are the patient's primary problems? Please be specific.

What do you hope to gain from the evaluation?

Growth

Birth Measures

1. Birth weight: lbs / oz _____ or gms _____

   Birth length: inches _____ or cm _____

   Birth head circumference: inches _____ or cm _____

   Gestational age *(length of pregnancy)*: weeks _____ or months _____

Please provide additional height, weight and head measures if available*

2. Date _____ Weight: lbs _____ or kg _____

   Age _____ Height: inches _____ or cm _____

   Head Circumference: inches _____ or cm _____

3. Date _____ Weight: lbs _____ or kg _____

   Age _____ Height: inches _____ or cm _____

   Head Circumference: inches _____ or cm _____

4. Date _____ Weight: lbs _____ or kg _____

   Age _____ Height: inches _____ or cm _____

   Head Circumference: inches _____ or cm _____

5. Date _____ Weight: lbs _____ or kg _____

   Age _____ Height: inches _____ or cm _____

   Head Circumference: inches _____ or cm _____

Birth Parents' Heights: Birth Mother: inches _____ or cm _____

Birth Father: inches _____ or cm _____

* This information may be available from the patient's physician or school nurse. If growth charts are available and can be photocopied and attached to this form, you need not fill out this section.

Physical Appearance and Health

1. **Photographs of the patient's face are very helpful to us.** The best photos are ones where the face fills the photo and the patient is not smiling. Pictures between ages 1 and 12 years are best.

   - Are such photographs available? ____ yes ____ no
   - Are one or two included with this form? ____ yes ____ no
   - Can others be brought to the clinic? ____ yes ____ no

Please staple photo(s) here:

Photo may be bigger than this space

2. **Was the patient born with (or later discovered to have) any birth defects (things like cleft lip, congenital heart defects, club foot, etc.)?** ____ yes ____ no _____ unknown

   If yes, please describe: _____

   _____

3. **Has this patient ever had:**

	yes	no	unknown		yes	no	unknown
Allergies	_____	_____	_____	Chronic illness of the heart	_____	_____	_____
Multiple ear infections	_____	_____	_____	Chronic illness of the kidneys	_____	_____	_____
Chronic sinusitis	_____	_____	_____	Chronic illness of the joints/limbs	_____	_____	_____
Chronic hearing loss	_____	_____	_____	Chronic illness of the stomach/ bowels	_____	_____	_____
Visual problems	_____	_____	_____				

4. **Has this patient ever had:**

   A. Operations (since birth) ____ yes ____ no ____ unknown

Describe Operation	Surgeon's Name	Patient's Age

   B. Any other hospitalizations ____ yes ____ no ____ unknown

Reason for Hospitalization	Hospital/Doctor	Patient's Age

   C. Physical abuse ____ yes ____ no ____ unknown Age(s): _____

   Was this evaluated by a physician? ____ yes ____ no ____ unknown

   D. Sexual abuse ____ yes ____ no ____ unknown Age(s): _____

   Was this evaluated by a physician? ____ yes ____ no ____ unknown

Neurological Issues

1. Has this patient ever had:

A. Seizures

____ yes ____ no ____ suspected ____ unknown

Type: _____

Age when seizure(s) started: _____

Name(s) of medication(s) given? _____

B. Loss of specific motor skills such as standing, walking, running, etc.

____ yes ____ no ____ unknown

If yes, please describe _____

C. Bed wetting or soiling after 8 years of age.

____ yes ____ no ____ unknown ___ not 8 years old yet

2. Has this patient ever had a head injury leading to unconsciousness or evaluation by a doctor?

____ yes ____ no ____ unknown

If yes, please describe _____

3. Has the patient ever had a CT scan or MRI scan of the brain

____ yes ____ no ____ unknown

If yes, was it described to be abnormal? ____ yes ____ no ____ unknown

Attention Deficit and Hyperactivity

1. Has the patient ever been evaluated for attention deficit/hyperactivity disorder (ADD / ADHD)

____ yes ____ no ____ unknown

If yes:

When was the evaluation done? Age: _____ Date: _____

Was the patient diagnosed with ADD or ADHD? ____ yes ____ no ____ unknown

Was the patient ever treated for ADD or ADHD? ____ yes ____ no ____ unknown

What medications have been tried?

Drug	Dose	Ages	Response

Mental Health Issues

1. Has the patient ever been evaluated by a psychiatrist, psychologist, or MH counselor?

____ yes ____ no ____ unknown

If yes, please list each psychiatrist, psychologist and/or counselor.

A. Type of professional: _____

Reason for assessment: _____

Type of therapy (i.e., behavioral, individual counseling, group counseling, family counseling, medicine): _____

_____

Age at the time of therapy: _____ Did the therapy help? ____ yes ____ no ____ unknown

If yes, how did it help? _____

_____

_____

B. Type of professional: _____

Reason for assessment: _____

Type of therapy (i.e., behavioral, individual counseling, group counseling, family counseling, medicine): _____

_____

Age at the time of therapy: _____ Did the therapy help? ____ yes ____ no ____ unknown

If yes, how did it help? _____

_____

_____

2. Has the patient ever been evaluated for mood problems (depression, anxiety, etc.) or phobia?

____ yes ____ no ____ unknown

If yes:

When was the evaluation(s) done? Age(s): _____ Date(s): _____

3. What medications have ever been tried and how well did they work?

Drug	Dose	Response	Currently Using?

School Issues

1. List ALL schools the patient has attended and the grades of attendance:

School	City	Grades Attended	Received Special Education, Resource Room, Tutoring, etc. yes	no	unknown

2. What learning problems does the patient have?

3. What behavioral problems does the patient have?

Alcohol Exposure

Please fill in this information as completely as possible.
This information is critical to the evaluation of the patient.

Alcohol use by the birth mother

- **Before pregnancy**: average number of drinks per drinking occasion: _____
  maximum number of drinks per occasion: _____
  average number of drinking days per week: _____
  Type(s) of alcohol: ___wine, ___beer, ___ liquor, ___ unknown, ___ other (specify) _____

- **During pregnancy:** average number of drinks per drinking occasion: _____
  maximum number of drinks per occasion: _____
  average number of drinking days per week: _____
  Type(s) of alcohol: ___wine, ___beer, ___ liquor, ___ unknown, ___ other (specify) _____

Which trimester(s) did the mother drink alcohol? ____ 1st ____2nd ____3rd ___unknown

	No	Yes	Unknown
Was the birth mother ever reported to have a problem with alcohol?	____	____	_____
Was the birth mother ever diagnosed with alcoholism?	____	____	_____
Did the birth mother ever receive treatment for alcohol addiction?	____	____	_____

If the above information is unknown, please provide any information that might help describe the mother's level of alcohol use DURING pregnancy _____

_____

_____

What is the source(s) of this information on alcohol use? _____

_____

Did the birth mother use any of the following substances during pregnancy?

Yes	No	Unknown	Type	Please List Specific Substance(s)	Month(s) of Pregnancy
___	___	___	Drugs	_____	_____
___	___	___	Tobacco	_____	_____
___	___	___	Medications	_____	_____
___	___	___	X-rays	_____	_____

Information about the Patient's Biological Parents

Acknowledgments

The development of this Guide was supported in part by the following agencies and contributors:

Centers for Disease Control and Prevention

Institute on Human Development and Disability,
University of Washington, Seattle WA

Division of Alcohol and Substance Abuse / Health Care Authority
Washington State Department of Social and Health Services

March of Dimes Birth Defects Foundation

John B. Chavez FAS Fund

I would like to acknowledge the University of Washington FAS Diagnostic & Prevention Network (FASDPN) clinical team members over the past 30 years who have used this Guide weekly and have helped hone the material on an ongoing basis: Special thanks is also extended to our patients and their families who have contributed a wealth of knowledge and information to the ongoing development of this Guide.

Preface

What's New in this 4th Edition, 2024?

The 1st, 2nd and 3rd editions of the Diagnostic Guide were printed in 1997, 1999, and 2004 respectively (Astley and Clarren, 1997, 1999, 2000; Astley 2004). It is now 2024 and a few key updates are warranted for this 4th Edition. These updates are based on our use of the 4-Digit Code for the past 30 years on over 3,000 patients, advancements in medical research, and feedback from over 1,500 clinicians worldwide trained to use the 4-Digit Diagnostic Code. We will continue to make modifications that enhance accuracy, improve clarity, and increase ease of use. We hope you will find this comprehensive approach to the diagnosis of individuals with prenatal alcohol exposure helpful and broadly applicable.

Since the 3rd edition was released in 2004, twenty years of published research has continued to validate the performance of the 2004 guidelines. Selected publications are presented below.

1. Astley SJ, Clarren SK. **(2000)**
   Diagnosing the full spectrum of fetal alcohol exposed individuals: Introducing the 4-Digit Diagnostic Code.

2. Astley SJ. **(2004a)**
   Fetal alcohol syndrome prevention in Washington State: Evidence of success. Video presentation by Susan (Astley) Hemingway in Poland, 2020.

3. Astley SJ, Aylward E, Olson HC, Kerns K, Brooks A, Coggins T, Davies J, Dorn S, Gendler B, Jirikowic T, Kraegel P, Maravilla K, Richards T. **(2009)**
   Magnetic resonance imaging outcomes from a comprehensive magnetic resonance study of children with fetal alcohol spectrum disorders.

4. Astley SJ. **(2011)**
   Canadian palpebral fissure length growth charts reflect a good fit for two school and FASD clinic-based U.S. populations.

5. Astley SJ **(2013)**
   Validation of the fetal alcohol spectrum disorder (FASD) 4-Digit Diagnostic Code.

6. Astley SJ. **(2014)**
   Twenty years of patient surveys confirm a FASD 4-Digit-Code interdisciplinary diagnosis afforded substantial access to interventions that met patients' needs.

7. Astley SJ. **(2015)**
   Palpebral fissure length measurement: Accuracy of the FAS Facial Photographic Analysis Software and Inaccuracy of the Ruler. Pictorial examples comparing the software to the gold standard measure obtained by a sliding digital caliper.

8. Astley SJ, Bledsoe JM, Davies JK. **(2016)**
   The essential role of growth deficiency in the diagnosis of fetal alcohol spectrum disorder.

9. (Astley) Hemingway SJ, Bledsoe JM, Brooks A, Davies JK, Jirikowic T, Olson EM, Thorne JC. **(2019)**
Comparison of the 4-Digit Code, Canadian 2015, Australian 2016 and Hoyme 2016 fetal alcohol spectrum disorder diagnostic guidelines. Link to video for Figure 2C.

10. Kesmodel US, Nygaard SS, Mortensen EL, Bertrand J, Denny C, Glidewell A, (Astley) Hemingway SJ **(2019)**
Are Low-to-Moderate Average Alcohol Consumption and Isolated Episodes of Binge Drinking in Early Pregnancy Associated with Facial Features Related to Fetal Alcohol Syndrome in 5-Year-Old Children?

11. (Astley) Hemingway SJ, Bledsoe JM, Davies JK, Brooks A, Jirikowic T, Olson EM, Thorne JC. **(2019)**
Twin study confirms virtually identical prenatal alcohol exposures can lead to markedly different fetal alcohol spectrum disorder outcomes - fetal genetics influences fetal vulnerability.

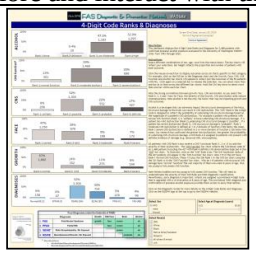
12. (Astley) Hemingway SJ **(2020)**
High facial specificity and positive predictive value are required to diagnose fetal alcohol syndrome when prenatal alcohol exposure is unknown.

13. (Astley) Hemingway SJ, Davies JK, Jirikowic T, Olson EM. **(2020)**
What proportion of the brain structural and functional abnormalities observed among children with fetal alcohol spectrum disorder is explained by their prenatal alcohol exposure and their other prenatal and postnatal risks?

14. (Astley) Hemingway SJ, Baldwin M, Pierce-Bulger M. **(2023)**
Washington and Alaska statewide FASD diagnostic clinical networks: Comparison of three decades of 4-Digit Code diagnostic outcomes and prenatal alcohol exposure histories.

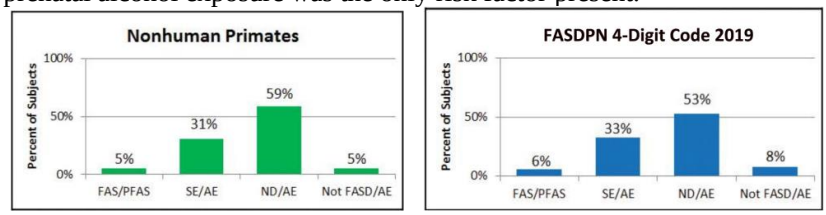
15. Pruner M, Jirikowic T, Baylor C, Hemingway SJA. **(2024)**
Developmental, sensory and behavioral outcomes among infants and toddlers with prenatal alcohol exposure.

16. (Astley) Hemingway SJ. **(1993-2024)**
FASDPN web-based interactive Tableau dashboards allow Users to explore and interact with the FASDPN data. The clinical/research database contains over 2,000 fields of information collected on over 3,000 individuals (newborn to adult) with prenatal alcohol exposure evaluated in the Washington State FASDPN clinics from 1993 through the present. All individuals received an FASD diagnostic evaluation by an interdisciplinary team using the FASD 4-Digit Diagnostic Code.



Research to date continues to confirm:

- **FASD is a spectrum of outcomes, not just severe outcomes** (Astley et al., 2019). The 4-Digit Code is currently the only FASD diagnostic system that includes "moderate" dysfunction (Neurodevelopmental Disorder / Alcohol Exposed (ND/AE)) as well as severe dysfunction (Static Encephalopathy / Alcohol Exposed (SE/AE)) under the umbrella of FASD. Nonhuman primate research confirms that moderate dysfunction (ND/AE) is the most prevalent outcome caused by prenatal alcohol exposure (Clarren et al., 1992). When using the 4-Digit Code, the prevalence of diagnostic outcomes observed in the University of Washington (UW) FASDPN diagnostic clinic matches the prevalence observed in a nonhuman primate model of FASD where prenatal alcohol exposure was the only risk factor present.



- **FASDs are disorders caused by the full continuum of prenatal alcohol exposure (PAE), not just higher exposures.** The higher the exposure the greater the risk, but lower exposures are not risk free (Kesmodel et al., 2019; Astley, 2013). Requiring a threshold level of PAE implies reported levels of PAE are reliably accurate. They are not. When thresholds of exposure are required for diagnosis, over half of individuals with confirmed PAE and severe brain abnormalities do not receive a diagnosis of FASD because details regarding quantity, frequency and timing of exposure are not available. Over half of individuals with the most severe outcome (FAS) have reportedly low to moderate PAE ((Astley) Hemingway, et al., 2019; Petryk et al., 2019). It is also important to note that the teratogenic impact of PAE is not just dependent on the quantity, frequency and timing of exposure. Our twin study confirmed fetal genetics influences fetal vulnerability to PAE ((Astley) Hemingway et al., 2019a). When twin pairs with virtually identical PAE were genetically identical (monozygotic), their FASD diagnoses were identical. When twin pairs with virtually identical PAE were genetically different (dizygotic), close to half (44%) presented with discordant FASD diagnoses. The same level of prenatal alcohol exposure that posed a lower risk for one twin, posed a high risk for the other twin.

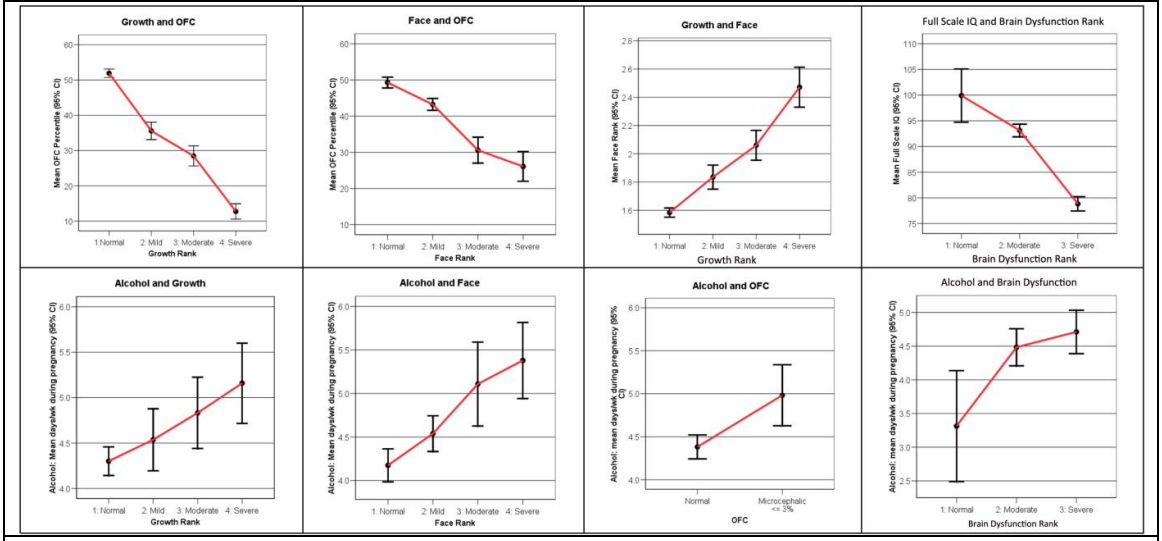
- **FASD is present at birth and can/should be diagnosed at birth to maximize intervention effectiveness** (Pruner et al., 2024; Astley et al., 2019; Astley et al., 2024). Fifteen percent of the patients diagnosed with FASD at the FASDPN over the past 30 years were birth to 3 years of age. Their diagnoses spanned the full continuum of FASD.

- **Growth deficiency (GD) is an essential diagnostic criterion for FASD** (Astley et al., 2016). Based on our empirical study of GD and FASD, GD was significantly correlated with prenatal alcohol exposure. Among individuals with PAE, GD was as prevalent as the other core diagnostic features (facial and brain abnormalities). GD occurred across the full spectrum of FASD diagnoses and increased in prevalence with increasing severity of diagnosis. The most prevalent form of GD was postnatal short stature. GD was as highly correlated with, and predictive of, severe brain dysfunction as the FAS facial phenotype. Individuals with GD had a

two to three-fold increased risk for severe brain dysfunction. Sixty percent of patients with severe GD had severe brain dysfunction. GD accurately predicted which infants had severe brain dysfunction that would not be detectable until later in childhood.

- **The Rank 4 FAS facial phenotype, as defined by the FASD 4-Digit Code, is the only facial phenotype** (Astley et al., 2019) **identified to date that provides sufficient positive predictive value (PPV) and specificity to prenatal alcohol exposure (100%) to allow the facial phenotype to be used as confirmation of prenatal alcohol exposure in a diagnostic setting when a written or verbal documentation of prenatal alcohol exposure is not available** (Astley, et al., 2020). The Rank 4 FAS facial phenotype can also be used to confirm an individual's prenatal alcohol exposure adversely impacted their fetal development. If the facial phenotype of FAS can only be caused by prenatal alcohol exposure, the following two conditions should hold true: 1) All individuals with the FAS facial phenotype have prenatal alcohol exposure (100% PPV); and 2) No individual with a confirmed absence of prenatal alcohol exposure will have the FAS facial phenotype (100% specificity). FASDPN data to date documents the Rank 4 FAS facial phenotype meets these two conditions.

- **FASD is defined by growth deficiency, FAS facial features and brain abnormalities caused by prenatal alcohol exposure (PAE).** If PAE causes FASD, one would expect: 1) strong intercorrelations between the growth, face and brain outcomes among individuals with PAE and 2) strong correlations between each of these three outcomes and prenatal alcohol exposure. This is exactly what is observed when using the 4-Digit Code. The plots below clearly demonstrate growth, face, brain and PAE all present along clinically meaningful continuums; the features are not simply present or absent. (Astley, 2013). The plots also demonstrate that growth, face and brain abnormalities are not only strongly intercorrelated with one another but also increase in severity with increasing PAE. This is powerful evidence supporting a causal association between PAE and these three outcomes.



Significant intercorrelations between growth, face, brain and prenatal alcohol exposure among 3,000 individuals with prenatal alcohol exposure diagnosed with FASD using the FASD 4-Digit Code.

Based on our published studies to date, we recommend the following updates when using this 4th edition of the guidelines (2024):

A. **Updated normal growth charts in electronic format are now widely available on the internet**. We recommend clinicians use the most current electronic charts for height, weight and head circumference that best match the age, sex, race/ethnicity, and country of origin of each patient (See Section III B.2). In our Seattle WA FASDPN clinic, we currently use the CDC, WHO and Rollins et al (2010) growth charts for OFC, weight and height and adjust for mid-parental height (Himes et al., 1985), when both parents' heights are available.

B. **We recommend using the free FAS Facial Photographic Analysis Software (2016, v2.1) distributed by the FASDPN to obtain the most accurate measures of the facial features** (Astley, 2015). The Facial Software incorporates an adjustment factor that is confirmed to accurately measure a palpebral fissure length from a 2-dimensional digital photo within 0.2 mm of the gold standard of measure (a sliding digital caliper). We do not recommend using a handheld ruler to measure PFLs. Numerous studies have confirmed the inaccuracy of the ruler method. We use the Iosub African American PFL charts (Iosub et al., 1985) for individuals that are full or half African American and the Stromland Scandinavian PFL charts for all other races (Stromland. et al., 1999). These charts come with our FAS Facial software and are available in our free excel PFL Z-score calculator. The Hall (1989) Caucasian PFL charts for birth to 16 years are no longer used and should not be used (Astley, 2011; Clarren et al., 2010).

C. **The University of Washington Lip-Philtrum Guides are the only guides that can be validly used to measure the lip and philtrum in accordance with the FASD 4-Digit Code** (Astley et al., 2019). Other Lip/Philtrum Guides may look similar, but are case-defined very differently (e.g., the Rank 4 thin upper lip on the North American Lip/Philtrum Guide (Hoyme et al., 2016) is equivalent to the Rank 2 moderately thick upper lip on the University of Washington Caucasian Lip-Philtrum Guide (Astley et al., 2019). The Seattle FASDPN clinic uses Lip-Philtrum Guide 1 for Caucasians and all races with thinner lips like Caucasians. Lip Philtrum Guide 2 is used for African Americans and all races with thicker lips like African Americans (e.g., Aboriginal Australians).

D. **The 4-Digit Code provides a classification scheme for the full spectrum of FASD and prenatal alcohol exposure that can be used in both the research and clinical arenas**. There are 246 different 4-Digit Codes that range from 1111 (normal development with confirmed absence of prenatal alcohol exposure) to 4444 (full FAS with high prenatal alcohol exposure). These 246 codes can be grouped into 19 different diagnostic categories. Only 108 of the 246 codes fall under the umbrella of FASD. These 108 codes are grouped into 6 distinct FASD diagnostic categories that differentiate individuals with different combinations of growth deficiency, FAS facial features, brain abnormalities and prenatal alcohol exposures. The clinical arena is best served by the smallest number of clinically distinct diagnostic categories that reflect the full spectrum of outcome and exposure. It is for this reason the FASDPN further collapses the 6 Diagnostic Categories for FASD into 3 clinically meaningful subgroups (FAS, SE/AE and ND/AE). FAS includes Diagnostic Category A (see Section IV). SE/AE includes Diagnostic Categories B and C. ND/AE includes Diagnostic Categories D, E and 4 codes in J. The research arena benefits most from a numeric approach to classification (the 4 digits) because the codes

can be used independent of clinical diagnostic nomenclature, can be sorted into any number of subgroups that best meet the study group requirements for the research question at hand and can be used as a universal method for describing FASD study group(s) enrolled across studies. Numeric codes expressed on ordinal scales (e.g., FAS facial phenotype absent, mild, moderate, severe) also provide greater statistical power to identify clinically meaningful correlations between outcomes and exposures than nominal categories expressed on dichotomous scales (e.g., FAS facial phenotype present/absent). Both the clinical and research arenas benefit from a FASD diagnostic system of classification (4-digit numeric codes) that is expressed in the universal language of numbers and portrays, at a glance, the magnitude of expression of each feature (e.g., 4-Digit Code 2334 reflects mild growth deficiency, moderate expression of the FAS facial phenotype, severe brain dysfunction and high prenatal alcohol exposure). Perhaps most importantly, as the clinical arena continues to strive for consensus on how to define and name the clinical subgroups under the umbrella of FASD, the 4-Digit Codes can be collapsed into any number of diagnostic categories The codes can be used independent of the clinical diagnostic names (FAS, SE/AE, ND/AE, ARND, ND-PAE, ARBD) one may apply to the subgroupings of the codes.

E. **The diagnostic term *Neurobehavioral Disorder / Alcohol Exposed* (ND/AE) has been replaced with the term *Neurodevelopmental Disorder / Alcohol Exposed (*ND/AE).** Neurodevelopmental disorders are defined as a group of conditions with onset in the developmental period, inducing deficits that produce impairments of functioning (Morris-Rosendahl & Crocq, 2020). This term is a better fit for the criteria used to define this 4-Digit Code diagnostic category; criteria that remain unchanged in this 4th edition.

F. **Diagnostic Categories A, B and C have been collapsed into a single Category A labeled FAS.** In the 3rd edition (Astley, 2004), Categories A, B and C distinguished *FAS/Alcohol exposed*, *FAS/Alcohol exposure unknown*, and *Partial FAS/Alcohol exposed*, respectively. These three categories have been collapsed into a single Category A labeled FAS for the following reasons. The 4-Digit Codes clearly reflect the various combinations of growth deficiency, FAS facial features, brain abnormalities and prenatal alcohol exposure that meet criteria for FAS. The 4-Digit Code no longer uses the term *Partial FAS* because too often the term was misinterpreted as a milder form of FAS (e.g. had less severe brain dysfunction), potentially jeopardizing an individual's opportunity to qualify for intervention services/supports. The only features that were partially expressed in *Partial FAS* were the growth and/or facial features, not the brain damage. The level of brain damage in Partial FAS was as severe as that required for *FAS*.

G. **Diagnostic Category D: FAS Phenocopy has been removed.** The 4 codes under this category (3431, 3441, 4431, 4441) have been moved to Category N: *Sentinel physical finding(s) / static encephalopathy / no alcohol exposure*. The name applied to Category N is more informative and avoids any potential chart lore confusion that *FAS Phenocopy* is FAS. The growth, face and brain ranks for these 4 codes meet criteria for FAS, but the confirmed absence of prenatal alcohol exposure rules out FAS. These 4-Digit Code outcomes could occur in an individual with growth deficiency and brain dysfunction whose familial facial phenotype happens to match that of FAS. Phenocopies such as these are expected to be rare and to date have never been observed in the FASDPN clinic.

H. **Two 4-Digit Codes (1432 and 1442) were moved from the 2004 Diagnostic Category: *K [sentinel physical finding(s) / static encephalopathy / alcohol exposure unknown*] to the new 2024 Category *A [Fetal alcohol syndrome*].** Since their sentinel physical finding was the Rank 4 FAS facial phenotype and the Rank 4 face provides confirmation of prenatal alcohol exposure when written or verbal evidence of alcohol exposure is unknown (Alcohol Rank 2); these two codes are more appropriately placed in Category A. Among over 4,500 patients evaluated in the FASD diagnostic clinics in AK and WA State (Astley et al, 2024) over 20 and 30 years respectively, only 4 individuals received a diagnosis of 1442. None received a diagnosis of 1432.

I. **Throughout this Guide, weblinks have been inserted** to provide clinicians with easy access to literature citations, diagnostic tools and forms, and training opportunities.

J. Finally, **all diagnostic forms in this Guide are posted on the FASDPN website and have been updated** to reflect this 4th edition of the Guide. The Online Course has also been updated. Those who have already completed the Online Course need not take it again.

FASD 4-Digit Code

Rank	**3** Growth	**4** Face	**3** Brain	**4** Prenatal Alcohol	3 Other Prenatal Risks	3 Other Postnatal Risks
4	severe	all 3 features	abnormal structure/neurology	high	high	high

2	mild	1-2 features	moderate dysfunction	unknown	unknown	unknown
1	normal	no features	normal function	none	none	none

FASD Umbrella

3 Diagnoses under the FASD Umbrella		Growth	FAS Face	Brain	Alcohol
1. FAS	Fetal Alcohol Syndrome	growth	face	severe	exposed
2. SE/AE	Static Encephalopathy / Alc-Exposed			severe	exposed
3. ND/AE	Neurodevelopmental Disorder / Alc-Exposed			moderate	exposed

I. Introduction

A. What is Fetal Alcohol Syndrome (FAS) and Fetal Alcohol Spectrum Disorders (FASD)

FAS is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The definition of the FAS has changed little since the 1970's when the condition was first described and refined at the University of Washington in Seattle WA (Jones and Smith, 1973; Rosett, 1980; Clarren and Smith, 1978; Sokol and Clarren, 1989; Stratton *et al*., 1996). The condition has been broadly characterized by prenatal and/or postnatal growth deficiency, a unique cluster of minor facial anomalies, and brain structural, neurological and/or functional abnormalities. Prenatal alcohol is a leading known cause of intellectual/developmental disabilities in the Western World (Abel & Sokol, 1987) and is preventable. The prevalence of FAS is estimated to be 1 to 3 per 1,000 live births (Stratton et al., 1996) in the general population, but has been documented to be as high as 10 to 15 per 1,000 in some high-risk populations like foster care (Astley et al., 2002).

The physical, cognitive, and behavioral deficits observed among individuals with prenatal alcohol exposure are not dichotomous, that is either normal or clearly abnormal. Rather, the outcomes, and the prenatal alcohol exposure, all range along separate continua from normal to clearly abnormal and distinctive. This full range of outcomes observed among individuals with prenatal alcohol exposure has come to be called Fetal Alcohol Spectrum Disorders (FASD). FASD is a spectrum of disorders **caused** by prenatal alcohol exposure. FAS is the most severe diagnosis under the umbrella of FASD.

Although reference to the harmful effects of prenatal alcohol exposure on infant outcome date back to biblical times, it was not until 1968 when the first reference was published in the medical literature by Lemoine and colleagues from France (Lemoine et al., 1968). Ulleland and colleagues from the United States published similar research findings in 1970 and 1972 (Ulleland et al., 1970; Ulleland, 1972). In 1973, Jones and Smith coined the term FAS (Jones & Smith, 1973) to describe a subset of alcohol-exposed children, obtained from Dr. Ulleland's study and their own clinical records, who shared a common pattern of malformation (Jones et al., 1973).

B. The Diagnostic Challenge

Individuals with prenatal alcohol exposure present with a wide range of outcomes, most of which are not specific to (caused only by) prenatal alcohol exposure and often manifest differently across the lifespan. Professionals from multiple disciplines (medicine, psychology, speech-language pathology, occupational therapy, etc.) are needed to accurately assess and interpret the broad array of outcomes that define the diagnoses. The pattern and severity of outcome is dependent in part on the timing, frequency, and quantity of alcohol exposure (which is rarely known with any level of accuracy) and the fetus' genetic vulnerability to prenatal alcohol exposure (Astley et al., 2019a). The pattern and severity of outcome is also dependent on the other prenatal and postnatal risk factors that are prevalent among individuals with prenatal alcohol exposure (Astley, 2020; Astley et al., 2020).

In the absence of accurate, precise, and unbiased methods for measuring and recording the severity of exposures and outcomes in individual patients, diagnoses have varied widely from clinic to clinic

(Aase, 1994; Astley & Clarren 2000; Chavez et al., 1988; Stratton et al., 1996). From a clinical perspective, diagnostic misclassification leads to inappropriate patient care, increased risk for secondary disabilities (Streissguth & Kanton, 1997) and missed opportunities for primary prevention. From a public health perspective, diagnostic misclassification leads to inaccurate estimates of incidence and prevalence (Stratton et al., 1996). Inaccurate estimates thwart efforts to allocate sufficient social, educational, and health care services to this high-risk population, and preclude accurate assessment of primary prevention intervention efforts. From a clinical research perspective, diagnostic misclassification reduces the power to identify clinically meaningful contrasts between FAS and control groups (Astley & Clarren, 2001). Non-standardized diagnostic methods prevent valid comparisons between studies.

The 4-Digit Diagnostic Code was first released in 1997 (Astley & Clarren, 1997) to address the following limitations in the conventional gestalt approach to diagnosing individuals with prenatal alcohol exposure.

1. *There have been no standardized operational definitions for FAS or for any of the other diagnoses that fall under the umbrella of FASD. Rather, there have been diagnostic guidelines that physicians have been encouraged to follow, but the guidelines have not been sufficiently specific to assure diagnostic accuracy or precision.*

   For example, according to the diagnostic guidelines published by Sokol and Clarren (1989), which were a minor modification of the 1980 definition of FAS by the Fetal Alcohol Study Group of the Research Society for Alcoholism (Rosett, 1980), which, in turn, were derived from the work of Clarren and Smith (1978): "The diagnosis of FAS can only be made when the patient has signs of abnormality in each of the three categories: 1) Prenatal and/or postnatal growth retardation [weight and/or length below the 10th percentile when corrected for gestational age], 2) central nervous system involvement (including neurological abnormality, developmental delay, behavioral dysfunction or deficit, intellectual impairment, and/or structural abnormalities, such as microcephaly [head circumference below the 3rd percentile or brain malformations found on imaging studies or autopsy] and 3) a characteristic face, currently qualitatively described as including short palpebral fissures, an elongated midface, a long and flattened philtrum, thin upper lip, and flattened maxilla."

   The 1996 guidelines for the diagnosis of FAS proposed by the Institute of Medicine (Stratton et al., 1996) took a similar approach. The diagnosis of FAS can be made when the patient presents with: "1) Evidence of growth retardation, as in at least one of the following: a) low birth weight for gestational age; b) decelerating weight over time not due to nutrition; or c) disproportional low weight to height; 2) Evidence of a characteristic pattern of facial anomalies that includes features such as short palpebral fissures and abnormalities in the premaxillary zone (e.g., flat upper lip, flattened philtrum, and flat midface); and 3) Evidence of brain neurodevelopmental abnormalities, as in at least one of the following: a) decreased cranial size at birth; b) structural brain abnormalities (e.g., microcephaly, partial or complete agenesis of the corpus callosum, cerebellar hypoplasia);c) neurological hard or soft signs (as age appropriate), such as impaired fine motor skills, neurosensory hearing loss, poor tandem gait, poor eye-hand coordination."

   Although these descriptions do provide guidance, they are not sufficiently specific to assure diagnostic accuracy and precision. They reflect a more "gestalt" approach to diagnosis. The guidelines for brain abnormalities do not address how many areas of deficit must be present, how

severe the deficits must be, or what level of documentation must exist to substantiate the presence of the deficit. The guidelines for the facial phenotype are equally nonspecific. How many facial features must be present, how severe must the features be, and what scale of measurement should be used to judge the severity? One need only read the clinical literature or review medical records, birth certificates, birth defect registries or ICD-9 codes to see how variably these criteria are interpreted, applied and reported (CDC, 1995, 1995a; Cordero et al., 1994; Ernhart et al., 1995; Stratton et al., 1996).

2. *There has been a lack of objective, quantitative scales to measure and report the magnitude of expression of key diagnostic features.*

   For example, although a thin upper lip and smooth philtrum are key diagnostic features (Astley & Clarren, 1996; Clarren & Smith, 1978; Jones & Smith, 1973; Smith, 1979; Stratton et al., 1996), prior to 1997, quantitative measurement scales were never used to measure thinness or smoothness, and guidelines had never been established for how thin or smooth the features must be. Objective quantitative scales not only improve accuracy and precision, but also establish a common numeric language for communicating outcomes in medical records and in the medical literature.

3. *The term fetal alcohol effects (FAE) was broadly used and poorly defined.*

   The term 'suspected fetal alcohol effects' was first introduced into the medical literature in 1978 and was defined as 'less complete partial expressions' of FAS in individuals with prenatal alcohol exposure (Clarren & Smith, 1978). Based on this definition, an individual whose mother drank a few glasses of wine intermittently throughout pregnancy and presented with attention deficit hyperactivity disorder would meet the criteria for FAE. So would an individual whose mother drank a fifth of vodka daily throughout pregnancy and presented with microcephaly, severe intellectual disability, growth deficiency and no facial anomalies. The broad use of this term and the reluctance to abandon it points to the clear need to develop diagnostic terms for individuals with prenatal alcohol exposure who present with physical anomalies and/or cognitive/behavioral disabilities, but do not meet the criteria for FAS. New diagnostic terms that more finely differentiate the variable exposures and outcomes of individual patients, without implying alcohol as the sole causal agent, were needed.

4. *Clinical terms like FAE* (Aase et al., 1995), *alcohol-related birth defects (ARBD) (Stratton et al., 1996,) alcohol-related neurodevelopmental disorder (ARND) (Stratton et al., 1996, Hoyme et al.,2016) and FASD without the Face (Cook et al., 2015) imply a causal link between alcohol exposure and outcome in an individual that, to date, cannot be medically confirmed. As far back as 1995, leading dysmorphologists in the field of FAS diagnosis formally requested that the term FAE no longer be used for this reason (Aase et al., 1995; Sokol & Clarren, 1989).*

   With the exception of the Rank 4 full facial phenotype of FAS, no other physical anomalies or cognitive/behavioral disabilities observed in an individual with prenatal alcohol exposure are necessarily specific to (caused only by) their prenatal alcohol exposure (Stratton et al., 1996). Features such as microcephaly, neurological abnormalities, attention deficit, intellectual disability, and growth deficiency frequently occur in individuals with prenatal alcohol exposure, and frequently occur in individuals with no prenatal alcohol exposure. The diagnostic terms

ARBD, ARND (Hoyme et al., 2016) and FASD without Sentinel Facial Features (Cook et al., 2015) introduce the same limitation as does FAE, namely, implying alcohol exposure caused the birth defect or neurodevelopmental disorder in an individual patient. The 4-Digit Code avoids this problem by using a nomenclature that reports the patient was *exposed* to prenatal alcohol rather than reporting the patient's outcomes are *alcohol effects* or *alcohol-related outcomes*. The 4-Digit Code also requires that all other adverse prenatal and postnatal risks be documented and ranked for they too serve as important risk factors that must be taken into consideration when deriving a diagnosis and intervention plan.

5. *Too often diagnoses depicting FASD are reported in the medical records and medical literature with no documentation of the method used to derive the diagnosis and little or no documentation of the data used to support the diagnosis.*

   Failure to report this information can limit the patient's ability to qualify for and receive appropriate intervention services from subsequent health care, social service, and educational providers. For example, simply reporting that an individual has FAS does little to convey the individual's strengths and disabilities. Some individuals with FAS have low IQs, some have normal IQs, some have attention deficits, some do not, some have challenges with memory, while others have language deficits. From a public health perspective, failure to report these data also prevents surveillance efforts from accurately tracking the prevalence of FASD diagnoses in the population. Suportine data are needed to validate the diagnoses. Accurate surveillance is vital for setting public health policy and assessing the effectiveness of primary prevention efforts. The 4-Digit Code requires data be collected not just to corroborate the diagnosis, but to derive the diagnosis. The 4-Digit Code provides a comprehensive FASD Diagnostic Form for recording all supportive data and provides a numeric classification scheme that is readily incorporated into clinical, research, and surveillance databases.

C. Meeting the Diagnostic Challenge

Each of the above limitations has been largely overcome with the development of the "*4-Digit Diagnostic Code*". The four digits reflect the magnitude of expression of four key diagnostic features of FASD in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) brain abnormalities, and (4) prenatal alcohol exposure. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic" presence of the FAS feature. Thus, the 4-Digit Code 4444 reflects the most severe expression of FAS (significant growth deficiency, all three FAS facial features, structural/neurological evidence of brain damage, and confirmed prenatal exposure to alcohol). At the opposite end of the scale is the 4-Digit Code 1111 reflecting normal growth, none of the three FAS facial features, no evidence of brain abnormalities, and confirmed absence of prenatal alcohol exposure. Every combination of 4-Digit Code has been observed among individuals with prenatal alcohol exposure evaluated in the WA State FAS Diagnostic & Prevention Network.

This diagnostic method was developed through the combined expertise of the University of Washington FAS Diagnostic and Prevention Network (FASDPN) interdisciplinary clinical teams (Clarren & Astley, 1997; Clarren et al., 2000) and the comprehensive records of over 3,000 patients (newborn to adult) with prenatal alcohol exposure diagnosed over 30 years at the FASDPN clinics.

D. Benefits of the 4-Digit Diagnostic Code

The 4-Digit Diagnostic Code:

1. Greatly increases diagnostic precision and accuracy through use of objective, quantitative measurement scales, image analysis software, and specific case definitions.

2. Diagnoses the full spectrum of outcomes (FASD) observed in individuals across all ages and all levels of prenatal alcohol exposure.

3. Offers an intuitively logical 4-digit numeric approach to reporting outcomes and exposure that clearly and objectively reflect the magnitude of growth deficiency, FAS facial phenotype, brain abnormality and prenatal alcohol exposure.

4. Documents the presence of prenatal alcohol exposure without implying a causal role.

5. Documents all other prenatal and postnatal adverse exposures and events that can also adversely impact outcome.

6. Most importantly, as the clinical and research fields of FASD strives to achieve consensus on diagnostic criteria and nomenclature worldwide, these 4-Digit Codes are expressed in the universal language of numbers and can be grouped and regrouped into any number of diagnostic categories under the umbrella of FASD and assigned any number of diagnostic names that best meet the widely varying medical systems of care worldwide (Appendix 1).

7. Can be taught to a wide array of health care and social service providers, thus greatly expanding the availability of diagnostic services. (Appendix 1)

The 4-Digit Code currently serves as the cornerstone of a fully integrated and highly successful screening, diagnostic, prevention and surveillance program in Washington State (Astley et al., 2002; Astley, 2004a, 2024; Hemingway (Astley) et al., 2024).

While this document might at first appear complex, clinicians that have used it find this diagnostic approach logical and easy to use, facilitating the proper description and classification of patients presenting along the full spectrum of adverse outcomes and prenatal alcohol exposures.

E. Other Syndromes

The methods of diagnosing FAS arise from the larger fields of teratology and dysmorphology (clinical genetics). It is essential to remember that many birth defect syndromes share *isolated* features, but each is differentiated by a unique *constellation* of features. A few examples of conditions that share some, but not all, of the features of FAS include fetal hydantoin syndrome, maternal PKU fetal effects, and fetal valproate syndrome. It is important to note that alcohol is a teratogen that can adversely impact the development of all fetuses, including fetuses with other syndromes. It is not appropriate to rule-out all other syndromes before rendering a diagnosis of FAS/D. And when rendering a diagnosis of FASD, alternate or co-existing syndromic, medical or psychiatric conditions should be considered at all times.

II. FASD Diagnostic Form

The FASD Diagnostic Form guides the interdisciplinary clinical team in the collection, recording, and interpretation of all key information used to derive accurate and precise diagnoses across the full spectrum of outcomes. All forms presented in this Diagnostic Guide are also available free in electronic format on the FASDPN website. Comprehensive assessments lead to accurate diagnoses and informed intervention plans. Although space has been provided to record a full complement of data, we are not implying all these assessments must be conducted to derive a diagnosis. It is the responsibility of the clinical team to select the most appropriate assessment battery for each patient.

The form also serves as a centralized data repository for efficient generation of the final medical report and is designed to facilitate data entry into a database.

Where is the Information for the Diagnostic Form Obtained?

The information recorded in the FASD Diagnostic Form is obtained from four primary sources:

1. The New Patient Information Form, completed by the caregivers prior to the diagnostic evaluation (Appendix 2), serves as a clinical intake form.

2. Medical/psychological/educational assessments conducted prior to the diagnostic evaluation.

3. Assessments administered by the clinical team at the time of the diagnostic evaluation.

4. The caregiver/patient interview conducted at the time of the diagnostic evaluation

When is the Form Completed and by Who?

Diagnosis of fetal alcohol spectrum disorders by an interdisciplinary team of professionals (medical doctor, psychologist, speech-language pathologist, occupation therapist) will result in the most accurate assessment and interpretation of the broad array of outcomes (growth deficiency, facial anomalies, and structural/neurological/functional brain abnormalities) that define the diagnoses. The FASD Diagnostic Form is completed by the clinical team before and during the patient's clinic visit. Typically, the physician completes the sections pertaining to growth, structural and neurological measures of the brain, facial features and other physical findings. The occupational therapist, psychologist, speech language pathologist, complete the sections pertaining to psychometric measures of brain function. All team members participate in the derivation of the 4-Digit Code and intervention plan.

FASD 4-Digit Code Diagnostic Short Form

A 1-page FASD 4-Digit Code Short Form is available free in electronic format for clinics that choose to record only the data needed to support the patient's 4-Digit Code.

MATERNAL ALCOHOL USE

Alcohol Consumption of the Birth Mother

Before Pregnancy	**average number of drinks** per drinking occasion:					
	maximum number of drinks per occasion:					
	average number of **drinking days per week**:					
	Type(s) of alcohol	wine	beer	liquor	unknown	Other (specify)

During Pregnancy	**average number of drinks** per drinking occasion:					
	maximum number of drinks per occasion:					
	average number of **drinking days per week**:					
	Type(s) of alcohol	wine	beer	liquor	unknown	Other (specify)

Trimester(s) in which alcohol was consumed	1st	2nd	3rd	unknown	none
Was the birth mother ever reported to have a **problem** with alcohol?	yes	suspected	no	unknown	
Was the birth mother ever **diagnosed** with alcoholism?	yes	suspected	no	unknown	
Did the birth mother ever **receive treatment** for alcohol addiction?	yes	suspected	no	unknown	
Was alcohol use during this pregnancy **positively confirmed** through verbal or written documentation?	yes	no			
If yes, **source** of verbal or written confirmation:					
Reported use of alcohol during this pregnancy is:	Reliable	Somewhat reliable		Unk. reliability	
Was the Rank 4 FAS facial phenotype used as a proxy measure of prenatal alcohol exposure?	yes	no			
Other information about alcohol use **during this pregnancy**					

4-DIGIT RANK for Alcohol Exposure

4-Digit Diagnostic Rank	Prenatal Alcohol Exposure Category	Description
4	High Risk	● Alcohol use during pregnancy is CONFIRMED. *and* ● Reported exposure pattern is consistent with the medical literature placing the fetus at "high risk" (generally high peak blood alcohol concentrations delivered at least weekly in early pregnancy, reports of intoxication, binge-drinking).
3	Some Risk	● Alcohol use during pregnancy is CONFIRMED. *and* ● Level of alcohol use is reported to be less than in Rank (4) or the level is unknown.
2	Unknown Risk	● Alcohol use during pregnancy is UNKNOWN (cannot be confirmed or ruled-out).
1	No Risk	● Alcohol use during pregnancy is CONFIRMED to be completely ABSENT from conception to birth.

Circle the 4-Digit Diagnostic Rank in the table above that best reflects the patient's Prenatal Alcohol Exposure

OTHER PRENATAL AND POSTNATAL RISK FACTORS

PRENATAL RISKS:

No known risk	Unknown risk	Some risk	High risk
1	2	3	4

See the "Diagnostic Guide for FASD" for instructions on deriving the rank for Other Prenatal Risks.

Prenatal:

1. Parity ____, Gravity ____ of this birth. Birth order if child is the result of a multiple birth pregnancy: _____ of _____
2. Prenatal care: ____ Yes, (If yes, when did it start?_____), ___ No, ___ Unknown
3. Complications (specify) _____

Genetics

1. Biological parents learning difficulties

   Mother ___ Yes ____ Suspected __ No __ Unknown. **Father** ___ Yes ____ Suspected ____ No ____ Unknown
2. Other conditions of heritability (ADHD, mental health, syndromes, etc.) that may be relevant to this case. *(specify)*

   _____

Prenatal Exposure to Other Substances (e.g., medications, tobacco, illicit drugs, other teratogens, etc.)

POSTNATAL RISKS:

No known risk	Unknown risk	Some risk	High risk
1	2	3	4

See the "Diagnostic Guide for FASD" for instructions on deriving the rank for Postnatal Risks.

Perinatal Difficulties (prematurity, extended stay in birth hospital, etc.): _____

_____

Medical Conditions: _____

_____

Postnatal Adversity (ACES, TESI, etc):

1. Number of out-of-home placements _____ Age at first out-of-home placement _____ Age at last placement _____
2. Please report the age range for all adversities experienced by the patient. If age is unknown, enter Yes, No Suspected or Unknown in each box.

Adversity	age range	Adversity	age range	Adversity	age range
sexual abuse		orphanage/group care		serious medical issue	
physical abuse		abandonment		substance abuse (patient)	
emotional abuse		homelessness		patient incarceration	
domestic violence		poverty		patient suicide attempt	
physical neglect		food insecurity		natural disaster	
emotional neglect		bullying		war, terrorism	
medical neglect		school violence		List others below	
family death		community violence			
family incarceration		discrimination			
parent separated/divorced		serious accident			
family mental health		home fire			
parent substance abuse		animal attack

III. Instructions for Deriving the 4-Digit Code

A. The 4-Digit Diagnostic Code

What are the 4 Digits?

The four digits reflect the magnitude of expression of the four key diagnostic features of FASD in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) brain abnormalities, and (4) prenatal alcohol exposure. Individuals with prenatal alcohol exposure often present with a myriad of other prenatal and postnatal risks that could also adversely impact growth and development. These too are documented. The 4-Digit Diagnostic Code is generated at the completion of the diagnostic evaluation using information recorded on the FASD Diagnostic Form. The code is derived following the directions in Section III. B.

FASD 4-Digit Code

Rank	**3** Growth	**4** Face	**3** Brain	**4** Prenatal Alcohol	3 Other Prenatal Risks	3 Other Postnatal Risks
4	severe	all 3 features	abnormal structure/neurology	high	high	high
3	moderate	2.5 features	severe dysfunction	some	some	some
2	mild	1-2 features	moderate dysfunction	unknown	unknown	unknown
1	normal	no features	normal function	none	none	none

FASD Umbrella

3 Diagnoses under the FASD Umbrella		Growth	FAS Face	Brain		Alcohol
1. FAS	Fetal Alcohol Syndrome	growth	face	severe		exposed
2. SE/AE	Static Encephalopathy / Alc-Exposed			severe		exposed
3. ND/AE	Neurodevelopmental Disorder / Alc-Exposed				moderate	exposed

Example above: If an individual presented with moderate growth deficiency, all 3 FAS facial features, severe brain dysfunction and high prenatal alcohol exposure, they would receive a 4-Digit Code 3434. Code 3434 is one of 40 codes that meet criteria for FAS (see Section V). FAS is one of three diagnoses under the umbrella of FASD. Other prenatal and postnatal risks are also ranked.

How are the 4 Digits Ranked?

The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong "classic" presence of the

FASD feature. The other prenatal and postnatal risks are also ranked on 4-point Likert scales. Specific criteria for each Rank are presented in Section III.B.

How Many 4-Digit Codes and Clinical Diagnostic Categories are There?

There are 256 possible 4-Digit Diagnostic Codes ranging from 1111 to 4444. The 256 codes and their corresponding clinical names are listed in numerical order in Section VI. Each 4-Digit Diagnostic Code falls into one of 19 unique Clinical Diagnostic Categories (labeled A through S) (see Sections IV and V). Only 108 of the 256 codes fall broadly under the umbrella of FASD in accordance with the FASD 4-Digit Code. These 108 codes are collapsed into 6 FASD diagnostic categories as portrayed in red font in Sections IV and V. These 6 FASD diagnostic categories are further collapsed into three clinically meaningful diagnostic categories under the umbrella of FASD: FAS, Static Encephalopathy/Alcohol-Exposed, and Neurodevelopmental Disorder/Alcohol-Exposed.

How Many of the Diagnostic Categories Fall Under the Umbrella of FASD?

Only 6 of the 19 diagnostic categories (A-E and J) fall broadly under the umbrella of FASD. These are highlighted in red font in Sections IV, V and VI). For example, 25% of the 4-Digit Codes end in 1 (Alcohol Rank 1, confirmed absence of prenatal alcohol exposure). An individual with confirmed absence of prenatal alcohol exposure cannot have FASD. Why keep 4-Digit Codes ending in 1 in this Diagnostic Guide? Codes ending in 1 help portray that the growth deficiency and brain abnormalities observed among individuals with prenatal alcohol exposure are also observed in individuals with confirmed absence of prenatal alcohol exposure. Presenting all combinations of 4-Digit Codes in this FASD diagnostic system also presents a valuable numeric method for classifying control or comparison groups in research studies designed to compare individuals with FASD to individuals with confirmed absence of prenatal alcohol exposure with and without adverse outcomes.

How are the Names of the Clinical Diagnostic Categories Constructed?

The following terms are used in varying combinations to name the 19 Diagnostic Categories. They include:

- **Sentinel Physical findings:**
  The term "S*entinel Physical Findings*" is used in this diagnostic system when the patient presents with growth deficiency at the Rank 3 or 4 level and/or presents with the FAS facial phenotype at the Rank 3 or 4 level. The term *"sentinel"* refers to the physical findings that are diagnostic indicators of FASD. These include a unique cluster of minor facial anomalies (short palpebral fissures, thin upper lip, and a smooth philtrum) and growth deficiency. Other physical findings (major or minor anomalies) may be detected instead of or in addition to these sentinel findings that may suggest alternate or additional conditions. There are places on the Diagnostic Form to record and interpret other physical findings.

- **Neurodevelopmental Disorder:**
  The term *"Neurodevelopmental Disorder"* is used to label the Diagnostic Category when the patient presents with functional impairments (cognitive, motor, language, etc) at the Brain Rank 2 level and no evidence of structural, neurological or functional abnormalities at the Brain Rank 3 or Rank 4 levels.

- **Static Encephalopathy:**
  The term *"encephalopathy"* refers to "any significant abnormal condition of the structure or function of brain tissues" (Anderson, 2002). The term *"static"* means that the abnormality in the brain is unchanging; neither progressing nor regressing. The term *"Static Encephalopathy"* is used in this diagnostic system when the patient presents with significant structural, neurological, and/or functional abnormalities that strongly support the presence of underlying brain damage at the Rank 3 and/or Rank 4 levels. The term does not define or suggest any specific pattern of structural, neurological, or functional abnormality.

Fetal Alcohol Syndrome

The term FAS is used to refer to patients who present with one of 40 4-Digit Diagnostic Code combinations reflecting growth deficiency; the FAS facial phenotype; significant structural, neurological, and/or functional brain abnormalities; and prenatal alcohol exposure confirmed by verbal or written record or the presence of the Rank 4 FAS facial phenotype (Astley & Clarren, 2001; (Astley) Hemingway, 2020). These 40 Codes are presented in Section V.

- **Alcohol (Exposed, Not Exposed, Exposure Unknown):**
  The last digit of the 4-Digit Code reflects prenatal alcohol exposure as determined through written or verbal documentation. The terms (Exposed) and (Not Exposed) are used when written or verbal documentation exists that confirms the presence or absence of exposure. If the presence or absence of exposure cannot be confirmed through written or verbal documentation, the term (Exposure Unknown) is applied. If exposure is ranked unknown, the Rank 4 FAS facial phenotype can serve as a proxy for confirmation of prenatal alcohol exposure. Alcohol exposure is reported independently of outcome(s) and does not imply that a causal association exists between the exposure and the outcome(s).

The names assigned to the 19 Diagnostic Categories (A-S) are listed in Sections IV and V. These names are constructed from the terms above and reflect the patient's clinical outcome and prenatal alcohol exposure. Five of the Diagnostic Categories A-E fall broadly under the umbrella of FASD as do 4 additional 4-Digit Codes in Category J that present with the Rank 4 FAS facial phenotype. Diagnostic Categories F and G reflect patients with confirmed prenatal alcohol exposure, who only present with growth and/or facial anomalies or no adverse outcomes whatsoever (normal growth, facial and brain outcomes). The 4-Digit Code does not consider these two diagnostic outcomes to be under the umbrella of FASD. The remaining 12 categories (H through S) reflect patients with unknown prenatal alcohol exposure or confirmed absence of prenatal alcohol exposure. These 12 categories present with the full spectrum of physical and functional abnormalities from normal to severe, but with a confirmed absence of prenatal alcohol exposure or the Rank 4 FAS facial phenotype do not fall under the umbrella of FASD.

Ultimately, establishing terms that are both clinically accurate, broadly applicable, and facilitate access to services remains a challenge. One of the greatest strengths of the 4-Digit Code is the assignment of a numeric 4-Digit Code to each patient that clearly captures the full spectrum of outcomes and exposure in the universal language of numbers. The 4-Digit Codes are independent of any proposed system for how to cluster them into diagnostic categories and what names to apply to each category.

How are the Names of the Clinical Diagnostic Categories Constructed?

- **Growth** deficiency and facial features are physical features. When either feature receives a Rank 3 or 4, *Sentinel physical finding(s)* is placed at the beginning of the name.
- When brain receives a Rank 3 or 4, the term *Static Encephalopathy* is included in the name. When **brain** receives only a Rank 2, the term *Neurodevelopmental Disorder* is included in the name.
- When **alcohol** exposure receives a Rank 3 or 4, *alcohol exposed* is placed at the end of the name. When alcohol exposure receives a Rank 2, *alcohol exposure unknown* is placed at the end of the name. When alcohol exposure receives a Rank 1, no *alcohol exposure* is placed at the end of the name.
- When the criteria for FAS are met, the term FAS is used in place of the more generic terms. For example, the term *FAS* would be used for the 4-Digit Code 3443 rather than *Sentinel physical finding(s) / static encephalopathy / alcohol exposed.*

FASD 4-Digit Code

	3	2	4 (2)	3		
Rank 4	severe	all 3 features	abnormal structure/neurology	high	high	high
3	moderate	2.5 features	severe dysfunction	some	some	some
2	mild	1-2 features	moderate dysfunction	unknown	unknown	unknown
1	normal	no features	normal function	none	none	none
	Growth	**Face**	**Brain**	**Prenatal Alcohol**	**Other Prenatal Risks**	**Other Postnatal Risks**

KEY

Growth and/or Face	Brain	Alcohol
Sentinel physical finding(s)	Static encephalopathy	Alcohol exposed
	Neurodevelopmental disorder	Alcohol exposure unknown

In the example above, the 4-Digit Code 3243 would receive the clinical name ***Sentinel physical findings / static encephalopathy / alcohol exposed*.** Note brain received both Rank 4 (for microcephaly) and Rank 2 (for moderate dysfunction). The higher brain Rank is used to derive the 4-Digit Code (3243). If brain receives a Rank 4, it is advised that both brain codes be reported as follows 324(2)3 conveying both the structural and functional status of the patient's brain. In another example, a code of 1222 would receive the clinical name *Neurodevelopmental disorder / alcohol exposure unknown*.

How to Explain the Diagnosis to the Patient

Generic summaries of each of the 19 Clinical Diagnostic Categories are presented in Section VII. These summaries can be used as the first page of the patient's final Medical Summary Note. Subsequent pages in the Medical Summary should document the findings and recommendations specific to the patient. We recommend the growth, face, brain, and exposure data, used to generate the 4-Digit Code, be reported in the Medical Summary to provide essential information for subsequent medical professionals and facilitate records-based public health surveillance efforts.

When sharing the diagnosis with caregivers, we have found that the following graphic provides a simple, clear way to present the results. Families receive a copy of this graphic at the end of the diagnostic appointment along with a comprehensive medical summary (see Section VII). We introduce FASD and the 4-Digit Code to the families as follows:

FASD is characterized by growth deficiency, minor facial anomalies, brain structural and/or functional impairment and prenatal alcohol exposure.

Each component is ranked on a 4-point scale. The higher the rank, the more severe the outcome or exposure.

Together, these ranks produce 4-Digit Codes that range from 1111 to 4444. A code of 1111 reflects an individual with normal growth, none of the FAS facial features, normal brain function and confirmed absence of prenatal alcohol exposure. A code of 4444 reflects an individual with the most severe presentation of FAS (severe growth deficiency, all 3 facial features of FAS, structural and/or neurological brain abnormalities and a confirmed high prenatal alcohol exposure

The 4-Digit Codes are grouped into three clinical diagnoses under the umbrella of FASD that reflect the full spectrum of FASD from moderate to severe. In the example presented, the 4-Digit Code 3434 is one of 40 codes that meet criteria for FAS.

As another example, Code 1134 reflects a person with normal growth, none of the 3 facial features of FAS, severe brain dysfunction and a high prenatal alcohol exposure. The Code 1134 meets criteria for SE/AE.

Other prenatal and postnatal risks may also be present and impact growth and development. These are also ranked on 4-point scales.

FASD 4-Digit Code

	3	**4**	**3**	**4**	3	3
Rank 4	severe	all 3 features	abnormal structure/neurology	high	high	high
3	moderate	2.5 features	severe dysfunction	some	some	some
2	mild	1-2 features	moderate dysfunction	unknown	unknown	unknown
1	normal	no features	normal function	none	none	none
	Growth	**Face**	**Brain**	**Prenatal Alcohol**	**Other Prenatal Risks**	**Other Postnatal Risks**

FASD Umbrella

3 Diagnoses under the FASD Umbrella		Growth	FAS Face	Brain	Alcohol
1. FAS	Fetal Alcohol Syndrome	growth	face	severe	exposed
2. SE/AE	Static Encephalopathy / Alc-Exposed			severe	exposed
3. ND/AE	Neurodevelopmental Disorder / Alc-Exposed			moderate	exposed

III. Instructions for Deriving the 4-Digit Code

B.1. Ranking Growth

What Type of Growth Deficiency Are We Looking For?

Growth deficiency plays an essential role in the diagnosis of FASD (Astley et al., 2016). Growth deficiency among individuals with prenatal alcohol exposure is highly correlated with and predictive of brain dysfunction. Growth deficiency can serve as a valuable marker for identifying infants with prenatal alcohol exposure at high risk for brain dysfunction that will typically not manifest until later in childhood.

We are looking for growth deficiency characteristic of a teratogenic insult, not characteristic of postnatal environmental factors such as nutritional deprivation or chronic or acute illness. We want to answer the question *'What is the patient's growth potential after controlling for parental height and postnatal environmental influences?'* Growth deficiency of teratogenic origin is likely to present as a relatively consistent impairment over a period of time (i.e., the patient's growth follows the normal curve, but is below genetic expectation for family background). In contrast, growth deficiency due to postnatal environmental influences (e.g., illness, nutritional deprivation, etc.) is likely to present as periodic fluctuations in the curve.

The method described below allows one to rank a patient's overall growth pattern on a single 4-point Likert scale with 1 equal to 'normal' and 4 equal to "significantly deficient". Not all patients will have complete growth curves available, therefore, a guide is provided below for prioritizing the ranking of the patient's growth over a lifetime.

How to Measure and Rank Growth: The 1st Digit of the 4-Digit Diagnostic Code

A. The height percentile should be adjusted for age and sex. Because there is a significant genetic component in attained stature, adjustment for mid-parent stature is also recommended when both parents' heights are known. Himes et. al., (1985) provide charts for mid-parent adjustment of recumbent length (birth to 3 years) and stature (3 to 18 years) of US children relative to National Center for Health Statistics growth charts.

B. The weight percentile should be adjusted for age and sex. Weight is not adjusted for height.

   Clinicians are encouraged to use the most current electronic growth charts that best match the age, sex, race/ethnicity and country of origin of each patient.

C. For ranking purposes, the growth record is separated into two parts:
   1. Prenatal growth (birth measures)
   2. Postnatal growth (all measures collected after birth)

   Select the part of the growth record with the greatest deficiency in the height percentile.

   If the prenatal height percentile is lower than all postnatal height percentiles, proceed to section D for instructions on how to rank prenatal growth.

If any of the postnatal height percentiles are lower than the prenatal height percentile, select the point or consecutive points in the growth record that reflect the lowest height percentiles that cannot be attributed to postnatal environmental influences such as nutritional deprivation or chronic illness. If the height deficiency is reflected in a series of points in the growth record, as opposed to a single point, rank the level of deficiency based on the percentile range where the majority of the points fall. Proceed to section D for instructions.

D. Rank the level of deficiency of the height and weight percentiles, for the part of the growth record with greatest deficiency in the height percentile by circling A, B, or C in the ABC-Score table at the bottom of page 1 of the FASD Diagnostic Form. Tables 1 and 2 below are also printed on the electronic images of the Lip-Philtrum Guides. This ABC-Score table is duplicated below as Table 1. The height and weight percentiles selected for ranking should be matched sets. For example, if the height at 10 years of age is selected for ranking, the corresponding weight percentile at 10 years of age should also be selected for ranking. One does not rank the height at one age and the weight at another age to generate an ABC-Score.

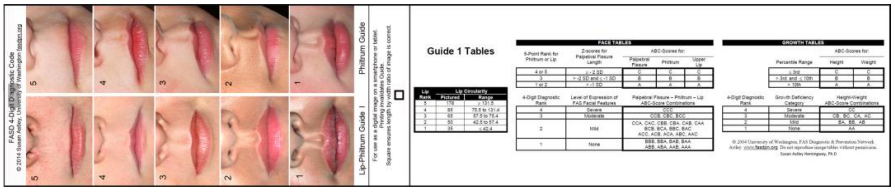

Table 1: Deriving the ABC-Score for Growth

	Circle the ABC-Scores for:	
Percentile Range	Height	Weight
≤ 3rd	C	C
>3rd and ≤ 10th	B	B
>10th	A	A

E. Next, refer to Table 2 to determine the *4-Digit Diagnostic Rank* of the Height-Weight ABC-Score recorded in Table 1. Transfer the resulting 4-Digit Diagnostic Rank for growth to the 4-Digit Diagnostic Code Grid at the top of page 1 of the FASD Diagnostic Form (Section II).

Table 2: Converting the Growth ABC-Score to a 4-Digit Diagnostic Rank for Growth

4-Digit Diagnostic Rank	Growth Deficiency Category	Height-Weight ABC-Score Combinations
4	Severe	CC
3	Moderate	CB, BC, CA, AC
2	Mild	BA, BB, AB
1	None	AA

Normal Growth Charts

Height, Weight, OFC:
Clinicians are encouraged to use the most current electronic charts for height, weight and head circumference that best match the age, sex, race/ethnicity, and country of origin of each patient. In our Seattle WA FASDPN clinic, we currently use the CDC, WHO and Rollins et al (2010) growth charts for OFC,, weight and height and adjust for mid-parental height (Himes et al., 1985) when both parents' heights are available.

Facial Measures:
We recommend using the free FAS Facial Photographic Analysis Software (Astley, 2016) distributed by the FASDPN to obtain the most accurate measures of the facial features (Astley, 2015). The Facial Software incorporates an adjustment factor that is confirmed to accurately measure a palpebral fissure length from a 2-dimensional digital photo within 0.2 mm of the gold standard of measure (a sliding digital caliper). We do not recommend using a handheld ruler to measure PFLs. Numerous studies have confirmed the inaccuracy of the ruler method (Astley, 2015). The FASDPN currently uses the Iosub African American PFL charts (Iosub et al., 85) for individuals that are full or half African American and the Stromland Scandinavian PFL charts for all other races (Stromland et al., 1999). These charts come with our FAS Facial software and are available in our free excel PFL Z-score calculator. The Hall Caucasian PFL charts (1989) are no longer in use (Clarren et al., 2010).

Example for Scoring Growth Deficiency

Patient's Growth Record:

	Age (years)	Height Percentile	Weight Percentile
birth	0.0	8 %	1 %
	1.5	14 %	16 %
	5.0	12 %	15 %
	7.0	12 %	15 %
	15.5	15 %	15 %

Assume in this case the clinical records rule-out any adverse environmental influence on the postnatal measures and mid-parental height is unknown.

Ranking:

- Priority would be placed on ranking the birth length and weight because the birth length percentile is lower than all postnatal height percentiles recorded.
- Birth length (8 %) would receive an **ABC-Score = B** (> 3rd and ≤ 10th percentile) (Table 1).
- Birth weight (1 %) would receive an **ABC-Score = C** (≤ 3rd percentile) (Table 1).
- The Height-Weight ABC-Score combination would be **BC** (Table 1).

Table 1: Deriving the ABC Score for Growth

	Circle the ABC-Scores for:	
Percentile Range	Height	Weight
≤ 3rd	C	**C**
>3rd and ≤ 10th	**B**	B
>10th	A	A

- The Height-Weight ABC-Score of **BC** reflects **Moderate** growth deficiency (Table 2)
- **Moderate** growth deficiency would receive a **Rank 3** in the 4-Digit Diagnostic Code (Table 2).

Table 2: Converting the Growth ABC-Score to a 4-Digit Diagnostic Rank for Growth

4-Digit Diagnostic Rank	Growth Deficiency Category	Height-Weight ABC-Score Combinations
4	Severe	CC
3	**Moderate**	CB, **BC**, CA, AC
2	Mild	BA, BB, AB
1	None	AA

- **Rank 3** would be transferred to the 4-Digit Diagnostic Code Grid on page 1 of the FASD Diagnostic Form (as duplicated below).

Result:

FASD 4-Digit Code

Rank	**3** Growth	Face	Brain	Prenatal Alcohol	Other Prenatal Risks	Other Postnatal Risks
4	severe	all 3 features	abnormal structure/neurology	high	high	high
3	moderate	2.5 features	severe dysfunction	some	some	some
2	mild	1-2 features	moderate dysfunction	unknown	unknown	unknown
1	normal	no features	normal function	none	none	none

III. Instructions for Deriving the 4-Digit Code

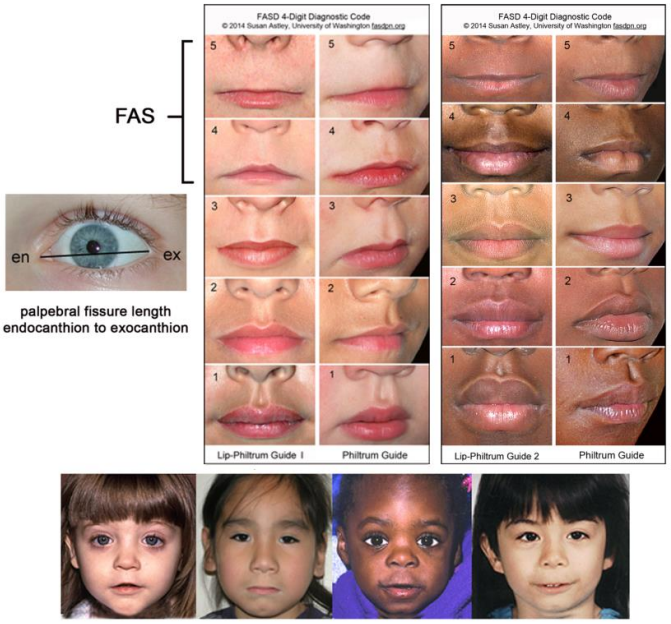
B.2. Ranking the Facial Phenotype

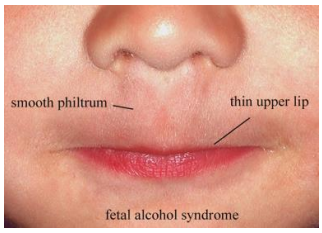
The FAS Facial Phenotype

The face of FAS is defined by the 4-Digit Code as the simultaneous expression of three facial features:

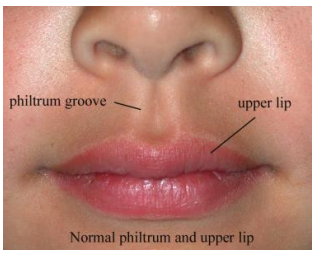
1. Short palpebral fissure lengths (2 or more standard deviations below the mean)
2. Smooth philtrum (Rank 4 or 5 on the University of Washington Lip-Philtrum Guides).
3. Thin upper lip (Rank 4 or 5 on the University of Washington Lip-Philtrum Guides).

If facial measures are available at different ages, the age when the expression of the FAS facial phenotype is most severe (highest Face Rank) should be used.





Rank 5 lip and philtrum



Rank 1 lip and philtrum

Three facial features of FAS. Examples of the University of Washington 4-Digit Code Rank 4 FAS facial phenotype (small eyes, smooth philtrum, and thin upper lip) across four races: Caucasian, Native American, African American, Asian American. © Susan Hemingway PhD

David Smith, M.D., who coined the term FAS in 1973, identified these features as the *key* diagnostic facial features in 1979 (Smith, 1979). A series of empirical studies conducted over the next 30 years confirmed: 1) The 4-Digit-Code Rank 4 FAS facial phenotype is the only facial phenotype that provides sufficient positive predictive value (PPV) and specificity (100%) to prenatal alcohol exposure (PAE) to allow the facial phenotype to serve as confirmation of alcohol exposure in a diagnostic setting when PAE is unknown. Even minimal relaxation of the phenotype (e.g., Face Rank 3) results in PPV (35%) and specificity (88.7%) values too low to use as confirmation of PAE. (Astley

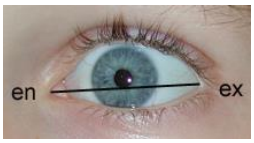
& Clarren, 1996, 2000, 2001; Astley-Hemingway et al., 2020). The clinical validity of these features has been confirmed through population-based screening and surveillance studies (Astley et al., 2002; Astley, 2004a) and empirical studies documenting remarkably strong correlations between these midline facial anomalies and decreased volume of the frontal lobe (Astley et al., 2009). The FAS facial phenotype presents on a clinically meaningful continuum. As the FAS facial phenotype increases in severity of expression from Rank 1 to Rank 4, the prevalence and severity brain damage/dysfunction, growth deficiency and prenatal alcohol exposure increase significantly (Astley et al., 2013).

How to Measure and Rank the Face: The 2nd Digit of the 4-Digit Diagnostic Code

There are two methods for measuring the 3 facial features of FAS: 1) direct measurement and 2) computerized analysis of a 2-dimensional digital facial photograph using the FAS Facial Photographic Analysis Software developed by the University of Washington FASDPN. The latter is confirmed more accurate (Astley & Clarren, 2001; Astley, 2015). A video demonstration of the software is available online. The FAS Facial Photographic Analysis Software 2016 v2.1 is available free from the FASDPN website. Animations demonstrating proper measurement technique are also available.

A. Palpebral Fissure Length (PFL)

Direct Measurement: The PFL is the distance from the endocanthion (en) to the exocanthion (ex). The PFLs can be measured to the nearest mm with a clear plastic, 15-cm ruler, held as close as possible to the eye without touching the eye or eyelashes. The patient is asked to open their eyes fully to allow accurate identification of the endocanthion and exocanthion landmarks (Astley & Clarren, 1996; Farkas, 1994). Numerous published studies have confirmed the inaccuracy of measuring PFLs with a ruler (Astley, 2015). Although sliding digital calipers are the most accurate method of measurement, use of calipers is too dangerous. The FASDPN recommends all facial features, including the PFLs be measured using the free FAS Facial Photographic Analysis Software 2016 v2.1.



Digital Photographic Measurement: Three standardized 2-dimensional digital photos of the face are taken with a ¾ inch machine-cut paper sticker placed between the eyebrows to serve as an internal measure of scale (e.g., a ruler in the photo) (Astley, 2015). Write the size of the sticker on the sticker. The camera is held 4 feet from the face to avoid lens distortion.

Standardized Photo Set

The digital images are analyzed using the FAS Facial Photographic Analysis Software (Astley, 2016). View a video demonstration of the software. The PFL is measured by clicking the mouse curser on the endocanthion and exocanthion landmarks of the right and left eyes. The length of each palpebral fissure and its z-score (number of standard deviations above or below the norm) are computed automatically based on formulas and normal charts embedded in the software. More detailed instructions are provided with the software.

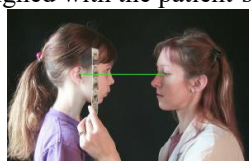
Ranking the PFL*:* The PFL is ranked according to its z-score (or how many standard deviations above or below the mean it is on a normal PFL growth chart) using the Face Tables on the backside of the Lip-Philtrum Guides (Figure 2). If the eyes are substantially different in size, (more than 2

mm different) rank the larger PFL. If the eyes are comparable in size, rank the mean of the right and left PFL. The FASDPN currently uses the Iosub African American PFL charts (Iosub, 1985) for individuals that are full or half African American and the Stromland Scandinavian PFL charts for all other races (Stromland, 1999). These charts come with the FAS Facial software and are available in our free Excel PFL Z-score calculator posted online. The Hall Caucasian PFL charts for birth to 16 years (1989) are no longer used and should not be used (Clarren et al., 2010).

B. Upper Lip Thinness and Philtrum Smoothness

Direct Measurement: Upper lip thinness (the red or vermilion portion of the upper lip) and philtrum smoothness are measured independent of one another using the 5-point pictorial Likert scale presented on the University of Washington Lip-Philtrum Guides (see Figure 2 below). Guide 1 is used for Caucasians and any race or racial mix with lips similar in thickness to Caucasians. Guide 2 is used for African Americans and any race or racial mix with lips similar in thickness to African Americans (e.g., aboriginal Australians). Which Guide was selected should be reported in the medical summary. The physician holds the Lip-Philtrum Guide next to the patient's face and identifies the picture that best matches the patient's upper lip and identifies the picture that best matches the patient's philtrum.

When measuring the upper lip thinness, the physician's eyes need to be aligned with the patient's Frankfort horizontal plane. The Frankfort horizontal plane is defined by a line (green line) that passes through the patient's external auditory canal and the lowest border of the bony orbital rim (orbitale). The physician's eyes (or camera lens) should be directly in line with this plane. If the physician stood above this plane looking down on the patient, the patient's upper lip could appear thinner than it truly is. View this animation demonstrating how to align yourself in the patient's Frankfort horizontal plane.



Lips must be *gently closed with no smile* to accurately measure philtrum smoothness and upper lip thinness (Astley et al., 1999). This is the same child with and without a smile. A smile makes the philtrum appear smoother and the upper lip thinner than they truly are. Note that without a smile, the lip and philtrum would both receive a correct Rank 2 on the Caucasian Lip-Philtrum Guide 1. With a smile, the lip and philtrum would both receive an *incorrect* Rank 5.

Digital Photographic Measurement: Lip thinness is measured from the frontal photograph using the FAS Facial Photographic Analysis Software. The red (e.g. vermilion) portion of the upper lip in the frontal photograph is outlined with the mouse to compute circularity (perimeter^2/area). The thinner the upper lip, the bigger the circularity.

Pictured is an example of the upper lip outlined to compute circularity. The circularity of this lip is 44.2, which is equivalent to Rank 2 on Lip-Philtrum Guide 1. Each Rank on the Lip-Philtrum Guide is defined by a range of circularities (See the Face Tables printed with the Lip-Philtrum Guide 1 in Figure 2 below). The software automatically ranks lip thinness using the circularity measure. The philtrum is measured by selecting the ¾ view picture on the University of Washington Lip-Philtrum Guide that best matches the patient's philtrum. More detailed instructions are provided in the software Instruction Manual.

Figure 2. University of Washington Lip-Philtrum Guides 1 (A) and 2 (B) are used to rank upper lip thinness and philtrum smoothness. The philtrum is the vertical groove between the nose and upper lip. The guides reflect the full range of lip thickness and philtrum depth with Rank 3 representing the population mean. Ranks 4 and 5 reflect the thin lip and smooth philtrum that characterize the FAS facial phenotype. Guide 1 is used for Caucasians and any race or racial mix with lips indigenously similar in thickness to Caucasians. Guide 2 is used for African Americans and any race or racial mix with lips indigenously similar in thickness to African Americans. Free digital images of these Guides and Tables for loading on a cell phone are available from astley@uw.edu. Circularity is perimeter^2/area and is measured using the FAS Facial Photographic Analysis Software (Astley, 2016). © Susan (Astley) Hemingway PhD.

C. Deriving the Facial ABC-Score

Rank the mean palpebral fissure length, philtrum smoothness, and upper lip thinness by circling A, B, or C in each column in the ABC-Score printed on the backside of the Lip-Philtrum Guide (Figure 2). This table is duplicated below as Table 1. The three facial features must be measured at the same age. In other words, one would NOT rank the philtrum at 10 years of age and the PFL and lip at 15 years of age. If facial measures are available at more than one age, rank the age when the expression of the FAS facial phenotype is most severe (has the highest Face Rank).

Table 1: Deriving the ABC-Score for Facial Phenotype

5-Point Likert Rank for Philtrum & Lip	Z-score* for Palpebral Fissure Length	Circle the ABC-Scores for: Palpebral Fissure	Philtrum	Upper Lip
4 or 5	≤ -2 SD	C	C	C
3	>-2 SD and ≤ -1 SD	B	B	B
1 or 2	> -1 SD	A	A	A

* Z-Score = (patient's mean PFL - mean PFL for a normal population) / (standard deviation of the mean PFL for a normal population)

Use the FAS Facial Photographic Analysis Software or the PFL Z-score Calculator to compute the z-score.

The z-score reflects how many standard deviations above or below the mean the patient's PFL is.

D. Deriving the 4-Digit Rank for Face: The 2nd Digit in the 4-Digit Code

Next, refer to Table 2 to determine the *4-Digit Diagnostic Rank* based on the ABC-Score derived from Table 1. Transfer the resulting 4-Digit Diagnostic Rank for face to the 4-Digit Diagnostic Code Grid on page 1 of the FASD Diagnostic Form (Section 11).

Table 2: Converting the Facial ABC-Score to a 4-Digit Diagnostic Rank for Face

4-Digit Diagnostic Rank	Level of Expression of FAS Facial Features	Palpebral Fissure - Philtrum - Lip ABC-Score Combinations
4	Severe	CCC
3	Moderate	CCB, CBC, BCC
2	Mild	CCA, CAC, CBB, CBA, CAB, CAA BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	None	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

Example: Ranking the Facial Phenotype

Patient Facial Measures at 10 Years of Age (male, Caucasian):

- **Mean PFL = 24.5 mm**: Left PFL = 24.6 mm. Right PFL = 24.4 mm.

  Mean PFL Z-score = -2.16 using Stromland's PFL growth charts for Caucasian males (Stromland, 1999).

  - Note: a normal PFL for a 10-year-old male using Stromland's PFL chart =27.43 mm.
  - Use the FAS Facial Photographic Analysis Software or the PFL Z-score Calculator to compute the Z-score.

- Philtrum smoothness received a **Rank 5** on the Caucasian Lip-Philtrum Guide (Figure 2).

- The circularity of the upper lip was 65.5. Thus, upper lip thinness received a **Rank 3** on the Caucasian Lip-Philtrum Guide (Figure 2 above). The circularity range for Rank 3 is 57.5 to 74.9.

Ranking

- The mean PFL z-score of -2.16 receives an **ABC-Score = C** (≤ -2 SD) (Table 3).
- The Rank 5 philtrum receives an **ABC-Score = C** (Table 3).
- The Rank 3 upper lip receives an **ABC-Score = B** (Table 3).
- The ABC-Score combination for Palpebral Fissure - Philtrum - Lip is **CCB** (Table 3).

Table 3: Deriving the ABC-Score for Facial Phenotype

5-Point Likert Rank for Philtrum & Lip	Z-score for Palpebral Fissure Length	Circle the ABC-Scores for: Palpebral Fissure	Philtrum	Upper Lip
4 or 5	≤ -2 SD	**C**	**C**	C
3	>-2 SD and ≤ -1 SD	B	B	**B**
1 or 2	> -1 SD	A	A	A

- The Facial ABC-Score of **CCB** reflects a **Moderate** level of expression of the FAS facial phenotype (Table 4).
- A **Moderate** expression of the FAS facial phenotype would receive a **Rank 3** in the 4-Digit Diagnostic (Table 4).

Table 4: Converting the Facial ABC-Score to a 4-Digit Diagnostic Rank

4-Digit Diagnostic Rank	Level of Expression of FAS Facial Features	Palpebral Fissure - Philtrum - Lip ABC-Score Combinations
4	Severe	CCC
3	**Moderate**	**CCB**, CBC, BCC
2	Mild	CCA, CAC, CBB, CBA, CAB, CAA, BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	None	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

- **Rank 3** would be transferred to the 4-Digit Diagnostic Code Grid on page 1 of the FASD Diagnostic Form (as duplicated below).

Result:

FASD 4-Digit Code

3

Rank	Growth	Face	Brain	Prenatal Alcohol	Other Prenatal Risks	Other Postnatal Risks
4	severe	all 3 features	abnormal structure/neurology	high	high	high
3	moderate	2.5 features	severe dysfunction	some	some	some
2	mild	1-2 features	moderate dysfunction	unknown	unknown	unknown
1	normal	no features	normal function	none	none	none

The FAS Facial Photographic Analysis Software produces a 1-page summary report for entry into the patient's medical record. Below is an example of an individual with none of the FAS facial features.

4-Digit Diagnostic Code for Face: 1: FAS features absent

III. Instructions for Deriving the 4-Digit Code
B.3. Ranking the Brain

Alcohol's Impact on the Developing Brain

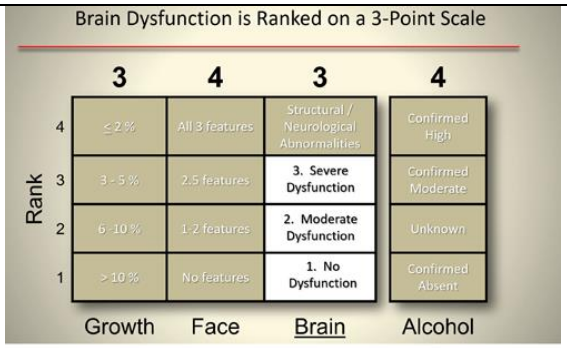
Alcohol is a teratogen that can alter the developing brain in a variety of ways from gross structural anomalies to subtle alterations in neurochemical levels (Stratton et al., 1996; West, 1986). Alterations in brain structure and/or chemistry can lead to altered brain function. Our ability to detect structural, neurological, and functional brain abnormalities is dependent on the sensitivity of today's measurement tools, which will continue to improve over time. Not all structural or neurological abnormalities result in *measurable* dysfunction and not all functional abnormalities are due to underlying brain damage. Some functional abnormalities result from adverse postnatal environmental factors and are transient in nature if the environment is improved.

How to Rank Brain: The 3rd Digit of the 4-Digit Diagnostic Code

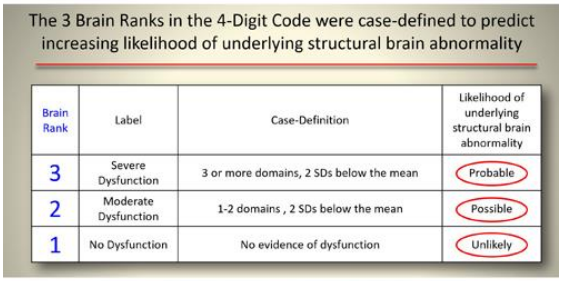
The 4-point Likert Scale for Brain documents: 1) that individuals with prenatal alcohol exposure can present with structural, neurological and/or functional brain abnormalities and 2) that these brain abnormalities occur along a continuum of severity.

An important point to keep in mind is that the Brain scale performs as two scales in one. In its first use, the full scale (from 1 to 4) documents increasing "probability" of underlying brain damage based on structural, neurological, and/or functional evidence. *The higher the Rank from 1 to 4, the stronger the evidence or higher the probability that there is underlying brain damage (Figure 3)* (Astley, 2013, Astley et al., 2009). In its second use, the scale (from 1 to 3) also documents increasing severity of brain dysfunction. *The higher the Rank from 1 to 3, the more severe and global the dysfunction.*

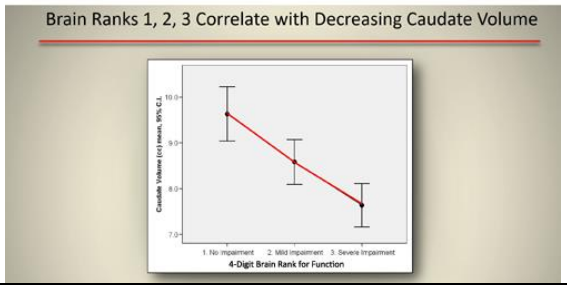
The descriptive labels assigned to Ranks 1 through 4 reflect the increasing probability that underlying brain damage exists. Rank 4 is labeled "definite" because structural/neurological abnormalities are definitive evidence of brain damage. Ranks 1, 2, and 3 are labeled "unlikely", "possible", and "probable" evidence of brain damage, respectively, because measures of dysfunction are not definitive evidence of underlying brain damage, but the probability of underlying brain damage increases with increasing severity of dysfunction. Data from the University of Washington FASDPN show this to be true. Among the first 1,500 patients diagnosed, those presenting with Rank 2 or Rank 3 level dysfunction had a 5.8-fold and 10.8-fold increased risk of having structural/neurological brain damage, respectively, relative to patients with no evidence of dysfunction (Rank 1). This correlation between brain function and structure was also confirmed in our FASD MRI study. The more severe the Brain Rank for function, the smaller the volume of the frontal lobe (Fig 12 from (Astley, 2013; Astley et al., 2009) below. As stated in the Institute of Medicine report (Stratton et al., 1996) "FAS can be characterized by behavioral or cognitive problems that are thought to result from *organic brain damage*, are not easily related to genetic background or environmental influences and may be resistant to improvement with traditionally effective intervention techniques".



A



B



C

Figure 12 from (Astley, 2013). A) The 4-Digit Code ranks brain dysfunction on a 3-point scale (none, moderate, severe). B) The 3 Brain Ranks were case-defined to predict increasing likelihood of underlying structural brain abnormality. C) MRI confirmed this to be true (Astley et al., 2009). The more severe the brain dysfunction (Rank 1, 2, 3), the smaller the caudate volume (significant linear trend F=13.5; p<.001; Duncan range test confirms each brain group is significantly distinct from the others).

All patients receive a Rank 1, 2 or 3 to document their level of brain dysfunction. Patients who present with significant structural and/or neurological evidence of brain damage will also receive a Rank 4. Thus, all patients with structural/neurological evidence of brain damage will have two Brain Ranks, one documenting their structural/neurological damage (Rank 4) and one documenting their level of dysfunction (Rank 1, 2 or 3). More specifically, they will receive either: (a) Brain Ranks 4 and 3 (structural/neurological damage with Rank 3 level dysfunction); (b) Brain Ranks 4 and 2 (structural/neurological damage with Rank 2 level dysfunction); or (c) Brain Ranks 4 and 1 (structural/neurological damage with no current evidence of dysfunction). When two Brain Ranks are applicable, the 4-Digit Code and Diagnostic Category are based on the *highest* Brain rank received, for it reflects the highest level of certainty there is underlying Brain damage. Both Brain

ranks should be circled in the Brain Column of the Diagnostic Grid and both numbers would be inserted in the Diagnostic Code with the lower Rank placed in parentheses 4(3). (See 4-Digit Diagnostic Code grid below). The Diagnostic Category would be based on the highest Rank in the Brain column.

FASD 4-Digit Code

4 (3)

Rank	Growth	Face	Brain	Prenatal Alcohol	Other Prenatal Risks	Other Postnatal Risks
4	severe	all 3 features	abnormal structure/neurology	high	high	high
3	moderate	2.5 features	severe dysfunction	some	some	some
2	mild	1-2 features	moderate dysfunction	unknown	unknown	unknown
1	normal	no features	normal function	none	none	none

Definitions of Brain Ranks 1 through 4.

Brain Rank 4: (Structural/Neurological Abnormalities) "Static Encephalopathy" "Definite" Evidence of Brain Damage.

Rank 4 Description: This rank is selected when the evidence for brain damage is defined through a traditional medical approach. It is our impression that "brain damage" or "static encephalopathy" is readily diagnosed by physicians when 'significant' structural abnormalities of the brain are detected or when neurological findings of presumed prenatal origin are found.

Structural evidence of brain damage may include, but is not limited to:

1. Microcephaly, defined as an occipital frontal circumference (OFC) 2 or more standard deviations below the mean. Head circumference 2 or more standard deviations below the mean has long been associated with functional impairment in the literature (Dolk, 1991; Pryor & Thelander, 1968). Among 999 patients with prenatal alcohol exposure evaluated at the FASDPN, those with microcephaly have IQs that on average are 10 points lower than those with normal head circumferences.

2. Significant brain abnormalities of presumed prenatal origin observable through imaging techniques. Abnormalities may include, but are not limited to hydrocephaly, heterotopias, and change in shape and/or size of brain regions. These abnormalities should be determined by appropriately trained medical professionals.

Neurological evidence of brain damage may include, but is not limited:

1. Seizures not due to a postnatal insult or other postnatal events.

2. Other hard neurological signs of presumed prenatal origin (e.g. cerebral palsy, tick disorders).
3. Hearing loss. Among children evaluated at the FASDPN, neurosensory hearing loss was 16-fold more prevalent among children with FAS (40%) than among children with other FASDs (2.4%) (McLaughlin et al., 2019), for whom the prevalence of hearing loss was similar to that estimated for the general U.S. adolescent population (2.3%) (Lin, et al., 2011)

***Rank 4 Criteria*:** At least one "significant" structural or neurological finding is required for a classification of Brain Rank 4 (Table 5). A significant finding is one that is 2 or more standard deviations below the mean if measured on a standardized scale or deemed "clinically significant" when assessed by an appropriate trained professional like a clinical radiologist or neurologist.

Documenting the Evidence that Supports a Rank 4 Classification: Structural and neurological findings are recorded under the STRUCTURAL and NEUROLOGICAL headings of the Brain section (page 3) of the FASD Diagnostic Form. A 'Severity Score' is provided along the left margin of the Form to allow the clinical team to rank the severity of all structural and neurological findings. Only structural and/or neurological findings that receive a Severity Score = 3 (Significant) can contribute toward a Brain Rank 4 classification. For example, a seizure disorder not due to a postnatal insult would receive a Severity Score = 3. Often this type of seizure would warrant medical treatment. A seizure that occurred just once during a high fever would receive a Severity Score = 2. Absence of any seizure-like activity would receive a Severity Score = 1. An OFC $\leq$ -2 SDs ($\leq 3^{rd}$ percentile) would receive a Severity Score = 3. An OFC > 3^{rd} percentile and $\leq 10^{th}$ percentile would receive a Severity Score = 2. An OFC > 10^{th} percentile would receive a Severity Score = 1. This Severity Score allows one to rapidly scan the FASD Diagnostic Form and identify significant findings that support a Rank 4 classification.

Brain Rank 3: (Severe Dysfunction) "Static Encephalopathy"
"Probable" Evidence of Brain Damage.

Rank 3 Description: Brain Rank 3 is assigned when a patient presents with severe brain dysfunction. These patients typically have challenges across multiple domains of function that may include, but are not limited to, executive function, memory, cognition, processing speed, academic achievement, language, motor, sensory, attention or activity level.

Rank 3 Criteria: Brain Rank 3 is assigned when there is evidence of "severe" impairment in 3 or more domains of brain function. "Sever" impairment is defined as performance 2 or more standard deviations below the mean (or its equivalent) on standardized, validated neuropsychological assessment tools (e.g., WISC, WIAT, CELF, D-KEFS, NEPSY, CVLT, VMI, etc.) administered and interpreted by qualified professionals (e.g., psychologists, occupational therapists, speech-language pathologists, etc). Developmental instruments, such as the Bayley Scales of Infant Development would typically not be used as a source of psychometric data to support a classification of severe brain dysfunction because developmental delay is not always predictive of underlying brain damage/dysfunction. The one exception to this rule would be developmental scores that reflect global developmental delay.

Documenting the Evidence that Supports a Rank 3 Classification*:* The clinical team records which functional domains are impaired and which tests/scores support their decisions on the Functional Domains page (page 7) of the FASD Diagnostic Form. Evidence to support a Rank 3 classification must come from standardized psychometric tests administered by professionals. The outcomes of these psychometric tests are recorded on pages 3-5 of the FASD Diagnostic Form. A 'Severity Score' is provided along the left margin of the Functional Domains page (page 7) to allow the clinical team to rank the severity of delay/impairment for each assessed domain. A functional domain must receive a Severity Score = 3 (Severe) to contribute toward a Brain Rank 3 classification. The Severity Score is described more fully below.

Brain Rank 2 (Moderate Delay/Dysfunction). "Neurodevelopmental Disorder (or Delay)" "Possible" Evidence of Brain Damage.

Rank 2 Description: This Rank should be given to two groups of patients, all of whom should have histories of behavioral, cognitive, and/or developmental problems.

One group includes infants/toddlers/young children (generally under 7 years of age) who are not developmentally mature enough to engage in assessments of higher order functions such as executive function, memory, higher order language skills. If a child is under 7-8 years of age at the time of assessment, they should be reassessed at 9 years of age when their brains are sufficiently mature to engage in assessment of higher order functions. *Note the term "neurodevelopmental disorder" is assigned to brain Rank 2. When this Rank is being assigned to infants/toddlers based primarily on developmental data, the clinical team may decide to replace the term "neurodevelopmental disorder" with "neurodevelopmental delay".*

The other group of patients is those whose testing did not reveal 3 domains of function 2 or more standard deviations below the mean required for a Rank 3 classification, but moderate to less severe impairments were identified nonetheless, preventing them from being classified Brain Rank 1 (normal function).

***Rank 2 Criteria*:** Rank 2 reflects a range of delay and/or dysfunction that suggests the possibility of underlying brain damage. At the mild end of the Rank 2 range are those who present with developmental delay that, by clinical judgment, precludes a Rank 1 classification and warrants intervention. At the severe end of the Rank 2 range are those who present with 1 or 2 domains of function 2 or more standard deviations below the mean, with multiple domains 1.5 standard deviations below the mean (Table 5). A Rank 2, by definition, is assigned to all who fall between Ranks 1 and 3. Evidence to support a Rank 2 classification can come from standardized psychometric tests, observational data, and/or caregiver interview. Deficiencies (or definite differences from normative expectations) recorded in the FUNCTIONAL section (pages 3-7) of the FASD Diagnostic Form serve to support a Rank 2 classification.

Documenting the Evidence that Supports a Rank 2 Classification: The clinical team records which functional domains are delayed or impaired and which tests/scores support their decisions on the Functional Domains page (page 7) of the FASD Diagnostic Form. Evidence to support a Rank 2 classification can come from standardized psychometric tests, observational data, and/or caregiver interview. These data are recorded on pages 3-6 of the FASD Diagnostic Form. A

'Severity Score' is provided along the left margin of the Functional Domains page (page 7) to allow the clinical team to rank the severity of delay or impairment for each assessed domain. Typically a patient that meets the criteria for Rank 2 will have at least one domain with a Severity Score = 2 (mild to moderate delay or impairment), but less than three domains with a Severity Score = 3 (severe impairment). The Severity Score is described more fully below.

Brain Rank 1 (No Current Evidence of Delay/Dysfunction)
"No" Current Evidence of Brain Damage.

A Rank 1 classification is assigned when no functional or developmental problems are discerned that are likely to reflect brain damage and no intervention recommendations are warranted. Evidence to support a Rank 1 can come from standardized psychometric tests, observational data, and/or caregiver interview. While this classification is typically quite rare in an FASD Diagnostic Clinic, it might help to think of this outcome in the context of a well-child assessment conducted in a general pediatric clinic where most children would be classified as Rank 1. On the other hand, if patients under 3 years of age with prenatal alcohol exposure present with normal development (Brain Rank 1) it would be important to conduct a re-evaluation later in childhood when they are old enough to engage in more sophisticated assessments of brain function. The neurodevelopmental impairments caused by prenatal alcohol exposure often do not fully manifest until later in childhood (Pruner et al., 2024). Infants/toddlers with prenatal alcohol exposure at greatest risk of severe brain dysfunction that will not manifest until later in childhood are those presenting with any of the sentinel physical features of FASD (growth deficiency, FAS facial features or microcephaly) (Astley et al., 2016).

Completing the Brain Section of the FASD Diagnostic Form

The Brain section appears on pages 3 through 7 of the FASD Diagnostic Form. These pages serve as a place to record pertinent structural, neurological, neuropsychological, and caregiver interview data available on the patient. Although space has been provided to record a full complement of assessments, we are not implying that all these assessments must be conducted to derive a diagnosis. It is the responsibility of the clinical team to select the most appropriate assessment battery for an individual patient. Recording data for the structural, neurological, and neuropsychological sections is self-explanatory. The Caregiver Interview section, however, warrants further explanation.

An important aspect of the FASD evaluation is an in-depth interview of the caregivers of the patient. This interview takes approximately one hour and is conducted by a qualified member(s) of the clinical team. At the University of Washington FASDPN clinic, this interview is conducted by the medical doctor while the patient is being formally assessed by the other clinical team members. As in any diagnostic situation, once records are reviewed and there is a preliminary case formulation, the diagnostic interview will address several questions, such as: What are the problems that led to the diagnostic referral? What do the caregivers hope to gain from the assessment? What are the caregivers' views of the patient's overall strengths and weaknesses? What is the child's social and medical history pertinent to this diagnostic evaluation? In an FASD diagnostic evaluation, we have found it very useful to also methodically ask questions that review age-appropriate functional abilities in areas that, according to the literature, are commonly problematic for alcohol-exposed individuals. These areas (planning/temporal skills, behavioral regulation/sensory motor integration,

abstract thinking/judgment, memory/learning/information processing, spatial skills/spatial memory, social skills/adaptive behavior, and motor/oral motor control) are presented on the FASD Diagnostic Form (page 6). Routinely inquiring about the patient's capabilities in these areas serves several purposes. First, the caregivers' answers to these questions give insight into their interpretation of the patient's behaviors and about their general relationship with the patient. Second, it is often helpful to compare this subjective assessment to the psychometric profile. This can reveal information about the pattern of neurodevelopmental difficulties that standardized testing may miss or provide evidence that is supportive of test results. The data recorded on page 6 of the Diagnostic Form are non-standardized observational measures. A summary of the first 1,400 caregiver interviews at the FASDPN clinic documented caregivers perceptions of their child's strengths and challenges were remarkably concordant with their child's neuropsychological test outcomes and FASD diagnostic classification (Astley, 2013; see Fig. 19).

Severity Score [0, 1, 2, 3]

Along the left margin of each Brain page is a Severity Score. This Severity Score serves two purposes. 1) It allows one to rapidly scan the left margin of the Brain pages to see what structural, neurological, and functional areas are most impacted. 2) The Severity Scores in the Structural/Neurological Sections and the Functional Domains page also serve to document what evidence was present to meet the criteria for Brain Ranks 2, 3, and 4, as described above. For example, at least one area in the Structural or Neurological Sections should have a Severity Score = 3 to meet criteria for a Brain Rank 4. At least three domains on the Functional Domains page should a Severity Score = 3 to meet criteria for a Brain Rank 3.

The clinical team ranks the level of impairment/abnormality as follows:

0	Unknown, Not Assessed
1	Within Normal Limits
2	Mild to Moderate
3	Severe

For outcomes measured on standardized scales, in general, outcomes two or more standard deviations below the norm would be judged severe, whereas outcomes between one and two standard deviations below the norm could be judged mild to moderate.

A comprehensive assessment will identify domains of strength, as well as domains with mild to severe impairment. Documenting the outcomes of all assessed domains, not just those with severe impairment, is important for treatment planning.

Primary Sources of Information Used and Generated by the Interdisciplinary Team to Derive the Brain Rank.

1. **Previous medical, school, psychological and mental health assessments**.

   Prior to the diagnostic evaluation, consent is obtained from the legal guardian to obtain the results of prior school, psychological and/or medical assessments that will be pertinent to the diagnostic evaluation. These assessments typically include:

   A. Medical records (growth, neurological evaluations, brain imaging, other medical conditions).
   B. School records (IEP, school psychological and/or achievement assessments).
   C. Psychological Records (neuropsychological assessments).
   D. Mental Health Records (mental health assessments, diagnoses, medications).

   These records are reviewed and discussed by the interdisciplinary team prior to the diagnostic evaluation.

2. **Caregiver interview conducted at the time of the diagnostic evaluation**.

   As described above, a semi-structured interview (page 6 of the *FASD Diagnostic Form*) is conducted with the caregiver(s) to document their concerns, impressions and experiences with the patient.

3. **Psychometric assessments conducted at the time of, or in preparation for, the diagnostic evaluation.**

   The primary goal in the diagnostic evaluation is to document/verify the presence of brain abnormalities. The battery of assessments administered by the interdisciplinary team will most likely differ for each patient. Assessments will be selected based on the patient's age and area(s) of perceived deficit. Many patients will have already had some level of prior assessment conducted by other educational and health care providers. Thus, assessments conducted by the interdisciplinary diagnostic team will be selected to compliment, not duplicate what has already been done. The FASDPN Psychometric and Behavior Observations Training Guide (Olson et al., 2005) provides a brief overview of psychometric assessments typically used to assess patients of all ages seen in the FASDPN clinics. Clarren et al., 2000 provides a description of a typical FASD interdisciplinary diagnostic evaluation at the University of Washington FASDPN clinic. The following published research reports document the neuropsychological, behavioral, sensory, sleep disorder, and psychiatric outcomes of individuals across the spectrum of FASD (Astley, 2010; Astley et al., 2009a; Chen et al., 2012; Franklin et al., 2008; Jirikowic et al., 2008; Jirikowic et al., 2008a; Jirikowic et al., 2013; Olson et al., 2007).

Table 5: Criteria for Brain Ranks 1 through 4

4-Digit Diagnostic Brain Rank*	Probability of underlying Brain Damage	Confirmatory Findings
4	Definite **Structural and/or Neurological Abnormalities** *Static Encephalopathy*	● Microcephaly: OFC 2 or more SDs below the norm. *and / or* ● Significant abnormalities in brain structure of presumed prenatal origin. *and / or* ● Evidence of abnormal neurological findings (e.g. seizures, tick disorders, etc.) likely to be of prenatal origin.
3	Probable **Severe Dysfunction** *Static Encephalopathy*	● Severe impairment (2 or more SDs below the mean) in 3 or more domains of brain function such as, but not limited to: cognition, achievement, memory, executive function, motor, sensory, language, attention, activity level, neurological 'soft' signs.
2	Possible **Moderate Dysfunction** *Neurodevelopmental Disorder*	● Evidence of delay or dysfunction that do not permit a Rank 1 classification, but also do not permit a Rank 3 classification.
1	Unlikely **No Dysfunction**	● No current evidence of delay or dysfunction likely to reflect brain damage.

* Transfer the resulting 4-Digit Diagnostic Rank for Brain to the 4-Digit Diagnostic Code Grid on page 1 of the FASD Diagnostic Form (Section II).

FASD 4-Digit Code

3

Rank	Growth	Face	Brain	Prenatal Alcohol	Other Prenatal Risks	Other Postnatal Risks
4	severe	all 3 features	abnormal structure/neurology	high	high	high
3	moderate	2.5 features	severe dysfunction	some	some	some
2	mild	1-2 features	moderate dysfunction	unknown	unknown	unknown
1	normal	no features	normal function	none	none	none

B.4. Ranking Prenatal Alcohol Exposure

Method for Ranking Alcohol: The 4th Digit of the 4-Digit Diagnostic Code

Alcohol exposure is ranked according to the quantity, timing, frequency, and certainty of exposure during pregnancy (Table 6). The case-definitions for the four Ranks address two important issues: 1) that exposure information in a clinical setting can be of limited availability or of unknown accuracy (Astley, 2013; Astley et al, 2019) and 2) and a clear consensus is not available concerning the amount of alcohol that can actually be toxic to each individual fetus (Stratton et al., 1996; (Astley)Hemingway et al., 2019a).

The case-definitions for prenatal alcohol exposure differentiate four clinically meaningful groups: Rank 4: confirmed exposure to high levels of alcohol; Rank 3: confirmed exposure, but the level is less than Rank 4 or the level is unknown; Rank 2: unknown exposure (neither confirmed absent nor confirmed present); and Rank 1: confirmed absence of exposure from conception to birth. These exposure Ranks are based on verbal or written records. High exposure is defined generally to be a blood alcohol concentration of greater than 100 mg/dL (a level that typically can be reached by a 55-kg woman consuming six to eight beers) weekly, early in pregnancy. In the absence of a clear consensus on the amount of alcohol that can actually be toxic to the fetus, this general definition should only serve as a guide, not a threshold.

One example of a 'Rank 4' exposure is the birth mother reported drinking to the point of intoxication weekly throughout pregnancy. Two examples of 'Rank 3' exposures include: 1) birth mother was observed to be drinking during pregnancy, but the amount is unknown, 2) birth mother reported drinking a single glass of wine weekly, but stopped drinking as soon as she learned she was pregnant at 2 months. Two examples of when alcohol exposure is ultimately unknown and thus coded as Rank 2 include: 1) the child is adopted and the birth records are closed, and 2) the birth mother is known to have a problem with drinking, but there are no records or direct observation of her drinking during the index pregnancy. A Rank 1 classification (confirmed absence of drinking from conception to birth) may not be as common as one would hope in the general population. Most women of reproductive age consume some level of alcohol and not all pregnancies are planned.

The Rank 4 FAS facial phenotype as defined by the 4-Digit Code can be used to confirm prenatal alcohol exposure when a written or verbal history of prenatal alcohol exposure is unknown (Alcohol Rank 2). The 4-Digit Code Rank 4 FAS facial phenotype is the only facial phenotype, to date, that provides sufficient positive predictive value (PPV) and specificity (100%) to prenatal alcohol exposure to allow the facial phenotype to serve as confirmation of alcohol exposure in a diagnostic setting when a verbal or written record of prenatal alcohol exposure is unavailable. Even minimal relaxation of the phenotype (e.g., Face Rank 3) results in PPV (35%) and specificity (88.7%) values too low to use as confirmation of prenatal alcohol exposure. (Astley & Clarren, 1996, 2000, 2001; (Astley)Hemingway et al., 2020). If the facial phenotype of FAS can only be caused by prenatal alcohol exposure, the following two conditions should hold true: 1) All individuals with the FAS facial phenotype have prenatal alcohol exposure (100% PPV); and 2) No individual with a confirmed absence of prenatal alcohol exposure will have the FAS facial phenotype (100% specificity). Data to date documents the Rank 4 FAS facial phenotype meets these two conditions ((Astley)Hemingway et al.,

2020). The Rank 4 FAS facial phenotype can also be used to confirm an individual's prenatal alcohol exposure adversely impacted their fetal development.

Table 6: Criteria for Prenatal Alcohol Exposure Ranks 1 through 4

4-Digit Diagnostic Rank	Prenatal Alcohol Exposure Category	Description of Alcohol Use During Pregnancy
4	High Risk	• Alcohol use during pregnancy is CONFIRMED. *and* • Reported exposure pattern is consistent with the medical literature placing the fetus at "high risk" (generally high peak blood alcohol concentrations delivered at least weekly in early pregnancy, reports of intoxication, binge drinking).
3	Some Risk	• Alcohol use during pregnancy is CONFIRMED. *and* • Level of alcohol use is reported to be less than Rank (4) or level is unknown.
2	Unknown Risk	• Alcohol use during pregnancy is UNKNOWN (neither confirmed absent nor confirmed present).
1	No Risk	• Alcohol use during pregnancy is CONFIRMED ABSENT from conception to birth.

Transfer the resulting 4-Digit Diagnostic Rank for Alcohol Exposure to the 4-Digit Diagnostic Code Grid on page 1 of the FASD Diagnostic Form (Section II).

FASD 4-Digit Code

Rank	Growth	Face	Brain	Prenatal Alcohol (4)	Other Prenatal Risks	Other Postnatal Risks
4	severe	all 3 features	abnormal structure/neurology	high	high	high
3	moderate	2.5 features	severe dysfunction	some	some	some
2	mild	1-2 features	moderate dysfunction	unknown	unknown	unknown
1	normal	no features	normal function	none	none	none

B.5. Ranking Other Pre- and Postnatal Risk Factors

The Importance of Documenting Other Risk Factors

A comprehensive diagnostic process must take into consideration all other adverse prenatal and postnatal adverse exposures and experiences, not just prenatal alcohol exposure. Many of the outcomes observed in individuals with prenatal alcohol exposure are not specific to (caused only by) prenatal alcohol exposure. A variety of other prenatal (poor prenatal care, pregnancy complications, familial genetics, and exposure to other potentially teratogenic agents, etc.), and/or postnatal (physical/sexual abuse, neglect, disrupted placement histories, trauma, head injuries, chronic substance abuse by the patient, etc.) risk factors could also contribute to the adverse outcomes presented by the patient. In the FASDPN clinical population, other prenatal and postnatal risk factors were 3 to 7-fold more prevalent than in the general population (Astley Hemingway et al., 2020).

The 4-Digit Diagnostic method requires the clinical team to record all pertinent prenatal and postnatal risk factors on the standardized FASD Diagnostic Form, rank their severity of risk on 4-point Likert scales, report them in the medical summary, and take them into consideration when deriving a diagnosis and intervention plan.

It is important to note that the presence of other risk factors does not reduce the teratogenic potential of alcohol. When multiple risk factors are present, including prenatal alcohol exposure, each risk factor has the potential of being fully responsible, partially responsible, or not responsible at all for any one particular outcome. Together these risk factors can have additive or multiplicative adverse impacts on development.

While there is currently no medical means to determine which risk factor is responsible for which outcome in an individual patient, group statistics can begin to shed light on this issue. A recent study addressed the question "*What proportion of brain structural and functional abnormalities observed among children with FASD is explained by their prenatal alcohol exposure and their other prenatal and postnatal risks*? (Astley Hemingway et al., 2020). The study revealed prenatal alcohol exposure was the dominant risk factor explaining the largest proportion of variance (52%) in regional brain size (total brain, frontal lobe, caudate, hippocampus and corpus callosum) and brain function (intellect, achievement, memory, language, executive-function, motor, adaptation, behavior-attention and mental health symptoms). Other prenatal and postnatal risk factors were 3 to 7-fold more prevalent among these children with FASD than documented in the general population. Individually, each risk factor explained a statistically significant, but smaller proportion of variance (5-15%) in brain outcome compared to prenatal alcohol exposure. In combination, the proportion of variance explained by the presence of multiple prenatal and postnatal risks rivaled that of prenatal alcohol exposure.

A. Other Prenatal Risk Factors: Rank Definitions

Prenatal exposures and experiences are recorded and assigned a Rank on page 9 of the Diagnostic Form. The definitions below are intended to provide guidance for ranking. The circumstances surrounding each patient case will be unique. Selecting a rank will require clinical judgement.

Rank 4: High Risk

This Rank is reserved for alternate genetic conditions (e.g., Fragile X, velocardiofacial syndrome, down syndrome, etc.) or exposure to known teratogens (e.g., dilantin, valproic acid, etc.) that have been clearly shown to produce physical abnormalities.

Rank 3: Some Risk

This category is used for potential genetic conditions, exposures or prenatal conditions that have been associated with physical or neurodevelopmental problems in a less well-established way, when compared to those falling in Prenatal Rank 4. Examples of conditions that would be placed in this category could include poor prenatal care; patients whose parents have attention deficit disorders, significant learning disabilities or learning problems thought to be due to a non-specific (and non-teratogenic) source; prenatal exposure to non-teratogenic drugs like marijuana; and cigarette smoking during pregnancy.

Rank 2: Unknown Risk

This category is used when the details of the family background and gestation are unknown – generally in the circumstance of a closed adoption.

Rank 1: No Known Risk

On occasion, the genetic, teratogenic, and prenatal histories are well documented and no factors can be identified that would explain the abnormalities found in the patient.

B. Postnatal Risk Factors: Rank Definitions

Postnatal risks are recorded and assigned a Rank on page 9 of the Diagnostic Form.

There is a growing body of literature on the prevalence and impact of traumatic childhood experiences among individuals with prenatal alcohol exposure (Price et al., 2017; (Astley) Hemingway SJA et al., 2020; Lebel et al., 2019: Rockhold et al., 2023). Documenting postnatal adverse experiences can be achieved retrospectively from historical records and/or prospectively from administration of parent-report questionnaires like the Adverse Childhood Experiences (ACES) (Felitti et al., 1998) or the Traumatic Events Screening Inventory (TESI) (Ghosh-Ippen et al., 2002).

Childhood adversity has been conceptualized variously as linking specific experiences with outcomes, cumulative risk (e.g. ACE score), dimensional approaches (threat / deprivation / unpredictability frameworks), and "topological" models which consider features like chronicity, intensity, and developmental timing of adversity along with child aspects like stress response phenotypes and environmental factors such as predictability and caregiver responses (Ellis et al., 2022; Rockhold et al., 2023; Gabard-Durnam & McLaughlin, 2020; Smith & Polak, 2021).

Until there is more empirical support for one of these approaches, we rely upon clinical judgement to rank the magnitude of risk posed by the adverse postnatal experiences and the likelihood that postnatal events contributed to growth and developmental differences. The definitions provided below are meant to provide guidance. Consider factors like severity, chronicity, number of risk factors, timing (e.g. developmentally sensitive period of the first 2-3 years or recency), child's perceptions of the events, and buffering by caregivers (resilience/resources or lack thereof) when evaluating the degree of adversity and how likely the postnatal environment is to have influenced the patient's outcomes.

Rank 4: High Risk

This Rank is used to note postnatal circumstances that have been shown to have a significant adverse effect on development in most instances. Examples include, but are not limited to, physical and/or sexual abuse, multiple disrupted placements with clear impact on the child, severe neglect (based on clinical judgment or apparent impacts such as failure to thrive), serious head injury, or medical conditions which lead to brain impacts (e.g., hypoxic/ischemic encephalopathy, kernicterus, severe malnutrition). Perinatal/prematurity factors like extremely low birth weight (ELBW), extremely premature (< 28 weeks), and intracranial hemorrhage grade 3-4 can be captured here as well). Other postnatal experiences that could contribute to a high-risk Rank 4 classification are presented on page 9 of the Diagnostic Form (page 16 of this Diagnostic Guide).

Rank 3: Some Risk

This Rank is used to note conditions akin to those in Rank 4, but the circumstances are judged less severe and so less likely to be a definite factor in the patient's present condition. Obviously, clinical judgment is needed in judging the magnitude of postnatal problems and interpreting this information into a Rank 3 or 4 placement.

Rank 2: Unknown Risk

This Rank is used when historical information is missing. This is sometimes the case with adopted children or those in foster care. Adult patients may, at times, be unable to reconstruct their own early histories.

Rank 1: No Known Risk

This Rank is used when a well-documented history confirms an absence of adverse postnatal exposures/events.

Transfer the resulting 4-Digit Diagnostic Ranks for Prenatal and Postnatal Risks to the 4-Digit Diagnostic Code Grid on page 1 of the FASD Diagnostic Form in Section II.

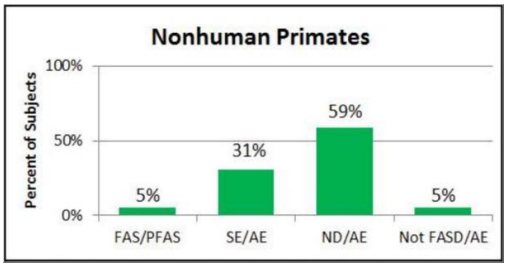
FASD 4-Digit Code

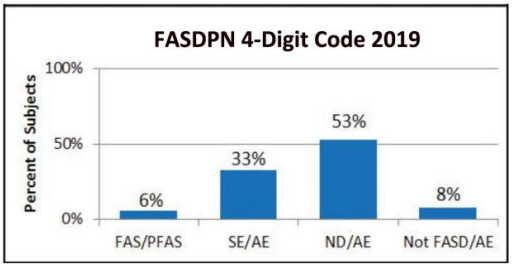
Rank	Growth	Face	Brain	Prenatal Alcohol	Other Prenatal Risks (3)	Other Postnatal Risks (4)
4	severe	all 3 features	abnormal structure/neurology	high	high	high
3	moderate	2.5 features	severe dysfunction	some	some	some
2	mild	1-2 features	moderate dysfunction	unknown	unknown	unknown
1	normal	no features	normal function	none	none	none

IV. Diagnostic Categories

Generic descriptions for each of the 19 Diagnostic Categories are presented on the following pages listed alphabetically from A through S. A complete list of the 19 categories is presented in Section IV. Note only 6 of the Diagnostic Categories (A-E and 4 codes in J highlighted in red) fall "broadly" under the umbrella of FASD in accordance with the 4-Digit Code. What do we mean by "broadly" under the umbrella of FASD?

Fetal Alcohol Spectrum Disorders are, by definition, adverse outcomes *caused* by prenatal alcohol exposure. When we label a diagnosis FAS, we are stating explicitly that alcohol caused the syndrome. *How do we know an individual's prenatal alcohol exposure caused their FAS?* FAS is characterized by growth deficiency, brain abnormalities and the FAS facial phenotype. Although a myriad of prenatal and postnatal risk factors including PAE can cause adverse growth and brain outcomes, only prenatal alcohol exposure can cause the FAS facial phenotype. But the diagnoses SE/AE and ND/AE do not require the FAS facial phenotype. *Do all individuals with SE/AE and ND/AE have FASD?* Not necessarily. Only the subset of individuals whose growth and/or brain impairments were caused (in whole or in part) by their prenatal alcohol exposure. Which subset of individuals is that? We currently have no way of knowing. Individuals with SE and ND caused by their alcohol exposure have FASD. Individuals with SE/AE and ND/AE that was not caused by their alcohol exposure do not have FASD. *What proportion of individuals with SE/AE or ND/AE have FASD?* Research to date would suggest it is likely the majority. Although the prevalence of other prenatal and postnatal risk factors is 3- to 7-fold higher in the FASDPN clinic population than in the general population, a recent study ((Astley) Hemingway et al., 2020) found among these children with prenatal alcohol exposure and other risk factors, alcohol was the dominant risk factor explaining the largest proportion (50%) of variance in regional brain size and brain function. Individually, each of the other risk factors explained a smaller proportion of the variance, but in combination explained an additional 20-30% of the variance. *What would the prevalence of FAS, SE/AE and ND/AE look like if alcohol was the only risk factor?* The 4-Digit Code was applied to a nonhuman primate model of FASD where the only risk factor was PAE ((Astley) Hemingway et al., 2019). The prevalence of the FAS, SE/AE and ND/AE caused by alcohol looked near identical to the prevalence of FASD diagnostic outcomes observed among 3,000 patients with prenatal alcohol exposure evaluated in the FASDPN over 30 years.





The 256 Diagnostic Codes can be logically grouped into 19 Diagnostic Categories.

Only the 5 Categories in red font (A-E) and 4 codes in Category J with the Rank 4 facial phenotype are considered to be broadly under the umbrella of FASD in accordance with the 4-Digit Code.

Category	Name
A	Fetal alcohol syndrome
B	Sentinel physical finding(s) / static encephalopathy / alcohol exposed
C	Static encephalopathy / alcohol exposed
D	Sentinel physical finding(s) / neurodevelopmental disorder / alcohol exposed
E	Neurodevelopmental disorder / alcohol exposed
F	Sentinel physical finding(s) / alcohol exposed
G	No sentinel physical findings or brain abnormalities detected / alcohol exposed
H	Sentinel physical finding(s) / static encephalopathy / alcohol exposure unknown
I	Static encephalopathy / alcohol exposure unknown
J	Sentinel physical finding(s) / neurodevelopmental disorder / alcohol exposure unknown)
K	Neurodevelopmental disorder / alcohol exposure unknown
L	Sentinel physical finding(s) / alcohol exposure unknown
M	No sentinel physical findings or brain abnormalities detected / alcohol exposure unknown
N	Sentinel physical finding(s) / static encephalopathy / no alcohol exposure
O	Static encephalopathy / no alcohol exposure
P	Sentinel physical finding(s) / neurodevelopmental disorder / no alcohol exposure
Q	Neurodevelopmental disorder / no alcohol exposure
R	Sentinel physical finding(s) / no alcohol exposure
S	No sentinel physical findings or brain abnormalities detected / no alcohol exposure

V. 4-Digit Diagnostic Codes Within each Diagnostic Category

Only the 4-Digit Codes in red font are considered to be broadly under the umbrella of FASD in accordance with the 4-Digit Code.

VII. Medical Summary Report & Generic Summaries for Diagnostic Categories

The FASDPN clinic generates a single comprehensive Medical Summary Report composed jointly by the interdisciplinary team.

An example of the format and content of our report is presented below for a fictitious patient. An electronic template of our Medical Summary Report is available free (contact Susan Astley Hemingway Ph.D. (astley@uw.edu)).

<Clinic Name>
Medical Summary Report Clinic Date: mm/dd/yyyy

Diagnosis	**Fetal Alcohol Syndrome**

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant brain damage/dysfunction that occur in individuals exposed to alcohol during gestation. On the attached pages are the specific findings in this patient's case that confirm they meet criteria for FAS.

Although this patient meets criteria for FAS, this does not mean that alcohol exposure during pregnancy is the only cause of the patient's current challenges. Other factors could also be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during gestation, and various experiences since birth. Such factors may partly explain why there is so much variability in the kinds of specific challenges that patients with FAS have.

Individuals with FAS have significant brain damage/dysfunction and should be viewed as individuals with disabilities. This FAS diagnosis has implications for educational planning, societal expectations, and health. On the attached sheets you will find a list of specific concerns that have been identified that need attention.

_____
<Name>, MD
<Name of Clinic>

Medical Summary Report <Patient name & birth date> p 1 of 18

Diagnosis: Fetal Alcohol Syndrome (4-Digit Code 4433)

FASD 4-Digit Code

Rank	4 Growth	4 Face	3 Brain	3 Prenatal Alcohol	3 Other Prenatal Risks	3 Other Postnatal Risks
4	severe	all 3 features	abnormal structure/neurology	high	high	high
3	moderate	2.5 features	severe dysfunction	some	some	some
2	mild	1-2 features	moderate dysfunction	unknown	unknown	unknown
1	normal	no features	normal function	none	none	none

Overview of Evaluation Procedure:

<Name> (10.2 of age) was accompanied today (mm/dd/yyyy) in clinic by his adoptive parents. A 4-hour interdisciplinary diagnostic evaluation using the 4-Digit Diagnostic Code[1] was conducted by the Fetal Alcohol Syndrome Diagnostic & Prevention Network (FASDPN) interdisciplinary clinical team composed of a pediatrician (<Name>, MD), an occupational therapist (<Name>, PhD, OTR/L), speech/language pathologist (<Name>, PhD, CCC-SLP), psychologist (<Name>, PhD), social worker (<Name>, MSW), family advocate (<Name>) and clinic director (<Name>, PhD). In the weeks leading up to this clinic appointment, prior school, medical, psychological and social service records were obtained and reviewed by the social worker. In addition, the patient's caregivers completed standardized questionnaires. Upon arrival today, the patient had his height, weight, and OFC measured and a clinical photograph taken of his face. Concurrently, the FASDPN diagnostic team participated in a 30-minute case presentation conducted by the social worker. Upon completion of the case presentation, the team pediatrician and social worker conducted a joint clinical interview with the caregivers. Concurrently, the patient received a 2-hour multi-disciplinary screening conducted by the occupational therapist, speech/language pathologist and psychologist. The team reconvened for 75 minutes and derived a diagnosis and treatment plan. The team shared the diagnosis with the patient's parents in the final 30 minutes of the appointment. The psychologist scheduled a 30-minute telephone conference with the caregivers for the following week to discuss the intervention recommendations.

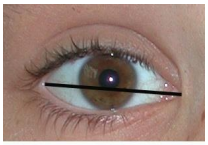
1. S.J (Astley) Hemingway. Diagnostic Guide for Fetal Alcohol Spectrum Disorders: The 4-Digit Diagnostic Code. 4th Edition, Seattle WA: University of Washington Publication Services, 2024.

Growth:

Individuals with FASD are often growth deficient either pre- or postnatally. Two key indices for growth are height and weight percentiles adjusted for age. <Patient's name> presents with severe growth deficiency (Growth ABC-Score = CC; Growth Rank 4) based on his postnatal measurements. After a birth ending in the 38th week of gestation, <Patient's name> was 44.8 cm in length (7th percentile) and weighed 2,879 g (20th percentile). His current height and weight are 130.2 cm (3rd percentile after adjustment for midparental height) and 23.7 kg (3rd percentile).

Face:

The face of fetal alcohol syndrome is characterized by the presence of all three of the following features: small eyes (as measured by palpebral fissure length), a thin upper lip and a smooth philtrum (the vertical groove between the nose and the upper lip). The palpebral fissures must be two or more standard deviations below the norm and the thin upper lip and smooth philtrum must be a Rank 4 or 5 on the Lip-Philtrum Guide. Based on the 4-Digit Code, if all three of these features are present, the Face is assigned a Rank 4. Moderate and mild expressions of these FAS facial features receive Face Ranks of 3 and 2 respectively. If none of these three facial features are present, the face receives a Rank 1.



palpebral fissure length

<Patient's name> palpebral fissure lengths were significantly small (22.4 mm, estimated to be 3.75 SDs below the mean on the Stromland PFL growth charts) for his age and race (Caucasian). <Patient's name> has a very smooth philtrum (Rank 5) and a moderately thin upper lip (Lip Circularity = 79.5; Rank 4) based on the use of UW Lip-Philtrum Guide 1. Based on these facial measures, <Patient's name> receives a Facial ABC-Score of CCC (or 4-Digit Face Rank 4). <Patient's name> presents with the full expression of the FAS facial phenotype. <Patient's name> also presented with hypertelorism (inner canthal distance 35.1 mm, estimated to be 2.01 SDs above the mean on the Hall inner canthal distance growth charts). In addition, <Patient's name> presented with epicanthal folds. See FAS Facial Photographic Analysis Software photo report below.

4-Digit Diagnostic Code for Face: 4: FAS features severe

University of Washington FAS DPN FAS Facial Photographic Analysis Software

Brain: Brain damage may be evidenced by abnormal brain structure (such as microcephaly or abnormal structure identified through brain imaging), abnormal neurological signs of presumed prenatal origin (such as seizures, tics or spasticity) and/or significant brain dysfunction as measured by standardized psychometric assessments. Based on the 4-Digit Diagnostic Code, a Brain Rank 4 is assigned when structural and/or neurological evidence of impairment is present, a Brain Rank 3 is assigned when there is evidence of significant brain dysfunction, a Brain Rank 2 is assigned when there is some evidence of brain dysfunction or delayed development, but not at the level of a Rank 3 and a Brain Rank 1 is assigned when there is no functional evidence of impairment.

Based on the information available to us to date, <Patient's name> met the criteria for a Brain Rank 3. This information is described more fully below.

Structurally, <Patient's name> head circumference has always been in the normal range. At birth his OFC was 32.7 cm (37th percentile for 38 weeks gestation) and is currently 51 cm (20th percentile). <Patient's name> has had his brain imaged. A cranial ultrasound in <year> was reported normal. Neurologically, <Patient's name> does not have a reported history of seizures or other neurologic problems.

Brain or central nervous system function was assessed both prior to and during this clinic visit.

Psychometric assessments administered today in clinic include the following:

Psychological Screen:
- *California Verbal Learning Test- Children's Version (CVLT-C)*
- *Child Behavior Checklist for Ages 6-18 (CBCL/6-18)*
- *Children's Sleep Habits Questionnaire (CSHQ)*
- *Delis-Kaplan Executive Function System (D-KEFS)*

Motor/Sensory/Developmental Screen:
- *Developmental Test of Visual Motor Integration, 6th Edition (VMI-6)*
- *Quick Neurological Screening Test-3R (QNST-3R)*
- *Short Sensory Profile (SSP)*

Language Screen:
- *Children's Communication Checklist-2 (CCC-2)*
- *Clinical Evaluation of Language Fundamentals - 4th Edition (CELF-4)*

Previous Testing:

Records from the following previous assessments were also available for our review and consideration:
- *KTEA-3, <year>*
- *ABAS-3, <year>*
- *BASC-3, <year>*
- *BOT-2, <year>*
- WISC-5, <year>

Previous records document <Patient's name> has a diagnosis of ADHD.

The standardized testing and clinical observations carried out in this FASD diagnostic clinic are conducted solely for the purposes of diagnosing alcohol-related disabilities and making related recommendations and referrals. This is not a comprehensive assessment of skills. To more completely understand <Patient's name>'s unique cognitive and behavioral profile, additional comprehensive psychological, neuropsychological, occupational therapy and speech assessments carried out by qualified professionals may be necessary.

The test outcomes presented in this report use a variety of scoring systems. Unless otherwise indicated, Standard scores are based on a scale in which the mean is 100 and the standard deviation is 15. This means that most individuals attain a Standard score between 85 and 115 (the "average" range). Scores that are 2 or more standard deviations below the mean are considered significantly below the mean. Thus, Standard scores at or below 70 are considered to be significantly below the mean. T-scores are based on a scale in which the mean is 50 and the standard deviation is 10. An average T-score falls between 40 and 60. A T-score at or below 30 is significantly below the mean. Some subtests use Scaled scores, in which the mean is 10 and the standard deviation is 3. An average Scaled score falls between 7 and 13. A Scaled score at or below 4 is significantly below the mean. Percentile ranks indicate where the individual's score falls relative to his age peers. Average scores fall between the 25th to the 75th percentile (the 50th percentile is in the middle of the average range and corresponds to a Standard score of 100). Scores below the 3rd percentile are significantly below the average range.

Psychological Screen conducted in clinic today at chronological age 10.2 years:

It was a pleasure working with <Patient's name> today. <Patient's name> was cooperative and engaged throughout the assessment. He shared his sense of humor and was talkative. <Patient's name> used emphatic gestures, established eye contact with the examiner, and engaged in reciprocal interactions. He remained at the table throughout the assessment although he fidgeted in his chair and required movement at times. He also responded impulsively and was inattentive to details on occasion. Despite these behaviors, he put forth appropriate effort and completed every task. Snack breaks and encouragement were helpful in supporting <Patient's name>'s performance. The results reported here are believed to be a valid indicator of <Patient's name>'s current functioning in the areas assessed. Therefore, these results are considered valid estimates of his thinking and reasoning ability.

The *California Verbal Learning Test - Children's Version (CVLT-C)* is a measure of multiple components of verbal learning and memory. Strategies and processes involved in learning and recalling verbal material are also assessed. On this test, <Patient's name> received the following scores:

CVLT-C		
Task	**Level of Recall**	
List A: Total Trials	T-Score	31
List A: Short Delay Free Recall	z-score	-2
List A: Short Delay Cued Recall	z-score	-1.5
List A: Long Delay Free Recall	z-score	-1.5
List A: Long Delay Cued Recall	z-score	-1.5
List B: Free Recall	z-score	-1

CVLT-C			
Learning Characteristics	*z-score*	**Recall Errors/Recognition Measures**	*z-score*
Semantic Cluster Ratio	0	Perseverations	-0.5
Serial Cluster Ratio	-0.5	Free-recall Intrusions	1
Learning Slope	-3	Cued-recall Intrusions	2
Percent Recall Consistency	-2	Discriminability	1

<Patient's name> demonstrated significant difficulty with verbal learning and memory. Rather than increasing the number of words he recalled from a list across five repeated trials, he recalled fewer than expected resulting in a *T*-score of 31, which is in the very low range compared to his same-aged peers. He also had difficulty recalling the list after a short delay with distraction and when cued to recall items within a specific category. During these memory tasks, he tended to add words that were within the categories but were not within the initial list. This performance indicates that <Patient's name> may be overwhelmed by too much information and unable to sustain attention. Additionally, he confabulates to appear and feel more competent or to please others, which may be interpreted by others as lying. Despite the difficulty of this task, <Patient's name> persisted without complaint and put forth good effort.

Delis-Kaplan Executive Function System (D-KEFS) consists of 9 independent tests designed to measure quantitative and qualitative aspects of executive functions.

The *D-KEFS Color-Word Interference Test* typically measures inhibition and cognitive flexibility. This subtest is comprised of four conditions. The first two conditions measure speed and accuracy of naming colors and reading color names written in black ink. The third condition evaluates the ability to inhibit the name-reading response to perform the less-automatic skill of naming the color of ink, while the fourth condition examines the ability to both inhibit and switch between two sets of rules. On this measure, <Patient's name> received the following scores:

D-KEFS Color-Word Interference	
Primary Measures	**Scaled Score**
Color Naming	7
Word Reading	8
Inhibition	8
Inhibition/Switching	10
Combined Naming + Reading	7
Primary Contrast Measures	**Scaled Score**
Inhibition vs. Color Naming	10
Inhibition/Switching vs. Combined Naming + Reading	11
Inhibition/Switching vs. Inhibition	12
Error Measures	**Scaled Score**
Inhibition Condition	3
Inhibition/Switching Condition	1

<Patient's name> was able to complete each of these tasks as quickly as expected for his age; however, he sacrificed accuracy for speed and made several errors. At times, he caught his errors and self-corrected, yet for several, he was unaware that he made a mistake. The number of errors significantly exceeded expectations compared to his same-aged peers indicating impulsive responding, poor cognitive flexibility, and difficulty with self-monitoring yet age-appropriate processing speed.

The *D-KEFS Trail Making Test* is a well-known drawing test that assesses planning, organization, sequencing, motor speed, and flexible thinking skills. This task is made up of five conditions. Four of the conditions are used to isolate the four skills necessary to perform the fifth task (which measures the ability to switch sets). On this measure, <Patient's name> received the following scores:

D-KEFS Trail Making	
Primary Measures	**Completion Times Scaled Score**
Visual Scanning	12
Number Sequencing	13
Letter Sequencing	3
Number-Letter Switching	3
Motor Speed	10
Combined Number + Letter Sequencing	8
Contrast Measures	**Contrast Scaled Score**
Switching vs. Visual Scanning	2
Switching vs. Number Sequencing	2
Switching vs. Letter Sequencing	0
Switching vs. Combined Number + Letter Sequencing	5
Switching vs. Motor Speed	3
Error Analysis	**Scaled Score**
All Error Types for Number-Letter Switching	3

<Patient's name> was able to scan an array of letters and numbers, sequence numbers, and connect dots on paper with a pencil as quickly as others his age. When sequencing letters, <Patient's name> needed help remembering that H came after G rather than J and he spent quite a bit of extra time searching for the letter J and incorrectly rehearsing the alphabet. Had the examiner not assisted <Patient's name> by giving him the correct letter, he would not have completed this task. Even with the help, his score is in the very low range. On the switching task, however, <Patient's name> remembered the correct order of the alphabet yet made a significant number of errors and took extra time reviewing and rehearsing the number and letter sequences. This performance is consistent with Color-Word Interference and indicates that <Patient's name> has difficulty with impulsive responding, cognitive flexibility, and self-monitoring.

The *Child Behavior Checklist for Ages 6-18 (CBCL/6-18)* is a caregiver checklist reporting on children's social competence and behavior problems. This questionnaire presents: (1) a list of behavior problems which are rated by the parent for frequency of occurrence (high scores reflect

deficits); and (2) a series of questions about social activities and school performance to provide information on the child's degree of participation in these activities and at school, and the quality of the child's performance (low scores reflect deficits). The patient's caregiver completed this checklist on mm/dd/yyyy. The caregiver's responses yielded the following scores:

CBCL/6-18			
Index/Scale	**T-Score**	**Behavior Problem Scales**	**T-Score**
Total Competence	**30-C**	Anxious/Depressed	66-B
Activities	52	Withdrawn/Depressed	68-B
Social	28-C	Somatic Complaints	72-C
School	24-C	Social Problems	70-C
Total Behavior Problems	**73-C**	Thought Problems	71-C
Internalizing	71-C	Attention Problems	92-C
Externalizing	65-C	Rule-Breaking Behavior	67-B
		Aggressive Behavior	64

B= scores are in the Borderline Range, C=scores are in the Clinical Range

The caregiver's ratings indicated that they perceive significantly elevated Externalizing and Internalizing Behaviors. The caregiver endorsed items indicating that <Patient's name> has Clinical levels of inattention, impulsivity, and social problems. Rule-breaking behaviors, such as lying, and thought problems, such as hording items and getting stuck on specific characters were reported. The caregiver also noted that <Patient's name> has a tendency to be moody and argumentative. Several ratings were consistent with <Patient's name>'s medical problems and diagnoses of attention deficit hyperactivity disorder and anxiety. Additionally, the caregiver reported concerns with school performance and academic learning in all areas. <Patient's name> currently has an Individualized Education Plan (IEP) at school. <Patient's name> was reported to get along with others and has friends. He engages in some age-appropriate activities such as soccer, basketball, and running. He also enjoys playing video games and drawing. Positively, the caregiver described <Patient's name> as loving towards friends, family, and pets. He cares greatly about people around him and is sympathetic when they are sad. He loves entertaining people and joking around.

The *Children's Sleep Habits Questionnaire (CSHQ; Owens 2000.)* Sleep disorders in children are often under-diagnosed. In children with Fetal Alcohol Spectrum Disorders, objective data on the presence of increased sleep disorders are emerging. Therefore, <Patient's name>'s caregiver was administered the CSHQ, which is a validated screening tool for identifying school-aged children with a possible sleep disorder. The CSHQ focuses on sleep disorders common to this age group in three domains: Dyssomnias, Parasomnias, and Sleep-Disordered Breathing. <Patient's name> scored 35 out of a possible 99 points. A score of 39 or higher reflects a potential sleep problem. Based on the CSHQ and parent interview, a referral to a sleep specialist is not indicated.

Motor/Sensory/Developmental Screen at chronological age 10.2 years:

The *Short Sensory Profile* measures a caregiver's report of behaviors related to sensory processing and integration abilities. The Short Sensory Profile is a standardized questionnaire of sensory processing abilities in children ages 3 to 10 years. The scores in each category are classified as Typical Performance, Probable Difference or Definite Difference. Probable or Definite Differences may suggest sensory processing and integration difficulties that are affecting behavior and daily life. On this test, <Patient's name> received the following scores:

SSP	
Test/Subtest	**Outcome**
Total Test	definite difference
Tactile Sensitivity	typical performance
Taste/Smell Sensitivity	probable difference
Movement Sensitivity	typical performance
Under-responsive/Seeks Sensation	definite difference
Auditory Filtering	definite difference
Low Energy/Weak	definite difference
Visual/Auditory Sensitivity	probable difference

Per caregiver report, it was endorsed that <Patient's name> has strengths in the areas of tactile sensitivity and movement sensitivity and challenges in the areas of taste/smell sensitivity, under-responsive/seeks sensation, auditory filtering, low energy/weak, and visual/auditory sensitivity. Results suggest that processing sensory information is challenging for <Patient's name>, and this may account for some of the behaviors that caregivers identified as concerning (e.g., difficulty staying on task, trouble listening to directions, avoidance of self-care tasks).

The *Developmental Test of Visual Motor Integration, 6th Edition (VMI-6)* measures eye-hand coordination copying various geometric forms of increasing complexity. Results on the VMI suggest that <Patient's name>'s visual motor skills are at the 2nd percentile range (standard score 70), placing his performance significantly below the average range when compared to same age peers.

VMI	
Test	Standard Score
VMI	70
Visual Perception	110
Motor Coordination	73

<Patient's name> received a standard score of 110 for visual perception (75th percentile), placing his performance in the average range. <Patient's name> received a standard score of 73 for motor coordination (4th percentile), placing his performance in the below average range. He would benefit from handwriting support and accommodations (e.g. learning to keyboard).

The *Quick Neurological Screening Test-3R (QNST-3R)* is a screening tool that measures neurological soft signs in ages 5 years of age through adulthood. It consists of items adapted from neurologic and neuropsychological examinations that sample fine and gross motor coordination, balance and vestibular function, visual and auditory perceptual skills, motor planning and sequencing, and spatial organization. Items on the QNST-3 reflect measures of neurological maturation or integrity. Deficient performance on several of these measures may be suggestive of an underlying developmental or neurological basis for learning or behavioral problems. Scores fall into one of three categories 1) Normal indicates performance at or above the 25th percentile; 2) Moderate Discrepancy indicates performance in the 6th through 25 percentile and 3) Severe Discrepancy indicates performance in the 5th percentile or lower. On this measure, <Patient's name> received an overall raw score of 58, which falls into the Severe Discrepancy category for a child his age.

<Patient's name> was cooperative and worked hard throughout the screening today. When asked to write a sentence, <Patient's name> remembered the sentence and demonstrated good spacing, but he struggled with letter sizing, line use, mixing upper- and lower-case letters, and overall legibility. <Patient's name> held the pencil in his right hand using an efficient tripod grasp. Although he has a good pencil grasp, <Patient's name> fatigued quickly during paper and pencil tasks. He would benefit from handwriting support and accommodations (e.g. learning to keyboard).

<Patient's name> was able to match shapes and skip for thirty feet, but he had difficulty with visual tracking, remembering and repeating patterns, and spatial awareness. Activities that required visual-motor integration (e.g. copying shapes), fine motor coordination (e.g. mazes), motor planning, strength/endurance, bilateral coordination, static balance (e.g. standing on one foot) and dynamic balance (e.g. walking on a line backwards) were also very challenging for him. He benefited from structure, sensory supports (e.g. a quiet room, movement breaks), and a reward system (e.g. verbal praise). <Patient's name> is a sensitive, creative, and engaging boy who was a pleasure to work with!

Language Screen at chronological age 10.2 years:

<Patient's name> came to clinic without previous speech-language testing. Results from today's assessment indicate age-appropriate language development at this time. Results are based on standardized testing, caregiver report, and structured clinical observations. Details presented below.

The *Children's Communication Checklist-2 (CCC-2)* is a parent-report checklist that assists in identifying communication problems. <Patient's name>'s caregiver completed this checklist and he received the following scores:

CCC-2			
Scale	**Scaled Score**	**Composite**	**Percentile**
Speech	5		5
Syntax	10		50
Semantics	3		1
Coherence	4		2
Initiation	7		16
Scripted Language	3		1
Context	7		16
Nonverbal Communication	6		9
Social relations	5		5
Interests	6		9
General Communication Composite	45	**74**	4
Social Interaction Difference Index (SIDI)	**2:** This score is in the expected range		

Results of this caregiver questionnaire indicate concerns for <Patient's name>'s overall success as a communicator with a General Communication Composite score of 74, where most children receive scores between 85 and 115 and lower scores indicate more concern. His pattern of performance indicates the most concern for vocabulary (semantics), coherence/organization of communication, and reliance on scripted language. Strengths include grammar (syntax), initiation, and use of context.

The *Clinical Evaluation of Language Fundamentals - 4th Edition (CELF-4)* examines an individual's grasp of the relationships among semantics, syntax/morphology, and pragmatics (form, content, and use) and the interrelated domains of receptive and expressive language. On this test, <Patient's name> received the following scores:

CELF-4	
Scaled Scores: scores between 7 and 13 are expected	
Formulated Sentences	12
Word Classes-Total	9
Word Classes-Receptive	9
Word Classes-Expressive	9

Results indicate age-appropriate development of grammar and vocabulary at this time.

Structured observations during today's assessment indicated that <Patient's name> uses an age-appropriate range of vocabulary in grammatical sentences to meet an expected range of communicative functions. He engages in reciprocal conversations, responds to and asks questions, shares personal experiences and opinions, clarifies messages, requests, uses humor, comments, explains, and uses language to problem solve. He provides his listener with background information to support understanding, organizes his information appropriately, and uses idioms appropriately to sustain engagement and convey his attitude/opinion.

Taken together these results indicate that language and discourse skills are a strength that <Patient's name> can use to support his access to strategies supporting other areas that may be more challenging for him.

Despite age-appropriate language development at this time, <Patient's name>'s prenatal alcohol exposure and early medical history are a risk for difficulty with later-developing, more complex aspects of language. Progress in this and all academic areas should be closely monitored so that appropriate support can be put in place.

Summary of Psychometric Assessments of Brain Function:

<Patient's name> came to clinic today with previous neurodevelopmental testing indicating moderate concerns for written expression, mathematics, adaptive skills, and motor development. There are moderate concerns for behavior, social skills, sleep, and adaptive skills. There are previous diagnoses including attention-deficit/hyperactivity disorder and attachment disorder. He has an individualized education program supporting academics, adaptive skills, and behavior.

Today's assessment indicated significant impairment (i.e., performance two or more standard deviations below the mean on standardized testing) in sensory-motor development (e.g., visual-motor integration, visual tracking, spatial awareness, motor planning, static and dynamic balance), in verbal memory/learning, executive functioning (performance monitoring, cognitive flexibility, inhibition). Definite differences in sensory processing were documented (sensory seeking, low-energy week, auditory attention).

Caregiver Interview:

We had the pleasure of interviews with <Patient's name>'s caregivers. His caregivers expressed concerns about <Patient's name>'s growth deficiency and noted that he is very smart but inattentive. He is eating better, sleeping well, and socially successful. Parents report <Patient's name> does well with lists and routines but struggles with multistep instructions. <Patient's name> is inattentive and can be quite impulsive, especially in answering questions before the question is finished and figuring out if he knows the answer. He rapidly cycles through activities but gets bored easily. It takes <Patient's name> longer to learn new academic skills and games, and he has inconsistent retrieval of learned information. He frequently has word recall and word mix-up challenges. Socially, <Patient's name> is very social and makes friends easily from age 5 to 15; he does misinterpret social scenarios at times. His motor abilities have been impacted by lower stamina, strength, and speed. <Patient's name> has so many strengths, including his inventive game characters, having excellent humor, and being social and kind.

Alcohol Exposure:
<Patient's name>'s biological mother confirmed she drank alcohol during this pregnancy, although the exact quantities, frequency, and timing of alcohol use during pregnancy were not reported. Confirmed exposure, but of unknown quantity or frequency, meets the 4-Digit Diagnostic criteria for an Alcohol Rank 3.

Co-Morbidities
When assessing the potential impact of prenatal alcohol exposure on an individual, it is important to document all other significant prenatal and postnatal exposures and events, for they too serve as potential risk factors for cognitive/behavioral dysfunction. Prenatal risk factors may include, but are not limited to poor prenatal care, genetic conditions that may run in the family and other potential teratogenic exposures. Postnatal risk factors may include but are not limited to perinatal difficulties, adverse home environments, multiple home placements, neglect, abuse and other events that could explain brain dysfunction like head injuries or a patient's own chronic substance abuse. While it is not possible with today's medical technology to determine which risk factor(s) may be responsible for each adverse outcome, it remains important to document all exposures and events and take them into consideration when deriving a diagnosis and intervention plan.

Potential risk factors reported to the clinic to date include:

Prenatal Rank 3:
- No prenatal care.
- Tobacco use during pregnancy

Postnatal Rank 3:
- Some neglect birth to 3 years of age.
- One out of home placement at 3 years of age.

The next section of the Medical Summary Report is the Intervention Recommendations. The intervention section starts on a new page so it can be shared with schools while maintaining the medical confidentiality of the information in the first section of the report. These recommendations cover a wide range of needs: medical, education, mental health, family support, community-based programs and activities, and anticipatory guidance (Jirikowic et al., 2010). The intervention recommendations below are reflective of what is generally available in Washington State in the 2020s. Availability of services will vary considerably by community and region worldwide.

Diagnosis: Fetal Alcohol Syndrome

Intervention Recommendations

Based on records review and assessments, observations and caregiver interviews completed today by the FASDPN interdisciplinary team, the following recommendations are offered:

A. Medical

Please note that recommendations that involve medical issues should be shared with <Patient's name>'s primary care physician before initiating any action.

A. <Patient's name> has been receiving excellent general and specialty medical care. Continue regular medical & dental checkups, specialty follow up, and periodic hearing/vision screenings.

B. <Patient's name> has unusually short palpebral fissure lengths (eye openings). If not already performed, he would benefit from a comprehensive ophthalmology evaluation that includes visualization of retina and optic nerve, as we might expect associated ophthalmological findings such as refractive errors, strabismus and fundus abnormalities.

C. <Patient's name>'s ADHD is having an impact on his performance. It could be worth another trial of ADHD medication. Stimulant medications could impact his growth but might be cautiously used, or you could try non-stimulant long-acting alpha-agonists.

B. Education

- <Patient's name> will continue to benefit from an individualized education program (IEP) to support his challenges with learning as a student with other health impairment. He will continue to benefit from support in adaptive, behavior, mathematics, reading, and written language skills. We would recommend that an occupational therapist be a part of his team to support fine motor skills (handwriting) and sensory processing needs. <Patient's name>'s impairments in sensory-motor development represent an important barrier to his access to age-appropriate curriculum and educational activities.

    - Sensory accommodations are recommended. Examples are a "wiggle pad" or a weighted lap pillow to be used during the school day or in homework sessions.
    - Modifications of the classroom environment may be useful, such as a "quiet office" space to assist in focusing at school, headphones, or the use of techniques such as keyboarding. Recess is an important chance for movement, which should *never* be eliminated as a classroom discipline strategy or to complete assignments. Scheduled "down time" in a quieter, calmer space can help. The occupational therapist (OT) at school or in a private practice should be able to consult on environmental modifications and sensory accommodations.
    - A good resource for educators is the book: *Building Sensory Friendly Classrooms* by Rebecca Moyes

- If not already in place, we also recommend that the accommodations from which <Patient's name> benefits be formalized in a written plan (so that accommodations will be available now and in future educational and workplace settings). Accommodations that are important for <Patient's name> include:
  - Preferential seating and a safe place to retreat when <Patient's name> needs to self-regulate.
  - Allow extra time for testing (up to 1.5X extra) and extra time on math and writing assignments.
  - Allow testing to occur in smaller settings with reduced distractions.
  - Reduce volume of workload so that <Patient's name> does not have to work longer than peers and thus miss opportunities for other extracurricular opportunities.
  - Allow extra time for processing (for example, when answering a question in class, wait longer for <Patient's name> to formulate an answer).
  - Have instructions presented in visual form (written) rather than just verbally stated.
  - After a period of learning/ instruction, provide a break so that <Patient's name> can be ready for new learning.
  - Identify a "trusted-adult" mentor that <Patient's name> can go to for help managing stress/anxiety.
  - Time-ins (with the teacher or trusted adult) versus time-out.

- Additional resources for children with prenatal alcohol exposure:
  - *Teaching Students with Fetal Alcohol Spectrum Disorder* https://depts.washington.edu/fasdpn/pdfs/teaching-students-with-fasd-2004.pdf
  - *Fetal Alcohol Spectrum Disorders Education Strategies* https://depts.washington.edu/fasdpn/pdfs/FASD%20Educational%20Strategies%20Handbook.pdf

C. Mental Health

- Continued counseling to support the development of emotion/behavior regulation and coping strategies is recommended. Cognitive Behavioral Therapy (CBT) is an evidence-based therapeutic intervention that has been shown to be an effective therapeutic modality with many individuals <Patient's name>'s age. Additionally, there is scientific data to support "mindfulness approaches" to emotion regulation, stress management, and improving life function. There are books that can teach people how to use mindfulness in daily life, such as *The Mindfulness Solution: Everyday Practices for Everyday Problems*, by Ronald Siegel and *The Yes Brain: How to Cultivate Courage, Curiosity, and Resilience in Your Child*, by Daniel Siegel and Tina Bryson.

  - <Patient's name> has experienced intrusive comments about his medical issues from peers. One aspect of therapy that would be helpful is role-playing responses to such comments and questions.
  - Continue to closely monitor <Patient's name>'s mental health as he develops so that appropriate support can be put in place if the need arises.

D. Family Support

- Here are several parenting resources for FASD:
  - FASD Parenting Toolkit (https://adai.uw.edu/fasdtoolkit/parents.htm) is available from the University of Washington
  - The CDC has a number of FASD resources – https://www.cdc.gov/ncbddd/fasd/families.html
  - Making Sense of Fetal Alcohol Spectrum Disorder (FASD) –
  - https://www.nhsaaa.net/media/5702/fasd-info-for-parents-carers-online.pdf is an excellent resource
  - Proof Alliance (https://www.proofalliance.org) has a nice 3-page handout on Parenting Children with FASD – https://adoptmed.org/s/Parenting-children-with-FASD.pdf
  - FASD United (https://fasdunited.org/index.php/tools-for-parents-and-caregivers/) has many tools and resources for parents
  - We also like Parenting Children with Affected by FAS: A Guide for Daily Living – https://adoptmed.org/s/daily_guide_for_living.pdf

- Because of the high maintenance and complexity of raising children who are prenatally exposed to alcohol, a resource such as The National Organization on Fetal Alcohol Syndrome Washington State (NOFAS Washington) is recommended. They provide programs such as FASt Friends (a caregiver and community provider support network), family summer camps, social skills and friendship groups, and online support. www.nofaswa.org..

E. Community-based Programs and Activities

- Continue to seek opportunities to participate in extracurricular activities in supervised and structured settings. This can provide positive social experiences, mentorship, and enjoyable and successful free time activities. Possibilities include therapeutic horseback riding, Boys and Girls Club, martial arts, Outdoors-for-All, swimming lessons, choir, gymnastics, and dance.
  - Information can be obtained at https://outdoorsforall.org

- A blended Special Olympics program (http://specialolympicswashington.org) could be a lovely way to work on <Patient's name>'s physical skills and help regulate his emotions.

- Martial arts provide many benefits that can include improvements in sensory-motor, emotional self-regulation, peer interaction, and self-confidence. Kung Fu Northwest is one local option. https://www.marysvillemartialarts.com/

- Consider involvement in music and theater activities. These activities could provide <Patient's name> with social connections and be an avenue for him to explore vocational and recreational interests that can continue throughout his life.

F. Anticipatory Guidance

- <Patient's name>'s genetic history and prenatal exposures place him at high risk for developing challenges with drug and alcohol abuse and dependence. We recommend that developmentally appropriate prevention education begin very early and be repeated regularly and often. This type of education is important for children, and will remain important through elementary, middle school, and high school. The social lessons learned about alcohol at home are an important component of this education process.

- We strongly encourage all caregivers to pursue avenues of self-care, including respite care opportunities, to ensure they may continue parenting as effectively as possible.

It was a pleasure seeing <Patient's name> in clinic today.
If you have any questions, please call our clinic <phone number>.

<Name of Clinic>

Generic First Page of Medical Summary Report

Note the first page of the Medical Summary Report above has a generic description of the diagnosis. The generic descriptions of all 19 Diagnostic Categories (A-S) are presented below. Simply copy and paste the generic description below that matches the patient's diagnosis into page 1 of the patient's Medical Summary Report. The text may require minor alterations or additions to conform to the specifics of an individual case. Diagnoses in red font are broadly under the umbrella of FASD.

A.
Diagnosis: Fetal Alcohol Syndrome

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant brain damage/dysfunction that occur in individuals exposed to alcohol during gestation. On the attached pages are the specific findings in this patient's case that confirm they meet criteria for FAS.

Although this patient meets criteria for FAS, this does not mean that alcohol exposure during pregnancy is the only cause of the patient's current challenges. Other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during gestation, and various experiences since birth. Such factors may partly explain why there is so much variability in the kinds of specific challenges that patients with FAS have.

Individuals with FAS have significant brain damage/dysfunction and should be viewed as individuals with disabilities. This FAS diagnosis has implications for educational planning, societal expectations, and health. On the attached sheets you will find a list of specific concerns that have been identified that need attention.

B.
Diagnosis: Sentinel physical finding(s) / static encephalopathy / alcohol exposed

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of brain damage/dysfunction in individuals exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, some but not all the characteristic growth and facial features associated with FAS were present and there was evidence of significant brain damage and/or dysfunction as you will see noted on the attached pages. There was also a confirmed history of exposure to alcohol during gestation. These outcomes meet the criteria for *Sentinel physical finding(s) / static encephalopathy / alcohol exposed*. The patient's brain abnormalities may include structural, neurological and/or functional problems. The diagnosis of *Sentinel physical finding(s) / static encephalopathy* in the presence of alcohol exposure does not mean that alcohol is the only cause of the problem. Other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during gestation, and various experiences since birth. These kinds of differences may partly explain why there is so much variability in the kinds of specific challenges that patients with static encephalopathy and alcohol exposure have.

Individuals with *Static encephalopathy* have significant brain damage/dysfunction and should be viewed as individuals with disabilities. The diagnosis of *Static encephalopathy* has implications for educational planning, societal expectations, and health. On the attached sheets you will find a list of specific problems that have been identified that need attention.

C.
Diagnosis: Static encephalopathy / alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of brain damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, no growth deficiency or characteristic set of facial features were found, but there was evidence of significant brain damage/dysfunction as you will see noted on the attached pages. There was also a confirmed history of exposure to alcohol during gestation. These outcomes meet the criteria for S*tatic encephalopathy / alcohol exposed*. The patient's brain abnormalities may include structural, neurological and/or functional problems. The diagnosis of *Static encephalopathy* in the presence of prenatal alcohol exposure does not mean that alcohol is the only cause of the problem. Other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during gestation, and various experiences since birth. These kinds of differences may partly explain why there is so much variability in the kinds of specific challenges that patients with static encephalopathy and alcohol exposure have.

Individuals with *Static encephalopathy* have significant brain damage/dysfunction and should be viewed as individuals with disabilities. The diagnosis of S*tatic encephalopathy* has implications for educational planning, societal expectations, and health. On the attached sheets you will find a list of specific problems that have been identified that need attention.

D.
Diagnosis: Sentinel physical finding(s) / neurodevelopmental disorder / alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant brain damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, some or all the characteristic growth and facial features associated with FAS were present and there was evidence of brain dysfunction as you will see noted on the attached pages. There was also a confirmed history of exposure to alcohol during gestation. These outcomes meet the criteria for *Sentinel physical finding(s) / neurodevelopmental disorder / alcohol exposed*. The diagnosis of *Sentinel physical finding(s) / neurodevelopmental disorder* in the presence of alcohol exposure does not mean that alcohol is the only cause of the problem. Other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during gestation, and various experiences since birth. These kinds

of differences may partly explain why there is so much variability in the kinds of specific challenges that patients with neurodevelopmental disorder and alcohol exposure have.

<Include the following paragraph if the patient is under 8 years of age at the time of diagnosis.>

The patient is still quite young and remains at risk for additional learning and developmental challenges because of prenatal alcohol exposure. It is important to note that the majority of children who have cognitive or other developmental challenges caused by prenatal alcohol exposure do not exhibit these challenges fully until school-age. All those working with and caring for the patient are advised to keep monitoring closely. This team would very much like to see the patient in clinic again to update assessment of brain functioning and overall diagnosis when the patient is old enough to allow for a broader range and depth of assessment. We invite the patient to return to our clinic after their 9th birthday. In the meantime, development should be closely monitored.

Individuals with *Neurodevelopmental Disorder* have brain damage/dysfunction and should be viewed as individuals with disabilities. This diagnosis of *Neurodevelopmental disorder* has implications for educational planning, societal expectations, and health. On the attached sheets you will find a list of specific problems that have been identified that need attention.

E.
Diagnosis: Neurodevelopmental disorder / alcohol exposed

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of significant brain damage/dysfunction in individuals exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, no growth deficiency or characteristic set of facial features were found, but there was evidence of brain dysfunction as you will see noted on the attached pages. There was also a confirmed history of exposure to alcohol during gestation. These outcomes meet the criteria for *Neurodevelopmental disorder / alcohol exposed*. The diagnosis of *Neurodevelopmental disorder* in the presence of prenatal alcohol exposure does not mean that alcohol is the only cause of the problem. Other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during gestation, and various experiences since birth. These kinds of differences may partly explain why there is so much variability in the kinds of specific challenges that patients with neurodevelopmental disorder and alcohol exposure have.

<Include the following paragraph if the patient is under 8 years of age at the time of diagnosis.>

The patients is still quite young and remains at risk for additional learning and developmental challenges because of prenatal alcohol exposure. It is important to note that the majority of children who have cognitive or other developmental challenges caused by prenatal alcohol exposure do not exhibit these challenges fully until school-age. All those working with and caring for the patient are advised to keep monitoring closely. This team would very much like to see the patient in clinic again to update assessment of brain functioning and overall diagnosis when the patient is old enough to allow for a broader range and depth of assessment. We invite the patient to return to our clinic after their 9th birthday. In the meantime, development should be closely monitored.

Individuals with *Neurodevelopmental Disorder* have brain damage/dysfunction and should be viewed as individuals with disabilities. This diagnosis of *Neurodevelopmental disorder* has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

F.
Diagnosis: Sentinel physical finding(s) / alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant brain damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

Some individuals present with growth deficiency and/or the characteristic facial features, but do not have evidence of brain damage or dysfunction. We refer to this condition as *Sentinel physical finding(s) / Alcohol exposed.* We do not consider this diagnosis under the umbrella of FASD. On the attached sheets are the specific findings in this patient's case.

<Include the following paragraph if the patient is under 8 years of age at the time of diagnosis.>

The patient is still quite young and remains at risk for additional learning and developmental challenges because of prenatal alcohol exposure. It is important to note that the majority of children who have cognitive or other developmental challenges caused by prenatal alcohol exposure do not exhibit these challenges fully until school-age. All those working with and caring for the patient are advised to keep monitoring closely. This team would very much like to see the patient in clinic again to update assessment of brain functioning and overall diagnosis when the patient is old enough to allow for a broader range and depth of assessment. We invite the patient to return to our clinic after their 9th birthday. In the meantime, development should be closely monitored.

G.
Diagnosis No sentinel physical findings or brain abnormalities detected / alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant brain damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, we conclude they were exposed to alcohol during gestation, but no physical findings or brain abnormalities were detected at this time, as you will see noted on the attached pages. No alcohol-related diagnoses are offered at this time.

<Include the following paragraph if the patient is under 8 years of age at the time of diagnosis.>

The patient is still quite young and remains at risk for additional learning and developmental challenges because of prenatal alcohol exposure. It is important to note that the majority of children who have cognitive or other developmental challenges caused by prenatal alcohol exposure do not exhibit these challenges fully until school-age. All those working with and caring for the patient are advised to keep

monitoring closely. This team would very much like to see the patient in clinic again to update assessment of brain functioning and overall diagnosis when the patient is old enough to allow for a broader range and depth of assessment. We invite the patient to return to our clinic after their 9th birthday. In the meantime, development should be closely monitored.

H.
Diagnosis Sentinel physical finding(s) / static encephalopathy / alcohol exposure unknown

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of significant brain damage/dysfunction in individuals exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, some but not all of the characteristic growth and/or facial features associated with FAS were present, and there was evidence of significant brain damage/dysfunction as you will see noted on the attached pages. In this situation, we use the term *Sentinel physical finding(s) /Static encephalopathy/ alcohol exposure unknown* to describe the patient's condition. Although it is unknown whether this patient was exposed to alcohol during gestation, other factors could also be contributing to the patient's current cognitive/behavioral problems such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. These kinds of differences may partly explain why there is so much variability in the kinds of specific difficulties that patients with brain abnormalities have.

The diagnosis made today is based on the information available at the time of this assessment. In the event a confirmed history of alcohol exposure is obtained, then a re-evaluation would be appropriate. Alternately other birth defect syndromes or conditions not related to alcohol exposure may also need reconsideration.

Individuals with *static encephalopathy* have evidence of significant brain damage/dysfunction and should be viewed as a person with a disability. The diagnosis of *static encephalopathy* has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

I.
Diagnosis: Static encephalopathy / alcohol exposure unknown

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant brain damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, no growth deficiency or characteristic set of facial features were found, but there was evidence of significant brain damage/dysfunction as you will see noted on the attached pages. In this situation, we use the term *Static encephalopathy / alcohol exposure unknown* to describe the patient's condition. Although it is unknown whether this patient was exposed to alcohol during gestation, other factors could be contributing to the patient's current cognitive/behavioral problems such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth.

The diagnosis made today is based on the information available at the time of this assessment. In the event a confirmed history of alcohol exposure is obtained then a re-evaluation would be appropriate. Alternately other birth defect syndromes or conditions not related to alcohol exposure may also need reconsideration.

Individuals with *Static encephalopathy* have evidence of significant brain damage/dysfunction and should be viewed as individuals with disabilities. The diagnosis of *Static encephalopathy* has implications for educational planning, societal expectations, and health. On the attached pages you will find a list of specific problems that have been identified that need attention.

J.

Diagnosis: Sentinel physical finding(s) / neurodevelopmental disorder / alcohol exposure unknown

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant brain damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, some or all the characteristic growth and facial features associated with FAS were present and there was evidence of brain dysfunction as you will see noted on the attached pages. These outcomes meet the criteria for *Sentinel physical finding(s) / neurodevelopmental disorder / alcohol exposure unknown*. Although it is unknown whether this patient was exposed to alcohol during gestation, other factors could be contributing to the patient's current cognitive/behavioral problems such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth.

The diagnosis made today is based on the information available at the time of this assessment. In the event a confirmed history of alcohol exposure is obtained then a re-evaluation would be appropriate. Alternately other birth defect syndromes or conditions not related to alcohol exposure may also need reconsideration.

Individuals with *Neurodevelopmental disorder* have evidence of brain dysfunction and should be viewed as individuals with disabilities. The diagnosis of *Neurodevelopmental disorder* has implications for educational planning, societal expectations, and health. On the attached pages you will find a list of specific problems that have been identified that need attention.

K.

Diagnosis: Neurodevelopmental disorder / alcohol exposure unknown

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of significant brain damage/dysfunction in individuals exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, none of the characteristic growth and facial features associated with FAS were present and there was evidence of brain dysfunction as you will see noted on the attached pages. These outcomes meet the criteria for Neurodevelopmental *disorder / alcohol exposure*

unknown. Although it is unknown whether this patient was exposed to alcohol during gestation, other factors could be contributing to the patient's current cognitive/behavioral problems such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth.

The diagnosis made today is based on the information available at the time of this assessment. In the event a confirmed history of alcohol exposure is obtained a re-evaluation would be appropriate. Alternately other birth defect syndromes or conditions not related to alcohol exposure may also need reconsideration.

Individuals with *neurodevelopmental disorder* have evidence of brain dysfunction and should be viewed as individuals with disabilities. This diagnosis of *neurodevelopmental disorder* has implications for educational planning, societal expectations, and health. On the attached sheets you will find a list of specific problems that have been identified that need attention.

L.
Diagnosis: Sentinel physical finding(s) / alcohol exposure unknown

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant brain damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, some or all the characteristic growth and facial features associated with FAS were present but there was no evidence of brain abnormalities as noted on the attached pages. These outcomes meet the criteria for *Sentinel physical finding(s) / alcohol exposure unknown*. Although it is unknown whether this patient was exposed to alcohol during gestation, other factors could be contributing to the patient's current cognitive/behavioral problems such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth.

The diagnosis made today is based on the information available at the time of this assessment. In the event a confirmed history of alcohol exposure is obtained, a re-evaluation would be appropriate. Alternately other birth defect syndromes or conditions not related to alcohol exposure may need consideration.

M.
Diagnosis: No sentinel physical finding(s) or brain abnormalities detected / alcohol exposure unknown

In this current assessment, it is unknown whether or not this patient was exposed to alcohol during gestation. Furthermore, no characteristic physical findings or brain abnormalities were detected in our examination.

No alcohol-related diagnoses are offered at this time. In the event a confirmed history of alcohol exposure is obtained, a re-evaluation would be appropriate.

N.
Diagnosis Sentinel physical finding(s) / static encephalopathy / no alcohol exposure

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of brain damage/dysfunction in individuals exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, some but not all the characteristic growth and facial features associated with FAS were present and there was evidence of significant brain damage and/or dysfunction as you will see noted on the attached pages. Since prenatal alcohol exposure was confirmed absent, the full spectrum of FASD is ruled out. These outcomes meet the criteria for *Sentinel physical finding(s) / static encephalopathy / no alcohol exposure*. The diagnosis of *Sentinel physical finding(s) / static encephalopathy* in the confirmed absence of prenatal alcohol exposure suggests other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during gestation, and various experiences since birth. The physical findings may suggest that other syndrome diagnoses be considered.

Individuals with *static encephalopathy* have significant brain damage/dysfunction and should be viewed as individuals with disabilities. The diagnosis of *static encephalopathy* has implications for educational planning, societal expectations, and health. On the attached sheets you will find a list of specific problems that have been identified that need attention.

O.
Diagnosis: Static encephalopathy / no alcohol exposure

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of significant brain damage/dysfunction occurring in patients exposed to alcohol during gestation.

In this patient's case, some but not all the characteristic growth and facial features associated with FAS were present and there was evidence of significant brain damage and/or dysfunction as noted on the attached pages. Since prenatal alcohol exposure was confirmed absent, the full spectrum of FASD is ruled out. The outcomes observed in this patient meet the criteria for *Static encephalopathy / no alcohol exposure*. The diagnosis of *Static encephalopathy* in the confirmed absence of prenatal alcohol exposure suggests other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during gestation, and various experiences since birth.

Individuals with *Static encephalopathy* have significant brain damage/dysfunction and should be viewed as individuals with disabilities. The diagnosis of *Static encephalopathy* has implications for educational planning, societal expectations, and health. On the attached sheets you will find a list of specific problems that have been identified that need attention.

P.
Diagnosis Sentinel physical finding(s) / neurodevelopmental disorder / no alcohol exposure

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of brain damage/dysfunction in individuals exposed to alcohol during gestation.

As noted on the attached pages, some but not all the characteristic growth and facial features associated with FAS were present and there was evidence of brain damage/dysfunction. A confirmed absence of prenatal alcohol exposure, however, rules out FASD. These outcomes meet the criteria for *Sentinel physical finding(s) / neurodevelopmental disorder / no alcohol exposure*. A confirmed absence of prenatal alcohol exposure suggests other factors could be contributing to the patient's current cognitive/behavioral problems such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. The observed physical findings may suggest that other syndrome diagnoses be considered.

Individuals with *Neurodevelopmental disorder* have evidence of brain dysfunction and should be viewed as a person with a disability. The diagnosis of *Neurodevelopmental disorder* has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

Q.
Diagnosis: Neurodevelopmental disorder / no alcohol exposure

Fetal alcohol syndrome (FAS) is defined by evidence of growth deficiency, a specific set of facial characteristics, and evidence of significant brain damage/dysfunction in individuals exposed to alcohol during gestation.

As noted on the attached pages, some but not all of the characteristic growth and facial features associated with FAS were present and there was evidence of brain damage/dysfunction. A confirmed absence of prenatal alcohol exposure, however, rules out FASD. These outcomes meet the criteria for *Neurodevelopmental disorder / no alcohol exposure*. A confirmed absence of prenatal alcohol exposure suggests other factors could be contributing to the patient's current cognitive/behavioral problems such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth.

Individuals with *Neurodevelopmental disorder* have evidence of brain dysfunction and should be viewed as a person with a disability. The diagnosis of *Neurodevelopmental disorder* has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

R.
Diagnosis: Sentinel physical finding(s) / no alcohol exposure

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of minor facial anomalies, and evidence of significant brain damage/dysfunction occurring in patients exposed to alcohol during gestation.

In this patient's case, some or all the characteristic growth and facial features associated with FAS were present but there was no evidence of brain abnormalities as noted on the attached pages. A confirmed absence of prenatal alcohol exposure rules out FASD. The outcomes observed in this patient meet the criteria for *Sentinel physical finding(s) / no alcohol exposure*. The physical findings might suggest that other syndrome diagnoses be considered.

S.
Diagnosis No physical findings or brain abnormalities detected / no alcohol exposure

In this current assessment, we conclude that this patient was not exposed to alcohol during gestation. Furthermore, no specific cognitive, behavioral, or characteristic physical findings were detected in our examination. The full spectrum of FASD is ruled-out. No diagnoses are offered at this time.

IX. Appendices

1. FASDPN WEBSITE https://depts.washington.edu/fasdpn/index.htm

The University of Washington FASDPN website provides a comprehensive overview of all clinical, research, and training activities conducted by the FASDPN. Below are links to FASDPN publications, and 4-Digit Code training opportunities, diagnostic forms, Lip-Philtrum Guides and the FAS Facial Photographic Analysis Software. All resources listed below are available free of charge.

A. Publications

Literature published by the FASDPN since 1993.

B. 4-Digit Code TRAINING PROGRAMS AND ONLINE COURSE

i. One-Day Clinical Observational Training Program. This training provides healthcare, social service, and educational professionals with insight into their role in the community for screening, referral, diagnosis, prevention, and intervention of FASD.

ii. Two-Day Interdisciplinary Clinical Training Program. This training program is offered twice a year at the University of Washington. Interdisciplinary clinical teams are taught how to use the 4-Digit Diagnostic Code in an interdisciplinary clinical setting.

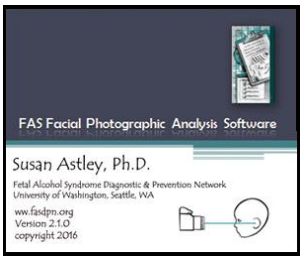
iii. FASD 4-Digit Code Online Course. This accredited course will provide healthcare, educational, and social service professionals with detailed instruction on the use of the 4-Digit Diagnostic Code in an interdisciplinary clinical setting.

A. Diagnostic Forms and Medical Summary Templates.

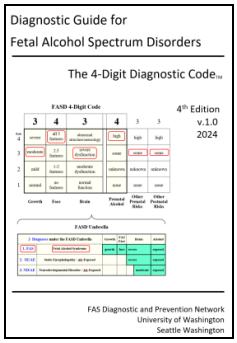
Electronic versions of the 4-Digit Code Diagnostic Forms are available free on the FASDPN website. An electronic template of our Medical Summary Report (see section VII) is available free (contact Susan Astley Hemingway Ph.D (astley@uw.edu)).

C. DIAGNOSTIC TOOLS AND SOFTWARE

i. FAS Facial Photographic Analysis Software (2016). This software is intended for use by healthcare and research professionals. The software allows one to measure the magnitude of expression of the key facial features of FAS from a 2D digital facial photograph. Video demonstration of the software. A free copy of the software can be obtained by submitting the FASDPN order form.



iii. FASD 4-Digit Diagnostic Guide (2024) and Lip-Philtrum Guides. Free electronic copies of the "*Diagnostic Guide for Fetal Alcohol Spectrum Disorders: The 4-Digit Diagnostic Code, 2024*" and the *Lip-Philtrum Guides* can be ordered from the FASDPN.



2. NEW PATIENT INFORMATION FORM (NPIF) (See form below).

This form is sent to families requesting a diagnostic evaluation at the University of Washington FASDPN clinic. The form allows the family to share with the clinic why they are seeking a diagnostic evaluation, what they hope to gain from the evaluation and what they currently know about the patient's exposure(s) and outcomes. We do not expect the family to be able to respond to all requests for information on the Form. During the intake, the clinical team will also obtain and review (with caregiver consent) all medical, school, and social service records on the patient, in preparation for the evaluation. This New Patient Information form serves as a clinical intake form. Families can download the NPIF from the FASDPN website along with instructions for how to request a FASD diagnostic evaluation. At the Seattle FASDPN clinic, a confirmed prenatal alcohol exposure is the only information required to be evaluated in the clinic. The NPIF is available in electronic fillable form on our website.

* This information may be available from the patient's physician or school nurse. If growth charts are available and can be photocopied and attached to this form, you need not fill out this section.

Physical Appearance and Health

1. **Photographs of the patient's face are very helpful to us.** The best photos are ones where the face fills the photo and the patient is not smiling.

   - Are such photographs available? ____ yes ____ no
   - Are one or two included with this form? ____ yes ____ no
   - Can others be brought to the clinic? ____ yes ____ no

2. **Was the patient born with (or later discovered to have) any birth defects (things like cleft lip, congenital heart defects, club foot, etc.)?** ____ yes ____ no _____ unknown

   If yes, please describe: _____

   _____

3. **Has this patient ever had:**

	yes	no	unknown		yes	no	unknown
Allergies	_____	_____	_____	Chronic illness of the heart	_____	_____	_____
Multiple ear infections	_____	_____	_____	Chronic illness of the kidneys	_____	_____	_____
Chronic sinusitis	_____	_____	_____	Chronic illness of the joints/limbs	_____	_____	_____
Chronic hearing loss	_____	_____	_____	Chronic illness of stomach/bowels	_____	_____	_____
Visual problems	_____	_____	_____				

4. **Has this patient ever had:**

   A. Operations (since birth) ____ yes ____ no ____ unknown

Describe Operation	Surgeon's Name	Patient's Age

   B. Any other hospitalizations ____ yes ____ no ____ unknown

Reason for Hospitalization	Hospital/Doctor	Patient's Age

Neurological Issues

1. **Has this patient ever had:**
   Seizures

   ____ yes ____ no ____ suspected ____ unknown

   Type: _____

   Age when seizure(s) started: _____

   Name(s) of medication(s) given? _____

2. **Has this patient ever had a head injury leading to unconsciousness or evaluation by a doctor?**

   ____ yes ____ no ____ unknown

   If yes, please describe _____

3. **Has the patient ever had a CT scan or MRI scan of the brain**

   ____ yes ____ no ____ unknown

   If yes, was it described to be abnormal? ____ yes ____ no ____ unknown

Attention Deficit and Hyperactivity

1. **Has the patient ever been evaluated for attention deficit/hyperactivity disorder (ADD / ADHD)**

   ____ yes ____ no ____ unknown

   If yes:

   When was the evaluation done? Age: _____ Date: _____

   Was the patient diagnosed with ADD or ADHD? ____ yes ____ no ____ unknown

   Was the patient ever treated for ADD or ADHD? ____ yes ____ no ____ unknown

   What medications have been tried?

Drug	**Dose**	**Ages**	**Response**

Mental Health Issues

1. Has the patient ever been evaluated by a psychiatrist, psychologist, or MH counselor?

____ yes ____ no ____ unknown

If yes, please list each psychiatrist, psychologist and/or counselor.

A. Type of professional: _____

Reason for assessment: _____

Type of therapy (i.e., behavioral, individual counseling, group counseling, family counseling, medicine): _____

_____

Age at the time of therapy: _____ Did the therapy help? ____ yes ____ no ____ unknown

If yes, how did it help? _____

_____

_____

B. Type of professional: _____

Reason for assessment: _____

Type of therapy (i.e., behavioral, individual counseling, group counseling, family counseling, medicine): _____

_____

Age at the time of therapy: _____ Did the therapy help? ____ yes ____ no ____ unknown

If yes, how did it help?_____

_____

_____

2. Has the patient ever been evaluated for mood problems (depression, anxiety, etc.) or phobia?

____ yes ____ no ____ unknown

If yes:

When was the evaluation(s) done? Age(s): _____ Date(s): _____

3. What medications have ever been tried and how well did they work?

Drug	Dose	Response	Currently Using?

School Issues

1. List ALL schools the patient has attended and the grades of attendance:

School	City	Grades Attended	Received Special Education, Resource Room, Tutoring, etc. yes	no	unknown

2. What learning problems does the patient have?

3. What behavioral problems does the patient have?

Alcohol Exposure

Please fill in this information as completely as possible.
This information is critical to the evaluation of the patient.

Alcohol use by the birth mother

- **Before pregnancy**: Average number of drinks consumed at one time: _____
  Maximum number of drinks consumed at one time: _____
  Average number of days per week (1 to 7) that alcohol was consumed: _____
  Type(s) of alcohol: __wine __beer __liquor __unknown ___other (specify) _____

- **During pregnancy:** Average number of drinks consumed at one time: _____
  Maximum number of drinks consumed at one time: _____
  Average number of days per week (1 to 7) that alcohol was consumed: _____
  Type(s) of alcohol: __wine __beer __liquor __unknown ___other (specify) _____

Which trimester(s) did the mother drink alcohol? ___ 1st ___2nd ___3rd ___unknown

	No	Yes	Unknown
Was the birth mother ever reported to have a problem with alcohol?	____	____	_____
Was the birth mother ever diagnosed with alcoholism?	____	____	_____
Did the birth mother ever receive treatment for alcohol addiction?	____	____	_____

If the above information is unknown, please provide any information that might help describe the mother's level of ALCOHOL USE DURING THIS PREGNANCY _____

_____

_____

What is the source(s) of this information on alcohol use? _____

_____

Did the birth mother use any of the following substances during pregnancy?

Yes	No	Unknown	Type	Please List Specific Substance(s)	Month(s) of Pregnancy
___	___	___	Drugs	_____	_____
___	___	___	Tobacco	_____	_____
___	___	___	Medications	_____	_____
___	___	___	X-rays	_____	_____

Information about the Patient's Biological Parents

Birth mother's name_____ Birth date _____

What to bring to Clinic

If the patient has had any of the following assessments, please bring them to Clinic on the day of your appointment if you have copies of the results. The Clinic will also make every effort to collect this information with your consent. This information is very important to the patient's diagnostic evaluation.

_____ Facial photographs of the patient from birth to 18 years of age, without a smile.

_____ Medical records which document the problems you have reported above.

_____ School Assessments including:
- Achievement tests
- IQ tests
- Language assessments
- Social Skills assessments
- Behavior assessments

_____ Neuropsychological Assessments

_____ Developmental Assessments (birth to 3 years of age) including:
- Motor Development (fine and gross motor)
- Cognitive Development

A Child with Fetal Alcohol Syndrome

Sterling K. Clarren, Heather Carmichael Olson, Sandra G.B. Clarren, and Susan J. Astley

Alcohol is a common human teratogen that, when ingested by a pregnant woman, can produce a wide array of fetal complications. The fetus's developing brain seems most sensitive to prenatal alcohol exposure: Alcohol-related brain damage can be quite diffuse, ranging from microcellular, neurochemical aberrations to macroscopic malformations (Stratton, Howe, & Battaglie, 1996). The neurological, cognitive, and behavior problems that arise from prenatal alcohol exposure are protean in their severity and diversity. Other prenatal determinants - for example, genetic factors or teratogenic exposures that lead to specific conditions, such as attention-deficit/hyperactivity disorder (ADHD) or learning disabilities-can further affect the developmental outcome of a child prenatally exposed to alcohol. Aversive experiences after birth and throughout life also can have a profound influence on an individual's performance in these domains. Complexity in etiology and outcome is the rule, not the exception, in working with children who have been exposed to alcohol.

Fetal alcohol syndrome (FAS) does not represent the totality of individuals exposed to alcohol in gestation or the entire group of people with impairments related to prenatal alcohol exposure. Rather, FAS is defined by specific aberrations in growth, facial form, and central nervous system (CNS) functioning (Stratton et al., 1996). FAS is noteworthy because it can be specifically identified as a condition due to gestational alcohol abuse. Thus, it is an important starting point for outreach to women who are at high risk of having other children with disabilities. In addition, this designation assists government systems related to education, social service, and criminal justice in planning for service needs.

The label *FAS* is actually less helpful for individuals who have the disorder themselves as it does not, in and of itself, guide parents or professionals in proceeding with interventions specific to the child. Moreover, the term excludes many individuals with the same degree of developmental delays related to alcohol exposure who do not have the diagnostic markers of FAS.
Nevertheless, there are two important reasons to examine whether a child's impairments are related to alcohol teratogenesis, especially to FAS. First, knowing that alcohol exposure occurred during pregnancy helps a clinician understand that if the child has a complex profile of cognitive or behavior difficulties, then alcohol-related damage may be one antecedent in a larger set of etiological factors. Children with FAS or related conditions may generally have some combination of ADHD, learning delays, language processing and usage difficulties, problems in planning and judgment, or increased soft neurological signs. In addition, if the child is school-age or older, "secondary disabilities" may have emerged form experiences of frustration, failures, and lack of acceptance by peers and adults, particularly if the full extent of the child's disability has not been recognized.

Clearly, a team approach to assessment and intervention is necessary for understanding such complex problems. A diagnosis often initiates an important spontaneous intervention by changing the attitude of family members and teachers working with the child, so they can see that the child "can't" rather than "won't" behave in an acceptable manner. Members of the child's community can then understand that the child is disabled and not simply disobedient (Streissguth, Barr, Kogan, & Bookstein, 1996).
Second, recognizing that a child has FAS may help prevent prenatal alcohol exposure in the biological mother's future pregnancies. In an assessment of FAS, both the biological mother and her child are the focus of the team's efforts. Women who have children with FAS usually drink regularly and in high volume during pregnancy. Although it is true that women who consume alcohol in the gestation period may by committing "fetal abuse", the case of a woman drinking purposefully during pregnancy to harm her child is rare. It is therapeutic to inform biological mothers of this problem so that they know that the child is receiving appropriate supports and everyone can proceed in a positive manner. Although the process of working with the biological mother can be complex and involves a different group of professionals than those needed to assess the child, it is critical and ethically necessary that these

From Guralnick MJ (ed.), Interdisciplinary Clinical Assessment of Young Children with Developmental Disabilities
Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

diagnostic and intervention efforts be linked (Astley, Bailey, Talbot, & Clarren, 1998).

ASSESSMENT FOR DIAGNOSIS OF FETAL ALCOHOL SYNDROME

The features of FAS are not dichotomous (present or absent) but, rather, each feature is on a continuum from clearly within the normal range to clearly the feature of FAS. Without suitable guides and standards, this leads clinicians to variable judgment in final diagnosis. To minimize clinical variability, the diagnosis of FAS or related conditions is made using a sequence of four 4-digit Likert scales (Astley & Clarren, 1997) in the clinics of the Washington State FAS Diagnostic and Prevention Network. Delays in growth, facial morphology, organic brain damage, and teratogenic exposure to alcohol are each evaluated separately. A "1" on any scale means a finding within the normal range. A "4" on any scale represents a finding that corresponds with accepted cases of FAS. A score of "2" or "3" specifically defines intermediate steps between clearly typical and atypical. It is important to note that these scales do not necessarily measure increasing severity; rather, they are scales of greater clinical confidence that the sought FAS characteristic is present. A child with a "4" for brain damage, for example, meets the medical criteria for a structurally altered brain but may be more cognitively or behaviorally within the normal range than a child with a score of "2" in whom the etiological relationship between brain structure and brain function is diagnostically indeterminate. Similarly, a child with a "4" for facial morphology has all of the facial diagnostic features of FAS yet may be somewhat more attractive than child with a score of "2"-who has an unusual face, but not the facial features common to FAS. The final category based on examination of the child is whether he or she has delayed growth. Establishing if a person's height or weight is "blunted", due to prenatal reasons, from its genetic potential is actually the most difficult part of diagnosis. Growth retardation is defined as a "4" when a child's measurements are less than 2 standard deviations (SD) from the mean after height (adjustment for mean parent height) and for weight.

The alcohol exposure scale is judged by whether the dose exposure pattern approaches on that causes fetal damage in animal models and whether the information is documented or speculative. Dose response relationships between maternal alcohol intake and fetal outcomes remain complex and somewhat vague for various reasons. Obtaining accurate information on alcohol intake during pregnancy is difficult because it is almost always recorded in retrospect, with the potential problems of the mother's poor memory or denial. Many maternal and fetal factors also play key roles in determining if any specific dosing pattern is damaging to that individual. In the majority of animal studies in multiple species, it has been necessary to give high dosage exposures, with peak blood alcohol concentrations (BAC) in the 100-200 milligrams per kilogram (mg/kg) range, and to deliver them at least weekly for the first several weeks of pregnancy. Even these high doses are not uniformly teratogenic; they are "high risk". When women report consumption likely to cause drunkenness (an approximate BAC = 100 mg/kg or higher) on a weekly basis, this is considered a "4". Any other pattern of definite exposure is judged a "3" because no dose is guaranteed to be absolutely safe.

The term FAS applies to children who have all "4"s or combinations of at least two "4"s and no more than two "3"s on the four scales. Other scores are converted to words in combinations of the descriptive terms: sentinel physical findings; static encephalopathy or neurobehavior disorder; and alcohol exposed, alcohol unexposed, and alcohol exposure unknown. A full explanation of this approach and its diagnostic terms as well as a method for judging the importance of these comorbidities, are available in the *Diagnostic Guide for Fetal Alcohol Syndrome and Related Conditions* (Astley & Clarren, 1997). The fetal alcohol diagnosis must be considered in the context of other prenatal and postnatal factors that contribute to the unique findings for each individual.

CASE STUDY INVOLVING AN INTERDISCIPLINARY TEAM ASSESSMENT

The FAS clinic team is comprised of individuals who help collect and interpret the data needed for diagnosis, assist in developing a comprehensive intervention plan, or both. Professionals are needed

From Guralnick MJ (ed.), Interdisciplinary Clinical Assessment of Young Children with Developmental Disabilities
Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

from the disciplines of medicine, psychology, speech-language pathology, occupational therapy, social work, public health nursing, and family advocacy. It is also helpful to have a staff epidemiologist who can create data forms and databases and direct clinical research efforts based on these data.
The remainder of this chapter presents the composite case of Anna, a child with FAS. This case illustrates the following steps in the diagnostic interdisciplinary team process: 1) preliminary team conference; 2) team assessment, including caregiver interview, physical examination of the child, and assessments of the child by occupational therapy, speech-language pathology, and psychology team members; 3) team deliberation; 4) case discussion and feedback to the parents; 5) additional case discussion and a therapeutic debriefing with the parents; 6) further case discussion and a therapeutic debriefing with the child (when appropriate); and 7) staff debriefing. Beside preserving patient confidentially, employing a composite case permits discussion of a combination of FAS characteristics that would not necessarily be found in any one case. Exploring the case of a primary school-age child allows a more extended developmental perspective. It also sensitizes the reader to the full scope of difficulties that children with FAS have by the time they reach elementary school, which generally are not clear in preschool. Overall, although Anna is fictitious, she presents the typical challenges in FAS diagnosis, treatment, and family support.

Record Review and Preliminary Team Conference

Anna's adoptive parents initially called the FAS clinic for an appointment. The family had been referred to the clinic by Anna's teacher, who had taken a workshop on FAS, and by her physician. As is frequently the case, Anna's doctor had not previously considered an alcohol-related diagnosis but agreed to the assessment when Anna's parents sought his advice (Clarren &Astley, 1998). The family had been sent an extensive intake form. This form was specifically designed to obtain historical data from the family that would help the clinic team reach a fair and complete conclusion. These data included 1) growth records; 2) childhood photos; 3) medical records of congenital abnormalities; 4) neurological problems and ongoing health issues; 5) previous evaluations of cognition and behavior; 6) reports of response to psychotropic medication; 7) specific documentation of alcohol exposure in pregnancy; 8) exposure to other drugs or additional complications during pregnancy; 9) academic problems or cognitive delays of the biological parents or their families; 10) a general overview of the family's genetic background; 11) reports of multiple placements and issues of caregiver attachment; 12) abuse or neglect; and 13) a general record of problems or difficulties with family, peers, and school. This intake form is available in the *Diagnostic Guide for Fetal Alcohol Syndrome and Related Conditions* (Astley & Clarren, 1997).

At the preliminary team conference, these extensive past records were reviewed, and the following summary was presented to the clinic staff by the physician and psychologist. Anna was 8 years and 1 month old. She was born to married, Caucasian parents when her mother was 28 years of age and her birth father was 35 years old. This was the third live born infant for Anna's birth mother. Her pregnancy was complicated by extensive alcohol use. The birth father reported that he would generally buy one case of beer daily and that when it was available he and his wife would each drink about half of this amount in the evening. This level of drinking persisted through the first half of the pregnancy. During the second half of Anna's gestation, Anna's birth father drank more while her mother drank less, although she still probably ingested about a six-pack daily until delivery. Anna's mother also used marijuana about once a month and smoked half a pack of cigarettes each day. The pregnancy was further complicated by physical abuse of the mother by her husband, although this abuse never led to a medical assessment during the pregnancy. Both biological parents reported that their own fathers, but not their mothers, had been heavy drinkers. Neither biological parent reported significant academic problems, and both had finished high school.

Anna was born at term, and her delivery was described as typical. At birth, she weighed 2.2 kilograms (kg) and her length was 44 centimeters (cm). Anna was always described as small. While in foster care, Anna received a nutritional evaluation and a thyroid screen. Anna grew steadily but more slowly than

From Guralnick MJ (ed.), Interdisciplinary Clinical Assessment of Young Children with Developmental Disabilities
Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

typically developing children. One previous foster parent repeatedly asked her physician to hospitalize the infant because she ardently believed that her inability to "fatten the baby up" meant that the baby was ill. Anna had an inguinal hernia that was repaired when she was 9 months old. She had chronic problems with otitis media until she reached age 3, though she never had a documented hearing loss. Despite these problems, she had been in good health overall.

After Anna was born, she lived with her parents for about 6 months, then she was removed from parental custody after the biological mother was several beaten by her husband. In addition, investigators found that the child was living in an unclean apartment without food or appropriate clothing. Six month-old Anna was placed in foster care and moved periodically over the next two and a half years while social service agencies determined that neither parent could control their drinking and regain custody. Anna was then made available for adoption and was retained by her last foster family (mother, father, and a brother 3 years older than Anna) when she was about 3 years of age. The adoption was legalized when Anna was almost 5 years old.

At the time of the clinic visit, Anna's adoptive parents reported that she had shown behavior problems since 30 months of age. Sometimes Anna was very negative and aggressive, especially with family members, while at other times she was cooperative and pleasant. Upon entering preschool, she was reported to be quiet but soon showed qualities similar to those observed at home. In fact, she was so aggressive with her peers that she was unsuccessful in two preschool programs. Her parents said that these behavior problems continued but had grown less frequent and violent since Anna started kindergarten.

Anna was evaluated by a developmental pediatrician at 6 years and 11 months of age, and she was diagnosed with severe ADHD. Anna was placed on methylphenidate but had an unanticipated response with a dramatic increase in irritability. Her parents stopped giving her the medication. Anna's reaction distressed her whole family, and her parents declined to try other medications, but they did attempt to reduce the amount of sugar in her diet with no apparent positive effect. A psychiatric evaluation produced a further diagnosis of oppositional defiant disorder, and Anna was described as "anxious".

At age 7 and midway through first grade, Anna was made a "focus of concern" by her school district because of poor academic progress and increasingly problematic behavior. As part of her school assessment she was evaluated using a standardized test of intelligence, the Wechsler Intelligence Scale for Children-Third Edition (WISC-III; Weschler, 1991). On that test, her verbal IQ score was a standard 68 (below expectations), and her performance IQ score was a standard 90 (within normal limits). A fullscale IQ score was not calculated because of the discrepancy between Anna's verbal and performance scores. Factor scores in the areas of verbal comprehension and freedom from distractibility revealed significant difficulties while Anna's factor score in the area of perceptual organization was in the lowaverage range. On an individually administered academic skills measure, the Woodcock-Johnson Test of Achievement-Revised (Woodcock & Johnson, 1989), Anna received the following scaled scores: Broad Reading (75), Broad Mathematics (71), Broad Written Language (80), and Broad Knowledge (86). Her standard score on the Vineland Adaptive Behavior Scales' (VABS; Sparrow, Balla & Cicchetti, 1984) Adaptive Behavior Composite was 52, and the subdomain scores were Communication (50), Daily Living Skills (45), and Socialization (64). School district recommendations were to provide resource room assistance given her ADHD diagnosis, but no specific educational plan was developed to address her cognitive and academic difficulties.

At the time of the FAS assessment, Anna's adoptive parents were confused and exhausted. They wished to understand how Anna's multiple diagnoses related to each other and how to maximize the effectiveness of her academic and mental health interventions.

Team Assessment

From Guralnick MJ (ed.), Interdisciplinary Clinical Assessment of Young Children with Developmental Disabilities
Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

The FAS clinic evaluation included an hour-long interview of Anna's adoptive parents and several assessments of the child (whose chronological age was 8 years and 1 month), which included a physical examination, an occupational/physical therapy assessment for soft neurological signs and fine motor problems, a specialized speech-language evaluation, and a limited amount of additional psychological testing. The goal of conducting these assessments was not necessarily to evaluate the full extent of Anna's development. Rather, it was to gather sufficient information to reach a diagnostic conclusion regarding the diversity and nature of her developmental functioning.

Caregiver Interview

A team physician and psychologist conducted an interview with Anna's adoptive parents. The interviewers guided the session to determine if Anna had the related conditions and functional impairments common in case of FAS. These questions probed the arenas of planning, behavior regulation, abstract thinking and judgment, information processing and verbal memory, spatial skills and memory, social skills and adaptive behavior, sensorimotor integration, and both oral-motor and motor control skills.

Anna's parents seemed appropriately concerned but confused about the many previous assessments of their daughter that had apparent nonoverlapping diagnoses. They commented that they sometimes understood the antecedents of her angry outbursts (but often did not) and that Anna was basically loving and caring. Nevertheless, Anna had never enjoyed being held or hugged for more than a brief period time. Furthermore, her parents said that she had always been very sensitive to loud noise and to rough or scratchy clothing.

Anna's parents noted that their daughter had difficulty organizing spaces; for example, she tended to crowd the letters of her name into one corner of a page and she could not put her toys away in their proper places. Her parents also agreed that their daughter had tremendous difficulty following directions. They reported that she generally failed to remember an instruction if more than a few minutes elapsed between the time the instruction was given and when she was expected to carry it out. Anna also could not successfully follow more than a one-step instruction. She could repeat instructions if she practices saying them many times (e.g., Question: "Anna, what do we do before we eat?"; Answer: "We was our hands"). Yet Anna usually forgot the rule without a direct reminder at the time the instruction was to be implemented. In fact, she did not understand lengths of time (e.g., the difference between an event taking place in a few minutes or one that was a few days away).

In the domain of social skills, Anna's parents described her as isolated with no friends. She seemed to enjoy the company of other children but often tried to direct all activities. This behavior usually led to marginalization by her peer group. When rejected, Anna sometimes played alone, but she usually responded to peer rejection or noncompliance with anger or physical aggression. Anna played well with younger children (ages 3 or 4 years) and was kind to animals.

In physical terms, Anna had trouble going to bed and often awoke in the night, but then she generally tired during the latter part of the day. Her mother commented ruefully that Anna could climb, in-line skate, and do other age-appropriate outdoor activities but did them in a frighteningly reckless and somewhat clumsy way. In general , Anna was described as having problems with self-regulation. Her parents had learned to send their daughter to her room when she was out of control. In time out, Anna quickly calmed down and seemingly forgot the entire event within minutes. Such outbursts could occur daily or even several times per day.

During the interview, Anna's parents confirmed the history of alcohol exposure that had been reported to them by the biological father. Apparently, Anna's biological mother had been in recovery at the time of the adoption and had given the adoptive parents the same facts. Anna's adoptive parents thought her biological mother was still living in the area and was once again drinking. They had not been in contact with her for several years.

From Guralnick MJ (ed.), Interdisciplinary Clinical Assessment of Young Children with Developmental Disabilities
Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

Pediatrics

The results of the physical examination conducted by the team physician revealed that Anna's height was 115 cms, her weight was 18k kgs, and her head circumference was 48.5 cms. The three facial features that defines the dysmorphic face of FAS were each carefully assessed. Her palpebral fissures (the horizontal length of the eyelid slit opening) measured 2.3 cms. Her philtrum (the vertical furrows between the nose and border of the red portion or vermilion border of the upper lip) was judged to be "flat" when compared to standard photos of philtrums of variable fullness. Similarly, the vermilion border was judged to be "very thin" using the photographic guide (available in the *Diagnostic Guide for Fetal Alcohol Syndrome and Related Conditions* [Astley & Clarren, 1997]). In addition, Anna had a small jaw and a mild overbite of her new secondary upper incisors. The rest of Anna's physical examination was unremarkable.

Occupational Therapy

Fine and gross motor skills were within normal limits using the Bruininks-Oseretsky Test of Motor Proficiency (Bruininks, 1978). Although Anna's parents had concerns about "clumsiness," that problem was not identified with this tool. The Quick Neurological Screening Test-Revised (QNST-R; Mutti, Sterling, & Spalding, 1978) was also administered. This tool is generally more useful to screen multiple areas of neuromotor integration and soft neurological signs. A normal score is less than 20; an abnormal score is more than 50. Anna's score was 45, in the "suspicious" range. Particularly difficult for Anna were coordinating rapid controlled movements, balance, and tasks involving spatial awareness of her body. These results fit with findings on the Beery-Buktencis Developmental Test of Visual-Motor Integration (VMI; Beery, 1997), signifying that Anna had below-average abilities in figure copying and a very disorganized approach to more complex visual information. A short sensorimotor history questionnaire completed by Anna's adoptive parents revealed sensitivities to tactile and auditory information, echoing descriptions from the caregiver interview. This sort of nonstandardized checklist is used in FAS clinics when there are concerns about sensory processing.

Speech-Language Pathology

Impairments with language, cognition, and social behavior are not unusual for children with FAS and related conditions, and they underlie difficulties in social competence and some aspects of academic performance. Research measures of social communication and social reasoning are used in FAS clinics to tap this common area of concern, and the results these measures produce capture something of the day-to-day problems that parents of children affected by alcohol describe. In addition, age- and developmentally appropriate standardized measures of receptive and expressive language are also employed in clinics to conduct a brief assessment of language development.

Anna's receptive and expressive language skills were broadly within the typical range; she nonetheless showed notable delays in storytelling and mental-state reasoning, two aspects of social communication and social reasoning. Anna was asked to retell a story she had just heard, suing a picture book without words as a cue. Anna's narrative was vague and poorly connected; in effect, she described elements in each picture without linking them into a story line. She could not take her listener's perspective into account in communicating the story. Anna understood the facts of the story but could not mentally "step into another person's shoes" when asked questions that required understanding another person's perspective. In these tasks, Anna did not give clear evidence that she understood what other people were thinking. These observations were congruent with reported information from the caregiver interview.

Psychology

As is often the case, the clinic was provided with valid and relatively recent testing by school and community professionals. To supplement these data, Anna was given the core assessment from the NEPSY, a Developmental Neuropsychological Assessment (Korkman, Kirk, & Kemp, 1998), a standardized battery of tasks that provides a developmental neuropsychological assessment for children ages 3-12 years. Anna's scores on the test's Core Domains of Language and Sensorimotor Function were low-average while visuospatial processing was in the borderline range. She scored well below average

From Guralnick MJ (ed.), Interdisciplinary Clinical Assessment of Young Children with Developmental Disabilities
Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

on Attention/Executive Function and Memory and Learning. Her scores on individual subtests were uneven and provided considerable insight regarding her problem-solving and learning styles. Of particular interest was Anna's very poor performance on a narrative memory task similar to one given in the speech-language assessment. In this task, which resembles school activities, the child listened to a story read aloud, attempted to tell it on her own, and then answered comprehension questions. Again, Anna's version of the story was vague and sparsely detailed. Even when cued, Anna often could not always remember the information offered in the story. When asked a question she often started to give an answer, then seemed to lose the aim of the task, and finally made unrelated responses that suggested she was guessing just to give an answer. She appeared very anxious during this task, shifting around in her chair, commenting on noises outside the room, and asking whether the testing was almost done.

To provide an estimate of behavioral function, Anna's adoptive mother completed the Child Behavior Checklist for 4- to 18-year olds (CBCL; Achenbach, 1991). Her second grade teacher completed the Teacher's Report Form (TRF; Achenbach, 1991). Parent report on the CBCL revealed overall behavior difficulties, with a Total Behavior Problems T score of 79, which is within the clinically significant range. The realm of internalizing problems was also clinically significant due to an elevated score suggesting anxiety. Externalizing behavior problems were also rated in the significant range, with elevated scores on scales of aggressive and "delinquent" behavior as well as difficulties with thinking, social skills, and attention span. Anna's Total Competence T score was 32, falling below the clinical cutoff, with poor scores on scales of social and school competence. This resonated with the mother's concerns about her daughter's inability to learn right from wrong: Anna sometimes attempted to hurt family members, yet she had a sense of humor and the ability to be loving and caring.
On the TRF, Anna's teacher expressed concern about behaviors in both Internalizing and Externalizing scales. Again, Anna's overall Internalizing problem score was elevated primarily because of her anxious behavior. Her Externalizing behavior problem score was elevated mostly due to her overactive and aggressive behavior. Anna's teacher reported that the child would destroy her own and others' possessions when angered. However, her rating showed that she could occasionally work hard and seem happy. Overall, Anna's teacher's ratings also indicated that her student was having some difficulty behaving appropriately and learning. She noted that Anna did better in small, highly structured environments than in the larger classroom setting. The teacher thought that Anna was very hard on herself, with very high expectations and a tendency to become very upset (even self-abusive) if she did not meet her own expectations.

For many children in the FAS clinic, only brief screening is carried out by the psychologist to supplement available test results from community professionals. For children who are old enough and have sufficient intellectual capability, the child and adult versions of the California Verbal Learning Test (CVLT; Delis, Kramer, Kaplan, & Ober, 1994) and the Rey Complex Figure Test (RCFT; Meyers, Meyers, & Kelly 1995) are highly informative. Used together these tools assess verbal learning and memory, nonverbal memory and visuospatial skills, the child's ability to organize hi or her behavior toward a complex end, and his or her behavior when carrying out demanding tasks. Literature on fetal alcohol effects suggests these might be areas of concern for individuals affected by prenatal alcohol ingestion. Findings from the CVLT and RCFT are often supplemented by several informal drawing tasks and a short interview. For children from preschool to late elementary school age, behavior observations are often carried out while the child is receiving the physical examination or other on-site testing and when the child is in an unstructured, highly stimulating environment (e.g., in the waiting room, on an elevator ride, during a walk through the building). Because a formal adaptive behavior assessment is often not part of a child's file, the psychologist will sometimes give the Summary Version of the VABS (Sparrow et al., 1984) prior to the caregiver interview.

Team Deliberation

Anna met the criteria for FAS in that she had been exposed to alcohol and had confirmed growth delays, specific atypical facial features, and evidence of CNS dysfunction. Details for these and other factors are

From Guralnick MJ (ed.), Interdisciplinary Clinical Assessment of Young Children with Developmental Disabilities
Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

provided as follows:

Growth
Anna's growth was considered definitely atypical, as her height and weight were both below the 3rd percentile after a height adjustment for mean parental height. Anna's height of 155 cms was at the 2nd percentile. The height of her biological parents averaged 174 cms. Adjusting for mid-parental stature determined that Anna was actually 3 cms smaller than would be predicted from her genetic background. Therefore, her atypical growth pattern was independent of her genetic background.

Dysmorphology
Those with FAS have short palpebral fissures ("short" when more than 2 SD below the mean) and a flat philtrum and thinned vermilion border. The philtrum and lip must each be judged a "4" or "5" on a 5-point rating scale in comparison to a standard set of five photos. Anna's palpebral fissures were measured at 3.5 SD below the mean. Her lip was judged a "5" while her philtrum was given a rating of "4". Her dental malocclusion, although not of relevance to the FAS diagnosis, was a common associated finding. Overall, she had the distinctive facial features that characterize FAS.

Central Nervous System Dysfunction
Evidence for CNS dysfunction can be defined structurally, neurologically, or by examining psychometric evidence. Anna had positive findings in all of these areas. Her head circumference was below the 2nd percentile. By itself, microcephaly is a sufficient finding for FAS diagnostic purposes, but Anna also had an atypical neurological exam, with a QNST score about the usual cutoff and evidence of visual-motor difficulties on the Developmental Test of Visual-Motor Integration. Anna's behavior was characterized by severe ADHD, adaptive behavior problems, clear social-communication impairments, a learning disorder, a significant verbal-performance discrepancy shown in IQ testing, and evidence of memory and attention/executive function problems in neuropsychological assessment. The descriptive diagnostic term *static encephalopathy*, with evidence of diffuse CNS dysfunction, applied to Anna.

Alcohol Exposure History
The history of alcohol exposure in utero was judged to be definite, as it was independently confirmed by both birth parents. Consumption of 6-12 beers or more, on a daily or nearly daily basis, would place a fetus at definite risk for damage due to alcohol exposure.

Comorbidities
There were no additional physical findings, problems in the genetic background, or other teratogenic exposures that suggested an alternate or additional prenatal etiological diagnosis. Based on record review, interview, and behavioral observations, the team was in agreement with the psychiatric diagnoses of oppositional defiant disorder and moderate anxiety. In part, these conditions were hypothesized by the team to be situational, arising from Anna's prolonged frustration from criticism by others as well as herself regarding her poor performance. In other words, these would be secondary disabilities.

Recommendations
After discussion to establish the diagnosis, the team began to develop a tentative list of recommendations to be shared with the family during the case conference. It is useful to divide suggestions into at least four categories: medical, mental health, formal/informal education, and social services. In certain cases, additional categories (e.g., legal, correctional) are needed.

Medical
Anna had a classic presentation of FAS. No further specific medical diagnostic evaluations were necessary in this case. However, this is not always the case. Individuals with prenatal alcohol exposure can have alcohol-related and other conditions or simply alternate conditions. Differential diagnosis often need to consider relatively common genetic conditions like fragile X syndrome or Turner syndrome as

From Guralnick MJ (ed.), Interdisciplinary Clinical Assessment of Young Children with Developmental Disabilities
Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

well as obscure dysmorphic syndromes of genetic or alternate teratogenic cause. Any FAS program must always be alert to the possibility of alternate diagnoses involving other syndromes.

Another noteworthy medical issue was that there was a strong history of family alcoholism. Both of Anna's parents and her grandfathers were alcoholics. Thus, there was a chance that Anna carried a genetic propensity for alcoholism independent of her condition of FAS. The team felt that Anna would need clear and regular warnings throughout childhood and adolescence that drinking could cause her to become an alcoholic. Such direct messages help some children withstand peer pressure to begin alcohol use in adolescence.

In addition, Anna was small but had consistently grown parallel to typical parameters. This fact, along with her generally unremarkable physical examination, meant that there was no reason to recommend further medical evaluation of her growth. (Intriguingly, many children with FAS have a robust growth spurt at the time of puberty, moving in the typical range for height at that time.) On this note, it is not surprising that Anna's physician had not considered FAS diagnosis or referral, because Anna's physical health was good and her problems were in areas not usually considered as health care problems.

Mental Health

Anna had clinical evidence of distractibility and inattention and had had an unexpectedly adverse reaction to methylphenidate. At the time of the clinic visit, it remained possible that Anna fit the diagnostic criteria for ADHD within broader diagnosis of FAS. Thus, Anna might still respond to methylphenidate prescribed at a lower dose or to an alternate stimulant medication. It was also possible that her inattention and distractibility were due to anxiety and could be resolved if her anxiety and other problems were addressed, perhaps with an alternative, nonstimulant pharmacological approach as well as situational remediation.

Some families are concerned by the use of medications with children already affected by prenatal alcohol exposure. It was important that Anna's family be reassured of the general safety and potential benefits of medications. Nevertheless, the team felt it better for Anna's overall emotional state to be judged and the adjustments in her educational program and family expectations to be evaluated before further drug trials. Based on the outcome of such monitoring, a psychiatrist might then be better able to prescribe psychotropic medications.

Making those additional changes would be difficult. Anna's parents were already frustrated and fatigued by caring for a child whose behavior problems had escalated while her adaptive function had declined. Anna demonstrated complex cognitive and behavior impairments. Managing the child's behavior and helping her to learn would require expert assistance. The team decided to encourage Anna's parents to work with a counselor in developing appropriate parenting strategies and addressing the stressed inherent in raising a child with FAS. However, it is difficult to find such counselors and to fund this type of ongoing counseling assistance. If the parents did find a counselor, the team felt it would be ideal if that person or Anna's psychiatrist functioned as a service coordinator. The case management goal would be to align home and school behavior programs, with dual foci on eliminating aggressive behaviors and building anger management and socialization skills.

Another possible source of assistance was parent networks. Such support groups are remarkably useful resources for families raising children with FAS. In the 1990s, parents increasingly began joining together to support and educate on another, to advocate for funding and missing services, and to promote societal recognition of and research on FAS and related conditions. The team planned to augment the parents' access to information and self-help advice by providing them with a telephone hotline number for FAS and copies of recent issues of FAS community education newsletters.

Formal/Informal Education

In some states, Anna would qualify for special education under the category of "health impaired" given

From Guralnick MJ (ed.), Interdisciplinary Clinical Assessment of Young Children with Developmental Disabilities
Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

either her diagnosis of FAS or of ADHD. She might also qualify as "neurologically impaired" based on microcephaly coupled with atypical neurological findings of fine motor delays and a significant number of soft neurological signs. In addition, Anna could qualify as "learning disabled" because of her psychological evaluation. Anna clearly met the criteria for, and needed, an individualized education program (IEP).

Most school districts have an approach to children with complex needs, such as Anna, that involves special education classes or resource room help for academic work; supplemental speech-language, occupational, and physical therapy services; and inclusion with typically developing peers during certain activities (e.g., recess, lunch, library time). These qualifying children may also be accompanied by a paraeducator for a portion of or the entire school day. This general plan seemed reasonable for Anna, although her pattern of special needs did not completely fit interventions such as those designed for children with mental retardation, learning disabilities, or severe behavior disorders. Therefore, individualized and flexible intervention planning at school was needed. Based on Anna's profile of test results, specific classroom techniques included 1) repeating practice of learning materials; 2) using less abstract materials; 3) limiting the need for Anna to remember spatial information; 4) breaking long instructions, stories, or lessons into smaller parts; 5) encouraging Anna to work slowly and carefully; 6) allowing time during transitions for Anna to become self-motivated and interested in the next activity; 7) analyzing strategies Anna used on her own during learning activities and offering more effective strategies as appropriate; and 8) informing Anna when she was doing well by rewarding effort and not achievement.

The team felt that Anna would benefit from occupational therapy services designed to assist her in better modulating incoming stimuli and to decrease performance anxiety by altering her classroom environment. If occupational therapy services could be provided at school, a private occupation therapist might be a useful addition to Anna's service team. Finally, speech-language consultation was recommended to enhance Anna's social-communication skills.
Furthermore, Anna would benefit from participation in extracurricular activities that she enjoyed and did well. Such activities could help raise her self-esteem and would be less likely to promote performance anxiety. Nevertheless, it was important to emphasize that Anna should only be enrolled in activities supervised by adults accustomed to working with children with special needs.

Social Services
At the time of Anna's adoption, fetal alcohol effects and the possibility of a lifelong disability were not raised with the family. Given the documented history of voluminous alcohol exposure during gestation and the history of growth problems from birth, the team believed that the issue of FAS should have been evaluated at the time of adoption. It would have been reasonable then to offer a subsidized adoption to offset added educational and mental health services that Anna would probably need. The team recommended that this issue be revisited with the appropriate social service agency. Subsidized adoption should include medical coverage, psychiatric benefits for the future if preapproved, and a monthly cost supplement. In addition, because Anna had permanent disabilities, she should qualify for Supplemental Security Income (SSI) coverage. As a child, eligibility is based primarily on functional ability, and the receipt of benefits is dependent on parental income. The issue of SSI funding could be reexamined later when Anna neared adulthood. The Division of Developmental Disabilities was another agency to contact for possible resources or benefits. The agency has strict qualifying criteria, but this option was worth pursuing.

Case Discussion: Feedback to Parents

The case discussion actually occurred in two phases. The first part consisted of elements typically discussed with parents during an assessment feedback session. The second phase, however, was a unique feature of the particular clinic that evaluated Anna.

From Guralnick MJ (ed.), Interdisciplinary Clinical Assessment of Young Children with Developmental Disabilities
Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

Part I

Diagnosis and treatment recommendations were shared with Anna's parents in a roundtable forum. Each team member who had tested Anna briefly stated his or her specific findings, gearing discussion of test results to support the recommendations that would be mentioned later. For example, the physician articulated the medical diagnosis of FAS, and then the occupation al therapist, the speech-language pathologist, and the psychologist who had tested Anna all stated their findings. The psychologist who interviewed the family then gave the team's recommendations in broad outline. All feedback was provided with careful sensitivity to the parents' emotional state and apparent level of comprehension.

In this large group setting, with all team members and some observers, the parents appeared fairly composed and quietly accepting of the diagnosis and intervention ideas. Nonetheless, their emotional responses were complex. On one hand, Anna's parents seemed pleased and relieved to receive an overall explanation for Anna's primary problems. On the other hand, they were troubled that Anna's complex neurological problems and her reactions to the accompanying difficulties had not previously been made clear. They also felt despair because they believed they had floundered for so long in caring for their daughter. Finally, they mentioned some fleeting anger at Anna's biological mother for causing these problems.

Part II

At this particular clinic, after clients have discussed the situation with the whole team, they have a quiet time when they can talk privately with one person on the team, usually the psychologist involved in the initial interview. This final phase with the caregivers provides a time for parents to catch their breath, express their feelings about the events of the day, and share their reaction to the diagnosis. Thereafter, they can hear and discuss the diagnosis and recommendations again to clarify their understanding and to begin initial planning for interventions based on clinic referrals. This final period honors the caregivers' and child's needs for a limited emotional closure to a stressful experience and for a way to review the many concepts and ideas they have just heard. Families often report how important this final time of consolidation is for them.

Anna's parents had endured an emotionally intense morning. At this second phase of the discussion process, the psychologist asked, "How are you doing? Does Anna's diagnosis make sense to you?" Then she waited and listened. Tears welled up in Anna's mother's eyes; her father let out a deep sigh. Finally, the father said how hard it was to hear that Anna did have FAS. The mother said she thought all along that Anna had FAS; Anna was so like the descriptions she had read. However, she kept wishing she would wake up and Anna would be just like her cousins and the kids next door. But now the mother knew Anna would never be an ordinary little girl, teenager, or adult. For several minutes the parents quietly cried, but they eventually regained their composure. The psychologist expressed her support. Then, Anna's mother asked what the family's next step should be.

The psychologist began to help the parents make sense of the diagnosis and recommendations. The psychologist read the diagnostic information and suggestions aloud to the parents to make sure the wording was clear and sufficiently informative. She clarified the meaning of a diagnosis of FAS. Using schematic drawings and straightforward descriptions the psychologist reviewed the word syndrome and each of the three basic aspects of the fetal alcohol syndrome: growth, facial features, and organic brain damage. She discussed how Anna met the growth criteria, as she had always been small, and her height and weight measurements during the assessment were below the 5th percentile compared to those of her peers. The psychologist explained the importance of small eyes and a thin upper lip and philtrum as physical markers for FAS and briefly described the embryology of these features. She also pointed out that Anna was a very pretty child and these facial characteristics did not stand out or negatively affect her looks. Then the psychologist explained the organic brain damage portion of the syndrome and how Anna demonstrated this characteristic. This was the time when the old and the new test data were analyzed. The parents asked many questions, and time was given to explain to them how Anna's profile of test results related to her learning and behavior problems. In particular, the results of the QNST,

From Guralnick MJ (ed.), Interdisciplinary Clinical Assessment of Young Children with Developmental Disabilities
Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

which had indicated an atypical pattern of neurological soft signs and motor weaknesses, and her low scores on adaptive problem solving on the VABS were reviewed because both lent support to the finding that Anna was functioning at the level of a child half her chronological age. Also, her limited linguistic understanding of another's point of view and the discrepancy between her verbal and average nonverbal reasoning were discussed to help the parents understand why Anna seemed well adjusted at one moment and then had such great difficulties and frustrations the next.

Specific telephone numbers were provided, and referrals to three possible counselors/behavioral consultants were made. The parents also signed a mutual exchange of information form so the psychologist could talk to Anna's teacher and school counselor at a future date. In addition, the psychologist provided handouts from the resource box of articles on FAS, copies of the most recent newsletters, and ordering information for books that might be of value to Anna's teachers.
The psychologist next asked if the parents thought Anna needed to talk about the diagnosis, and the parents said they did not think she would understand. To Anna, this day of testing was similar to her assessment process at school. In the future, they thought they could explain her diagnosis or they would contact the clinic for assistance. As a rule, feedback is given to an older child, a teenager, or an adult. If the child is briefed, there are several topics that generally should be considered for discussion with the child and the caregivers together. The feelings the child or caregivers may have about the biological mother's role and the frustration of ongoing problems in learning, behavior, and growth need to be recognized. The team should emphasize that they know the child works hard but has difficulties and may have been misunderstood over the years. In addition, the professionals need to clarify that the diagnosis explains why learning and being calm have been hard. Also, the child must be encouraged that he or she can learn and work but may need extra time and assistance. Again, the child also needs to be informed of his or her risk of becoming alcoholic. Finally, definite closure of the team assessment has to be made. This is the time to determine if the child requires follow-up with the clinic. In Anna's case, the psychologist closed the session by expressing her appreciation to the caregivers for their courage, good parenting, and cooperation as well as acknowledging how difficult the process had been. She stated she would be available to telephone Anna's teacher if necessary. Then the psychologist walked to the area where Anna was playing and shook the child's hand, told her what a good job she had done, and thanked her for coming to clinic.

CONCLUSION

The reader may wonder why a school-age child was used as a case example when the primary focus of this book is assessment in the early childhood years. Although younger children are assessed for FAS and related conditions, an older child's case demonstrated the richness and complexity of the accompanying performance problems that are not well described or measured until elementary school. Yet early diagnosis is important. It is likely that proper planning will reduce secondary disabilities and perhaps even improve cognitive performance when a diagnosis is made at the earliest possible time. Furthermore, the younger the child at the time of diagnosis, the more probable it is that the biological mother is still of childbearing age and would ingest alcohol during future pregnancies.

Unfortunately, the diagnosis of FAS cannot always be established conclusively in young children; even if the diagnosis is established in the preschool years, it is rarely clear what specific cognitive and behavior problems will follow. After all, the diagnosis of FAS relies on independent evidence of growth delays, a cluster of specific atypical facial features, organic brain damage, and a history of prenatal exposure to alcohol. The physical findings of poor growth and facial alteration and the history of alcohol exposure can all be fairly assessed in preschoolers, but detecting subtle levels of brain damage is much more problematic. If the child has microcephaly, hard neurological signs, or has had a brain image that discloses structural aberrations, this component of the diagnosis can be confirmed. If these observations are typical, alcohol-related brain damage could still be present at a microscopic level that can only be detected with late 20th century clinical techniques through a battery of psychometric testing. Reliable and valid testing of this type is not available for very young children. Furthermore, even if the diagnosis

Baltimore, Maryland: Paul H. Brookes Publishing Co., 2000; 307-326.

can be established through physical observations, the child's functional problems could be wide ranging and only well understood through formal assessments done over several subsequent years. As of 2000, there is no solid evidence that the facial characteristics and growth delays in children with FAS predict that there will be definite brain impairments or any specific level of delay. These findings cannot be used as proxy measures for brain performance itself. For infants, toddlers, and preschoolers, a senorimotor history questionnaire, developmental screening (e.g., the Bayley Infant Neurodevelopmental Screener [Aylward, 1995] or the Miller Assessment for Preschoolers [MAP; Miller, 1988]), and observation of parent-child interactions are often carried out by the FAS clinic occupational therapist and psychologist working together. Although these assessments are useful, they can rarely predict the types of processing difficulties that are at the heart of the ongoing FAS disability. Anna was noted to have had problems with anger and socialization in preschool although the cause was not understood at that time. Actually, many children who are later found to have significant cognitive and behavior problems seemed, to both their parents and teachers, to be developing typically before the age of 4 or 5 years.

As of 2000, the approach to the problem of FAS diagnosis in young children is twofold. First, the most complete assessment possible is conducted along the lines discussed in this chapter. Then the interdisciplinary team assesses the risk factors of each client (i.e., the biological mother and the child). If the mother drank substantially during this child's gestation and is still drinking and of childbearing age, she needs direction toward appropriate interventions to prevent subsequent adverse birth outcomes. She also needs support in rearing her child if she has custody. The child is considered at risk as well, based on the exposure history itself. Whether the child meets criteria for FAS, a related condition, or is found to be typically developing at the time of assessment, he or she needs appropriately stimulating home and preschool experiences and reassessments in the age period from kindergarten to second grade. As of 2000, few specific preschool programs have been specifically developed for children with FAS and related conditions (see Olson & Burgess, 1997). The need for more such programs is imperative for improving the quality of these children's lives.

Abstract - A 5-year, FAS primary prevention study was conducted in Washington State to: 1) assess the feasibility of using a FAS Diagnostic and Prevention Clinic as a center for identifying and targeting primary prevention intervention to high-risk women (namely, women who had given birth to a child with FAS), 2) generate a comprehensive, lifetime profile of these women and 3) identify factors that have enhanced and/or hindered their ability to achieve abstinence. The results of this study are presented in two parts: Objective 1 is summarized in Part I below; Objectives 2 and 3 are summarized in Part II, published separately. This project demonstrated that a multidisciplinary FAS Diagnostic and Prevention Clinic (FAS DPN) could successfully attract and meet the diagnostic and treatment planning needs of patients presenting with prenatal alcohol exposure. One out of every three patients evaluated in the FAS DPN clinics was diagnosed with FAS or static encephalopathy/alcohol exposed. The birth mothers of one out of every three of these children diagnosed with FAS or static encephalopathy/alcohol exposed could be located and directly contacted. Half of the birth mothers directly contacted were still at risk for producing more children damaged by prenatal alcohol exposure. Thus, one out of every 18 children evaluated in the FAS DPN clinics had a birth mother who could be found and was at risk for producing more children damaged by prenatal alcohol exposure. Primary prevention programs targeted to this high-risk population could lead to measurable, cost-effective reductions in the incidence of FAS. Using this approach, the cost of raising a child with FAS would be roughly thirty times the cost of preventing FAS in the child. The benefit to the children, their mothers and society would be immeasurable.

INTRODUCTION

The fetal alcohol syndrome (FAS) is a permanent birth defect caused by heavy maternal use of alcohol during pregnancy. FAS is characterized by pre- and/or postnatal growth deficiency, central nervous system dysfunction (CNS) and a unique cluster of minor facial anomalies (Clarren and Smith, 1978). The presentation of each individual feature of the syndrome may be variably expressed with age. Estimates of the incidence of FAS range broadly from 1 to 3/1,000 live births documented in epidemiological studies to 1/10,000 live births documented in birth defect registries (Stratton et al., 1996; Abel, 1998). FAS is one of the leading known, non-genetic causes of mental retardation in the Western World (Abel and Sokol, 1987).

Although FAS is entirely preventable, the factors associated with maternal alcohol use during pregnancy are complex and resistant to change (Beckman, 1984a). Maximizing primary prevention efforts will require targeting limited prevention resources to women at highest risk for producing children damaged by prenatal alcohol exposure. Primary prevention refers to preventing the birth of children damaged by prenatal alcohol exposure. One such population is women who have already given birth to a child with FAS. FAS studies consistently report that women who have had one child with FAS, and who continue to drink, have progressively more severely affected children with subsequent pregnancies (May *et al*., 1983; Davis and Lipson, 1984; Abel, 1988).

It is axiomatic that the evolution of effective prevention and treatment programs for nearly any medical condition rests on the identification of sufficient numbers of patients so that interventions that are hypothesized to be effective can be appropriately evaluated. The identification of "patients" is made more difficult than usual in conditions like FAS when both the child and the parent should each be appropriately identified as "the patient." Unfortunately, the diagnosis in the child often is made after the child is no longer in the birth mother's custody and the diagnosticians have no direct access to the birth mother or her records. FAS is vastly misdiagnosed (Cordero *et al*., 1994; Floyd *et al*., 1994) and the birth mothers of children with FAS are rarely if ever identified and targeted for primary prevention intervention. Failure to identify and intervene with these two populations results in primary and secondary disabilities that come at high cost to the child, mother and society (Beckman, 1984; Abel and Sokol, 1987; Streissguth and Kanton, 1997).

The failure to medically diagnose FAS has complex antecedents. Based on our interactions with thousands of families attending our FAS diagnostic clinics and hundreds of medical professionals attending our diagnostic training sessions, in our opinion, these antecedents include three apparently commonly held beliefs. First, some physicians remain ignorant of the existence of FAS or the diagnostic approach to this syndrome, or any syndrome. Second, many physicians believe that intervention programs are equally effective for individuals with any etiologic form of mental retardation or attention deficit disorder and they fail to recognize the more complex and subtle brain damage in alcohol affected individuals. They also fail to recognize their role in helping to identify the birth mother for future prevention efforts through recognition of FAS in the child. Third, patients with FAS and their families often need help with foster or adoption support services, educational interventions, alcohol treatment, vocational rehabilitation, and/or the criminal justice system. Most physicians are not trained to lead intervention programs

*Author to whom correspondence should be addressed at: Children's Hospital and Medical Center, 4800 Sand Point Way N.E., CH-47, Seattle, WA 98105, USA.

in these these arenas, nor are they likely to have well-established referral linkages to professionals in these other firleds. Further, many physicians may believe these issues are truly outside of the appropriate purview of pediatrics and 'healthcare'. Putting these false beliefs into practice sets up a self-defeating cycle. When physicians fail to perceive that a diagnosis of FAS will benefit the patient, the birth mother, the family, and society, FAS remains under-diagnosed. When individuals are not diagnosed, it is not possible to demonstrate the benefits of diagnosis to the child or the parent, nor can surveillance be done accurately enough to monitor the success of prevention efforts.

Although physician attitudes and training limit the availability and accuracy of FAS diagnostic services, we have found tremendous interest by families and professionals from social service, educational, and correctional facilities to obtain diagnostic confirmation of CNS dysfunction among individuals with prenatal alcohol exposure. They have shared with us that these diagnoses facilitate their intervention efforts with these individuals.

The ideas that stimulated this prevention project in 1992 arose from our experiences in the 1980s. Increasing knowledge of FAS in the medical literature and public media, and countless medical trainings on the subject did not seem to be changing medical practice in diagnosing FAS. Rather, we felt that a new team approach to diagnosis and treatment planning was needed in clinics dedicated to FAS issues if the beliefs described above were to be effectively challenged.

We believed that clinics dedicated specifically to FAS were the critical missing step in helping to solve this problem (Clarren and Astley, 1998). First, FAS clinics could provide a mechanism for demonstration of community interest in the diagnosis of FAS and an opportunity to determine which professionals or social/health care systems seek consultation and what issues or problems drive those referrals. The clinics could accurately make FAS diagnosis using appropriate and consistent assessments of physical, cognitive, and behavioral abnormalities. The clinics could recommend treatment programs and over time determine if these programs were available and, if available, effective. The clinics would stimulate ideas for novel treatment modalities and would generate enough patients and sufficient linkage to treatment venues that implementation and assessment could be done.

Second, clinics would become a critical resource in public awareness - FAS prevention programs. As the general public is made aware of FAS and related conditions and warned to avoid alcohol use in pregnancy, families who have children who might have FAS are also made aware of the disorder and they often become concerned. These families deserve to have appropriate diagnostic facilities nearby to answer their questions and provide appropriate diagnosis and treatment planning.

Third, clinics would be necessary to support active screening of high-risk populations like foster care or juvenile rehabilitation. Patients who screened positive would require a resource for final accurate diagnosis and counseling which could only be reliably met through dedicated clinics.

Fourth, the clinics could be a critical tool for primary prevention. Not all women alcoholics appear to be at equal risk for having children with FAS (Abel, 1995). Although women who have one affected child often have more, to date there is no anticipatory biologic or sociologic markers that distinguish the mothers of children with FAS from other women who drink in pregnancy and bear normal or nearly normal children. Treatment of women for alcoholism during pregnancy probably comes too late to prevent brain damage in affected fetuses even if the correct high-risk, alcoholic women are selected for therapy. While it would be ideal to identify and treat all alcoholic women prior to pregnancy, resources for such an effort are not available. However, each patient with FAS (as identified through a FAS diagnostic clinic) has a mother who has a proven potential to give birth to a child damaged by prenatal alcohol exposure. Focusing prevention efforts on this select and high-risk group of women could reduce the incidence of FAS births dramatically without unduly overburdening the current health care and alcohol treatment systems.

A Cooperative Agreement with the Centers for Disease Control and Prevention (CDC) from 1992 to 1997 allowed for the development of an FAS Clinic at the University of Washington that could demonstrate our conviction that misdiagnosis of FAS was occurring and could be corrected, and that the birth mothers of the patients could be found. Once found, the mothers could be interviewed to generate comprehensive lifetime profiles which, in turn, could be used to develop intervention programs targeted to meet their needs.

The specific objectives of this FAS diagnostic and prevention effort were to: (1) To assess the feasibility of using a FAS Diagnostic Clinic as a center for identifying and targeting primary prevention intervention to high-risk women. Specifically: (a) to establish an FAS Diagnostic Clinic; (b) determine the rate at which individuals with FAS could be identified; (c) determine the feasibility of identifying their birth mothers. (2) To generate a comprehensive, lifetime profile of their birth mothers as a first step in the development of a FAS primary prevention program targeted to meet their needs. Specifically, administer a personal, structured interview to the birth mothers of children diagnosed with FAS to document their: (a) sociodemographic profile; (b) social/health care utilization patterns; (c) adverse social experiences; (d) social support networks; (e) intelligence quotients (IQ); (f) mental health profiles; (g) reproductive and family planning histories; (h) alcohol use and treatment histories. (3) To identify factors that have enhanced and/or hindered the birth mothers' ability to achieve abstinence.

This report represents the first in a series of two reports that present the methods and outcomes of this FAS diagnostic and prevention project. This first report presents the complete methodology for the project and summarizes the project's success at identifying high-risk birth mothers through the diagnosis of their children (Objective I). The second report presents a lifetime profile of 80 birth mothers who gave birth to a child with FAS and identifies factors that enhanced and hindered their ability to achieve abstinence and/or practice effective family planning (Objectives II and III) (Astley *et al*., 2000).

METHODS

Establishment of the University of Washington FAS Diagnostic and Prevention (FAS DPN) Clinic

The first step in meeting the objectives above was to establish a multidisciplinary FAS diagnostic and prevention clinic at the University of Washington. The ultimate purpose of the clinic was to identify and target primary prevention services to women who had given birth to a child with FAS. To achieve this goal, the clinic had to effectively attract patients with FAS. After 25 years of experience making diagnoses in a variety of clinical settings, it was clear that this could best be accomplished by establishing a multidisciplinary clinic prepared to meet not only the diagnostic needs, but also the social service, educational and behavior management needs of the patients and their caregivers. This multidisciplinary approach to FAS diagnosis and prevention is described in detail in separate publications (Clarren and Astley, 1997; Clarren et. al., 2000).

Sources of Patients

Two sources of patients with FAS were used to address Objectives 1 through 3: 1) patients diagnosed through the CDC-sponsored University of Washington FAS Clinic and 2) patients diagnosed through other University of Washington or Children's Hospital and Regional Medical Center neurodevelopmental and genetics clinics. The CDC-sponsored FAS Clinic opened in 1993. Patients were identified through this clinic prospectively at the time of their diagnostic evaluation. The University of Washington and Children's Hospital clinics opened in the 1970s and were operational throughout this study. Patients were identified through these clinics both retrospectively and prospectively through research and medical records. The diagnosis of FAS did not begin with the CDC-sponsored University of Washington FAS Clinic in 1993. The diagnosis of FAS has been actively made in these clinical systems since the early 1970s when David Smith, M.D. and his colleagues identified the first cases in the United States (Jones and Smith, 1973). Dr. Clarren has been actively making the FAS diagnosis, using the same criteria, since entering practice in 1978 (Jones and Smith, 1973; Clarren and Smith, 1978; Rossett, 1980; Sokol and Clarren, 1989).

To assess the feasibility of using a FAS Clinic as a center for identifying and targeting primary prevention services to high-risk women (Objective I), patients diagnosed with FAS prospectively in the CDC-sponsored University of Washington FAS Clinic were used. This single clinic expanded into the Washington State FAS Diagnostic and Prevention Network (FAS DPN) of seven clinics in the third year of the study to meet the ever-increasing demand for diagnosis. This expansion is described in more detail below.

To generate a lifetime profile of birth mothers of children with FAS and to identify factors that enhanced and hindered their ability to achieve abstinence (Objectives II and III), patients from both sources were used. The addition of this second source of patients served to increase the total number of birth mothers enrolled in the study and served to increase the maternal follow-up period of observation subsequent to the birth of the index child with FAS. The longer the period of follow-up on the birth mothers, the more meaningful the lifetime profiles and identification of factors that enhanced and hindered abstinence and family planning.

Diagnostic Criteria

The diagnoses of FAS and 'static encephalopathy/alcohol exposed' were made using the clinical gestalt guidelines published by Sokol and Clarren (1989) and the 4-Digit Diagnostic Code created by Astley and Clarren (1997, 1999, 2000). The diagnosis of FAS was accepted when Dr. Clarren made that diagnosis or when the diagnosis was made by another clinician and Dr. Clarren had reviewed the data and concurred.

In the last year of this project, a new, comprehensive, case-defined method for diagnosing FAS called the 4-Digit Diagnostic Code was established by the University of Washington FAS Clinic under a separate contract (Astley and Clarren, 1997, 1999, 2000). This new method was created in response to both the Institute of Medicine's recommendations that a more reliable and valid set of diagnostic definitions be adopted (Stratton *et. al*., 1996) and our Washington State Senate's mandate that we assure diagnostic reproducibility among all Washington State FAS DPN clinics. This new diagnostic system documents the magnitude of expression of the four key components of the syndrome: 1) growth impairment, 2) the FAS facial phenotype, 3) evidence of brain damage and 4) prenatal alcohol exposure, on separate 4-point Likert scales (Astley and Clarren, 2000). Likert Rank 1 represents normal. Likert Rank 4 represents the most severe expression of the feature. Generally speaking, a diagnosis of FAS requires ranks of 3 or 4 in all four categories. This new system of diagnosis was implemented in the U.W. FAS Clinic during the last six months of this project.

Maternal Study Population

The target population for this prevention project was initially birth mothers of children who received a gestalt diagnosis of FAS. Implementation of the 4-Digit Code method of diagnosis in the last six months of the project allowed us to expand the maternal target population to all women who gave birth to infants with documented brain dysfunction and prenatal alcohol exposure, not just the subset who gave birth to children with FAS. One of the many benefits of the 4-Digit Code is that is clearly differentiates patients with organic brain damage and prenatal alcohol exposure from the much larger and heterogeneous group previously labeled through the gestalt method of diagnosis as possible fetal alcohol effects (PFAE). With the implementation of the 4-Digit Code, the diagnostic criteria were expanded to include all children who received a diagnosis of static encephalopathy (4-Digit brain Likert ranks of 3 or 4) and confirmed prenatal alcohol exposure (4-Digit alcohol Likert ranks of 3 or 4) with or without the FAS facial phenotype or growth deficiency. Children who also presented with the FAS facial phenotype and growth deficiency were the subset of children with static encephalopathy who met the criteria for a diagnosis of FAS. To obtain a 4-Digit brain rank of 3 or 4, a patient must present with microcephaly, a seizure disorder, an abnormal CT or MRI, a full scale IQ < 60, or performance of greater than two standard deviations below the norm across three or more of the following domains in a psychometric assessment battery (intelligence, achievement,

adaptation, neuropsychology and language). This expanded target population reflects a very high-risk group of women (Abel, 1988), who are not only uniquely and conveniently identifiable through a FAS Diagnostic Clinic, but ideally targeted for primary prevention intervention. Women who were eligible to enroll in this study met the following criteria:(1) they gave birth to at least one child with a medical diagnosis of FAS or static encephalopathy/alcohol exposed rendered or confirmed by SKC following the clinical guidelines of Sokol and Clarren (1989) or Astley and Clarren (1997, 1999, 2000); (2) they were of any age or race; (3) they were a resident of Washington State at the time of study enrollment; (4) they consented to participate in the study.

Identification, Location and Enrollment of Birth Mothers

This study was reviewed and approved by the University of Washington Human Subjects Review Board. The process for identifying individuals with FAS and identifying, locating and inviting their birth mothers to enroll in this study was done in compliance with medical and research policy for protecting patient confidentiality.

Birth mother identification, location and enrollment was conducted by a social worker over a 36-month period. Identification and location of the birth mothers was accomplished either through direct contact with them when they accompanied their child to the diagnostic examination, or through letters or phone calls of invitation delivered by family, friends and social/medical providers when they did not attend their child's diagnostic examination. Public records such as phone directories, driver's license bureaus, birth and death certificates and Department of Correction registries were used when necessary to identify and locate the women.

Birth mothers who attended their child's diagnostic evaluation in any clinic in which SKC was the diagnosing physician were invited to enroll in the study by SKC at the time of the diagnostic evaluation or through receipt of a letter from SKC. Women who did not attend their child's diagnostic evaluation, but whose names were documented in their child's diagnostic record received a letter of invitation from SKC as the child's treating physician. Women whose names were not known by the FAS DPN clinic were sent letters of invitation from SKC through a family member, friend or medical/social service professional that did know the women. This allowed the birth mother to be invited to learn more about the study without revealing her name or location to the FAS DPN study staff. If she was interested in participating, the letter of invitation included a stamped, response postcard, addressed to the FAS DPN, allowing her to contact us or give us permission to contact her.

Every effort was made to facilitate the woman's participation in the study. Offering child-care, transportation, flexible scheduling, and mobile interviewing were key in enrolling women. Additionally, as long as the parameters of the interview were maintained (private room, no interruptions), women were encouraged to choose the setting of the interview. Interviews took place in a variety of settings – public health centers, hospitals, community centers, treatment centers, libraries, correctional facilities, and homes – and at a time convenient to the women.

Maternal Interview

A four-hour structured personal interview was developed to generate a lifetime, comprehensive profile of each birth mother's sociodemographics, reproductive and family planning history, social and health care utilization patterns, adverse social experiences, social support network, alcohol use and treatment history, psychosocial profile and intelligence quotient. The interview included 2,044 questions. The questions focused on three time periods in the women's lives: (1) at the birth of the index child with FAS; (2) at the time of the interview; (3) over their lifetime. The interview included the following standardized (indicated by *) and non-standardized instruments: (1) Sociodemographic and Lifetime Social/Health Care Utilization Questionnaire; (2) Reproductive and Family Planning History Questionnaire; (3) Social Support Questionnaire (Short Version)* (Sarason *et al*.,1987); (4) Quick Diagnostic Interview Schedule III R* (Bucholz *et al*., 1996); (5) Shipley-Hartford Institute of Living Scale* (Shipley, 1967); (6) Alcohol Use and Treatment History Questionnaire.

The Sociodemographic and Lifetime Social/Health Care Utilization Questionnaire was constructed to document lifetime education, employment, physical and social home environment, social/health care utilization patterns, and adverse social experiences. The Reproductive and Family Planning History Questionnaire was constructed to document: 1) for all conceptions (mother's age, birth outcome, form of birth control used, planfulness of conception and alcohol exposure) and for all types of birth control available (age when used, ever failed, currently using, if stopped using-why and if available at no cost-would she use it now). The Alcohol Use and Treatment History Questionnaire documented lifetime drug and alcohol use and all concerted efforts to reduce alcohol use. The women were first asked to list all concerted efforts to reduce intake by date and then to provide the following details on three specific efforts; the most successful, the least successful and the effort closet to the birth of the index child with FAS. For each of these three efforts they were asked to report: (1) their level of alcohol use; (2) reasons for attempting to reduce their intake; (3) pertinent sociodemographics; (4) alcohol treatment program parameters; (5) family support; (6) need and access to social/educational/medical services during their treatment; (7) their perceived level of success or failure in reducing their alcohol use; (8) reasons they attributed to their success or failure. This questionnaire was designed to address many of the issues raised by Beckman and Braiker on the treatment needs of women alcoholics and the structural, personal and environmental barriers to treatment (Beckman, 1980, 1984, 1984a; Beckman and Amaro, 1984; Braiker, 1984). It also incorporated questions that addressed key findings of a 1993 Seattle-based survey of chemical dependency treatment programs serving women (Seattle-King County Task Force for Chemically Dependent Women, 1993). The Short Social Support Questionnaire is a standardized instrument of twelve questions (Sarason *et al*., 1987). The respondent is asked to list the number of people they can depend on to provide them with help or support (e.g., "Whom can you count on to console you when you are very upset?") and to rank their level of satisfaction with the support they receive on a six-point scale. The Shipley-Hartford Institute of Living Scale is a standardized instrument of 60 self-administered questions used to derive an

estimate of the WAIS-R full-scale intelligence quotient (I.Q.) (Shipley, 1967). The National Institute of Mental Health Quick DIS-III-R is a computerized interview used to diagnose lifetime psychiatric disorders in accordance with DSM-III-R criteria for positive symptoms (Busholz *et al*., 1996). The following components were administered by the trained interviewer: demographics, panic disorder, generalized anxiety disorder, agoraphobia, social phobia, simple phobia, post-traumatic stress disorder, major depressive episode, manic episode/bipolar disorder, schizophrenia/schizophreniform, anorexia, bulimia, alcohol disorder and antisocial personality. The computer program reports the diagnostic outcome (+/-) for each disorder and the age at onset of symptoms.

At the completion of the 4-hour study interview, the women received $75 and referrals to services specific to their needs. The interview was constructed through a collaborative effort between medical and social service providers at the University of Washington, Washington State Department of Public Health, Seattle/King County Department of Public Health and the CDC. The interview was administered by a single registered nurse with a master's degree in addictions nursing.

Analysis

t-tests, Mann-Whitney Rank Sum tests and chi-square (or Fisher Exact) tests were used to compare outcomes between two independent groups when the outcomes were measured on continuous, ordinal or nominal scales respectively.

RESULTS

Establishment of the FAS Diagnostic Clinic

The UW FAS Clinic opened in January 1993. The format and function of the clinic are described in full in Clarren and Astley (1997) and Clarren et. al (2000). Briefly, the clinic at the University of Washington was and continues to be held one day per week and sees two to four patients and their caregivers per day. A multidisciplinary team that includes a pediatrician (SKC), educational and clinical psychologists, an occupational therapist, a speech language pathologist, maternal advocate and a family advocate staff the clinic. Applications for appointments are taken over a telephone hotline. Patients seek their own appointment or are seen on referral. Referrals come primarily from social service agencies, educational facilities, the criminal justice system and rarely from physicians or other health care providers. All persons who call are sent a New Patient Information Form to complete. The form documents the patient's physical and developmental history, gestational exposures and caregiver's concerns. The completed and returned forms are reviewed and prioritized based on the urgency of the request. Caregivers are asked to bring copies of previous school, medical and psychological evaluations to clinic on the day of their appointment. The caregivers are interviewed jointly by the pediatrician and psychologist, and the patient is examined to determine if he/she has the physical features of FAS. The patient also receives brief language, neurologic and psychometric assessments. After the interview and clinical examination, the clinic team completes the FAS Diagnostic Evaluation Form (Astley and Clarren, 1997) derives a 4-Digit diagnosis and generates a referral plan for treatment and services for the patient, their family and the birth mother if appropriate. The caregivers then meet with the Clinic team to discuss the diagnosis and referrals. The caregivers receive a complete medical summary within three weeks after their clinic visit.

The clinic was so successful in meeting the diagnostic needs of families, as demonstrated by the patient satisfaction surveys presented above, that it was unable to deal with the very large demand for services. Working first with the Western Washington Chapter of the March of Dimes Birth Defects Foundation and then with the Washington State Legislature, a law was passed in 1995 which directed us to develop community-based clinics like the one at the University throughout the state. This was the beginning of the Washington State FAS Diagnostic and Prevention Network (FAS DPN). The FAS DPN is a consortium of six community-based clinics located at major population centers around Washington State led by the core diagnostic and training clinic at the University of Washington. While this was not a specific objective of this CDC cooperative agreement, ensuring the continuation of this project through other forms of support beyond the 5-year Cooperative Agreement was certainly a positive outcome. It also led to an increased capacity to identify birth mothers in the last two years of this study.

The mission of the FAS DPN is primary and secondary prevention of FAS through clinical screening, diagnosis, research and training. To accomplish this mission, comprehensive, case-defined methods for FAS screening (Astley and Clarren, 1996) and diagnosis (Astley and Clarren, 1997, 1999, 2000; Astley *et al*., 1999) were developed and implemented. A clinical training program was established at the University of Washington core site to provide FAS training to local community professionals and multidisciplinary clinical teams worldwide. The screening, diagnostic and training tools were all developed from the FAS DPN clinical database. This database also serves as a confidential registry of over 1,200 consistently diagnosed patients eligible to enroll in ongoing prevention/intervention research. The FAS DPN clinics are unique from other genetic and neurodevelopmental programs that typically provide services to these children in three fundamental ways: 1) The FAS DPN clinics all follow the same comprehensive, case-defined method for diagnosis (Astley and Clarren, 1997, 1999, 2000), 2) the clinics provide a multidisciplinary approach to diagnosis and treatment planning (Clarren and Astley, 1997; Clarren et. al., 2000) and 3) the clinics focus their intervention efforts on both the child and the birth mother (diagnosis and treatment planning for the child with primary prevention intervention for the child's birth mother). The patient satisfaction survey presented to all patients seen in the FAS DPN revealed that 87% of patients felt they had received services they were unable to obtain anywhere else. Ninety-nine percent reported they would recommend the clinic to families in similar need. The Network is currently funded through multiple sources including in-kind support, fee for service, and specific grants and contracts to provide targeted services within the community.

Proportion of Patients Receiving a FAS Diagnosis in the FAS DPN Clinics

The FAS DPN clinics received 3,002 requests for diagnostic evaluations in its first five years of operation (1993

through 1997). Operating at capacity, the clinic conducted 811 diagnostic evaluations.

Gestalt Method. The first 454 patients evaluated in the FAS Clinic were diagnosed using the gestalt method. Of the 454 patients, 110 (24.2%) received a gestalt diagnosis of FAS or atypical FAS (AFAS) and 344 (75.8%) received a gestalt diagnosis of PFAE. AFAS is FAS without the growth deficiency. Using the gestalt method, one out of every four patients received a diagnosis of FAS/AFAS.

4-Digit Code Method: Patients 455 through 811 were diagnosed using the 4-Digit Diagnostic Code method. All 454 patients diagnosed prior to implementation of the new diagnostic method had their gestalt diagnostic outcomes converted over to the new, more stringently case-defined 4-Digit Code. Thus, of all 811 patients evaluated at the FAS DPN, 39 (4.8 %) received a 4-Digit diagnosis of FAS/AFAS (Diagnostic Categories A-C) and 559 (68.9 %) received a 4-Digit diagnosis (Diagnostic Categories E-I) comparable to the gestalt diagnosis of PFAE. Using the 4-Digit Code method, one out of every 21 patients evaluated in the FAS DPN Clinics received a 4-Digit diagnosis of FAS/AFAS. A lower proportion of patients were diagnosed with FAS using the 4-Digit Code relative to the gestalt method because the 4-Digit Diagnostic system demands more stringent adherence to the diagnostic criteria of FAS through the use of specific case definitions (Astley and Clarren, 2000).

Impact of the 4-Digit Code on Identifying High-Risk Mothers

In contrast to the maternal population initially targeted in this study through their child's gestalt diagnosis of FAS, the 4-Digit diagnostic system allowed a much broader and more appropriate maternal population to be accurately identified and targeted for primary prevention. In other words, rather than target the birth mothers of just the children with FAS/AFAS, the birth mothers of all children receiving a 4-Digit diagnosis ending in 33, 34, 43, or 44 could and should be targeted. These codes reflect strong evidence of organic brain damage (static encephalopathy) and a confirmed history of maternal alcohol exposure. Of the 811 patients evaluated at the FAS DPN, 238 (29 %) received a diagnosis of static encephalopathy/alcohol exposed. Thirty-nine of these 238 patients (16.4%) also presented with growth deficiency and the FAS facial phenotype and thus received a 4-Digit diagnosis of FAS/AFAS. Thus one out of every three patients evaluated in the FAS DPN Clinics received a 4-Digit diagnosis of static encephalopathy, alcohol exposed. This is the maternal population currently being targeted for primary prevention intervention in the FAS DPN clinics.

Identification and Enrollment of Birth Mothers

A total of 257 women who had given birth to one or more children with a gestalt diagnosis of FAS (Sokol and Clarren, 1989) or a 4-Digit diagnosis of FAS or static encephalopathy (Astley and Clarren, 1997, 1999, 2000) were identified as potentially eligible to enroll in this study (Table 1). One hundred and forty-seven (57%) were identified prospectively from the FAS DPN clinics and 110 (43%) were identified both retrospectively and prospectively from other clinics. Of the 257 mothers, 92 were confirmed to be eligible to enroll in this study, 58 were confirmed to be ineligible and the eligibility of the remaining 107 remained unknown. Of the 92 mothers confirmed to be eligible, 80 (87%) were enrolled and interviewed. Of the 58 women who were deemed ineligible, 31 no longer lived in Washington State and 27 were deceased. Of the 107 women whose eligibility status could not be determined, 97 were identified by name, but none of them could be located.

Key challenges to locating the birth mothers included: 1) 80% of the children were no longer in the custody of their birth mothers at the time of the child's diagnosis, and 2) medical confidentiality limited the exchange of patient/birth mother information between our study staff and outside agencies who could be instrumental in assisting us. It required, on average, 6.7 (range = 1 to 36) attempts to contact each of the 80 women over an average of 3.8 months (range = 0 to 36 months) per woman to identify, locate and enroll them into the study. We found that public health and social service providers were very willing to help locate the women when they could. Most often, they would telephone or forward letters of invitation from us to the eligible women.

Success at identifying, locating and enrolling women was comparable between the two clinical sources (Table 1). The majority of the children diagnosed with static encephalopathy/alcohol exposed came from the FAS DPN clinics because the majority of children diagnosed in the other clinics were diagnosed before the 4-Digit Code was created and only children seen by SKC in the other clinics were diagnosed using the 4-Digit Code. The patient population at the FAS DPN also had a slightly higher proportion of Caucasians than the patient populations identified through the other clinics.

Representativeness of the Maternal and Patient Study Populations

The maternal population that the FAS DPN clinics will target for primary prevention efforts are the birth mothers of children with FAS and static encephalopathy who can be identified and located with reasonable effort and live within Washington State where they are eligible to receive social and health care services. This target population is defined by the eligibility criteria presented above for this study. Eighty (87%) of the 92 women confirmed to be eligible to enroll in this study were enrolled and interviewed (Table 1). Of the 12 eligible women who did not enroll, six were identified by name and location, but could not be reached directly to invite into the study. Of the six women who were contacted, but declined to interview, five of them had given birth to the index child with FAS over 17 years ago and one had given birth to the index child with FAS only four months ago. Two of these six patients had been diagnosed over ten years ago. Four of these women said they were too old or unhealthy to participate, one said that she was too busy, and one did not provide a reason. Based on the percent of eligible women interviewed (87%), this study population should be reasonably representative of the target population. Although the primary objective of this

Table 1. Summary of maternal identification, location and enrollment stratified by whether the child was identified prospectively in a FAS Diagnostic & Prevention Network clinic (FAS DPN) or retrospectively/prospectively in another clinic.

Characteristic	Source of Patient with FAS or Static Encephalopathy: Prospective FAS DPN Clinics n	(%)	Retrospective/Prospective Other Clinics n	(%)	Total n	(%)

prevention project was to demonstrate the feasibility of targeting primary prevention services to birth mothers identified prospectively through the FAS DPN clinics; women identified from other diagnostic clinics were also enrolled to increase the sample size and duration of follow-up. Inclusion of women from outside the FAS DPN did not appear to impact the overall maternal profile. The sociodemographic profiles of the two clinical populations were very comparable. The 46 mother/child pairs identified through the FAS DPN and the 34 mother/child pairs identified through the other clinics did not differ significantly in maternal race, maternal education level, maternal age at the time of the child's birth, maternal age at the child's diagnosis, maternal age at the time of the interview; child's race, child's gender or the child's age at the time of the maternal interview. The mean age of the patients diagnosed in the FAS DPN clinics was older than the patients diagnosed in the other clinics (9.4 ± 6.2 compared to 5.7 ± 4.8; $t = 2.8$, $p = 0.006$) because the FAS DPN clinics see both children and adults. The other clinics were all pediatric clinics. Patients identified through the other clinics had been diagnosed longer ago relative to the patients identified through the FAS DPN (4.8 ± 4.2 years compared to 1.4 ± 1.1 years; $t = 4.4$, $p = 0.000$), which was expected since the other clinics opened in the 1970s. The magnitude of these two contrasts is not likely to have a meaningful impact on the overall profile of the maternal target population.

One additional contrast that will be of interest to some is a comparison of the 80 women who were enrolled versus the remaining 177 who were identified as having given birth to a child with FAS or static encephalopathy, but were not enrolled. The following sociodemographic characteristics were comparable between the two groups: the child's diagnosis, mother's race, mother's age at the child's birth, mother's age at the child's diagnosis and mother's age at the time she was identified as potentially eligible to be enrolled in the study. A complete sociodemographic profile of the 80 women enrolled in the study can be found in Table 1 in Part II of this series (Astley *et al*., 2000). The children of the mothers who were not enrolled were on average three years older at the time of their diagnosis (10 ± 9 compared to 8 ± 6; $t = 2.6$, $p = 0.01$), were more likely to be female (45% compared to 31%; chi-square = 4.2; $P = 0.04$) and were diagnosed 1 year earlier (4.4 ± 4.3 compared to 3.5 ± 3.0; $t = 3.6$, $P = 0.000$) than children of the women enrolled. Again, it would appear that the maternal

population enrolled is reasonably representative of the population of all mothers identified through the diagnosis of their children.

*Profile of the 80 Children whose Mothers were Enrolled***.**

A profile of the 80 children whose mothers were enrolled in the study is presented in Table 2. They were predominantly Caucasian, 7.8 years of age at the time of their diagnosis with over half no longer living with their birth mother at the time of the diagnosis. The racial distribution was comparable to the racial distribution in WA State with the exception of a slight over representation of Native Americans. Eighty-nine percent had a gestalt or 4-Digit diagnosis of FAS, the remaining 11% had a 4-Digit diagnosis of static encephalopathy/alcohol exposed without the full FAS facial phenotype.

DISCUSSION

This project demonstrated that the multidisciplinary FAS DPN of clinics could successfully attract and meet the diagnostic and treatment planning needs of patients presenting with prenatal alcohol exposure. The clinical database generated from this patient population allowed for the development of screening and diagnostic tools that, in turn, allowed the clinic and its diagnostic method to be replicated statewide and nationally. The FAS DPN was successful at attracting a patient population at high risk for organic brain damage and prenatal alcohol exposure. Using the original gestalt method of diagnosis, one out of every four patients evaluated received a diagnosis of FAS. Using the 4-Digit Diagnostic Code method of diagnosis that demands more stringent adherence to strict diagnostic criteria, 238 (29 %) of the 811 patients evaluated through the FAS DPN Clinics received a diagnosis of static encephalopathy/alcohol exposed. Thirty-nine of these 238 patients (16.4%) also presented with growth deficiency and the FAS facial phenotype and thus received a 4-digit diagnosis of FAS/AFAS. Thus one out of every three patients evaluated in the FAS DPN clinics received a 4-Digit diagnosis of static encephalopathy, alcohol exposed. The birth mothers of these children with documented organic brain damage and prenatal alcohol exposure represent the FAS

DPN's current target population for primary prevention intervention. While only 20 % of the patients evaluated in the FAS DPN clinics are accompanied by their birth mother, the clinic was able to identify 95% and locate 57% of them. Forty-six percent of the 80 women interviewed in this study were still at risk for producing alcohol-damaged children at the time the index child received a diagnosis of FAS or static encephalopathy. They were at risk because they were still fertile and either actively drinking or at risk of drinking. Thirty-five had given birth to 61 additional children in the years following the index child's diagnosis. Seventy-five percent of the 61 children were exposed to alcohol in utero. Thus, based on what we have learned from this study: 1) that these women are at high risk for producing more children damaged by alcohol exposure, 2) that they, themselves, are often facing serious adverse social, mental and physical health issues, and 3) that some are often just a few phone calls away, one could argue that it would be unethical to ignore their existence and ignore the opportunity to provide them with advocacy support and primary prevention intervention (Astley *et al*., 2000).

Current Status of the Washington State FAS DPN Primary Prevention Program

The Washington State FAS DPN meets monthly with pertinent state agencies and programs (Department of Health, Department of Social and Health Services, Department of Corrections, Office of Public Instruction, Medical Assistance Administration, Family Advocacy, Western Washington March of Dimes and the University of Washington Fetal Alcohol and Drug Unit) to facilitate efficient and effective provision of FAS screening, diagnostic, prevention and educational services statewide. The FAS DPN is currently working with the State to facilitate referral of high-risk women identified through the FAS DPN to appropriate primary prevention intervention services. One state-supported service that provides very high-risk mother/infant pairs with home-based paraprofessional advocacy from birth to three years of age is the Washington State Parent-Child Assistance Program (P-CAP) directed by Therese Grant, Ph.D., at the University of Washington. P-CAP has proven to be highly effective and efficient at leading women into sobriety and effective family planning (Grant *et al*., 1999, Ernst *et al*., 1999). When the FAS DPN of clinics first opened in 1995, P-CAP had only one site in Seattle, Washington and enrolled only women who were in their last trimester of pregnancy with chronic alcohol and/or drug use during pregnancy. In 1999, the Washington State legislature supported the expansion of P-CAP into four of the six major metropolitan areas of Washington State where FAS DPN clinics exist and expanded the enrollment criteria to include birth mothers of children diagnosed with FAS or static encephalopathy through the FAS DPN clinics. While not all birthmothers targeted for primary prevention through the FAS DPN clinics need the intense services of P-CAP, those that do are well held.

Rate of Identification of Children and Mothers and Cost of FAS Prevention

Based on the results of this study, one out of every three patients evaluated in the FAS DPN clinics is diagnosed with FAS or static encephalopathy/alcohol exposed. The birth mothers of one out of every three of these children diagnosed with FAS or static encephalopathy/alcohol exposed can be directly contacted. Half of the birth mothers directly contacted will still be at risk for producing more children damaged by prenatal alcohol exposure. Thus one out of every 18 children evaluated in the FAS DPN clinics has a birth mother who can be found and is at risk for producing more children damaged by prenatal alcohol exposure.

Providing diagnostic and intervention services to both mother and child through a FAS Diagnostic Clinic not only benefits the mother and child, but has the potential of being a very cost effective approach to FAS primary prevention. The cost to society to raise a child with FAS is estimated to be $1,000,000 (Abel and Sokol, 1987). A diagnostic evaluation for a child through a FAS DPN clinic costs approximately $1,200. Providing effective intervention to the highest risk birth mothers through the Parent-Child Assistance Program costs $3,800 per year per woman for three years (Grant *et al*., 1999). If, on average, 18 children must be diagnosed to identify and intervene with one high-risk mother, the approximate cost to find and provide effective intervention services to the birth mother would be $33,000 ($22,600 to diagnose 18 children and $11,400 to provide three years of advocacy services to the mother through the P-CAP program). Thus, the cost of raising a child with FAS would be roughly thirty times the cost of preventing FAS in the child. The benefit to the mothers, their children and society would be immeasurable.

Acknowledgements -- We would like to thank the following individuals and agencies for their help in designing, implementing and analyzing this study: Kathy Briggs-Jones, Serena Harris, B.A., Heather Grigg, B.A., Jill Crank, Washington State Department of Health, Washington State Department of Corrections, Seattle-King County Department of Public Health and all the collateral contacts who helped us identify and enroll the birth mothers. We extend a very sincere thank you to the birth mothers who so generously and openly contributed to this project in the hopes they may help women in similar need. This study was supported by Cooperative Agreements U84/CCU-008707 and U59/CCU-006992 from the Centers for Disease Control and Prevention. Additional support was received from the Washington State Department of Social and Health Services, the Washington Chapter of the March of Dimes Birth Defects Foundation, the John B. Chavez Memorial FAS Fund and the Center on Human Development and Disability at the University of Washington.

(Received 1 *December* 1999*; in revised form* 11 *April* 2000*; accepted* 5 *May* 2000*)*

Abstract -- A 5-year, FAS primary prevention study was conducted in Washington State to: 1) assess the feasibility of using a FAS Diagnostic and Prevention Clinic as a center for identifying and targeting primary prevention intervention to high-risk women, 2) generate a comprehensive, lifetime profile of these women and 3) identify factors that have enhanced and/or hindered their ability to achieve abstinence. The results of this study are presented in two parts. Objective 1 is summarized in Part I and is published separately. Objectives 2 and 3 are summarized in Part II below. Comprehensive interviews were conducted with 80 women, who had given birth to a child diagnosed with FAS, to document their sociodemographics, reproductive and family planning history, social and health care utilization patterns, adverse social experiences, social support network, alcohol use and treatment history, mental health and intelligence quotient. This high-risk population of women was diverse in racial, educational and economic background, was often victims of abuse and was challenged by mental health issues. Despite their rather harsh psychosocial profile, many demonstrated the ability to overcome their alcohol dependence over time. The women who had achieved abstinence had significantly higher I.Q.s, higher household incomes, larger more satisfactory social support networks, were more likely to report a religious affiliation and were more likely to be receiving mental health treatment for their mental health disorders relative to the women who had not achieved abstinence. The rate of unintended pregnancies and alcohol-exposed pregnancies was substantial. Key barriers to achieving effective family planning were maternal alcohol and drug use, lack of access to birth control and lack of support by their partner to use birth control. A FAS Diagnostic and Prevention Clinic can be used to identify women at high risk for producing children damaged by prenatal alcohol exposure. Primary prevention programs targeted to this population could lead to measurable reductions in the incidence of FAS.

INTRODUCTION

The fetal alcohol syndrome (FAS) is a permanent birth defect caused by maternal use of alcohol during pregnancy. FAS is characterized by pre- and/or postnatal growth deficiency, central nervous system dysfunction (CNS) and a unique cluster of minor facial anomalies (Clarren and Smith, 1978). Prevention of FAS requires targeting primary prevention interventions to women at highest risk to produce children damaged by prenatal alcohol exposure. FAS studies consistently report that women who have had one child with FAS, and who continue to drink, have progressively more severely affected children with subsequent pregnancies (May *et al*., 1983; Davis and Lipson, 1984; Abel, 1988).

Although women who have one affected child often have more, to date there is no anticipatory biologic or sociologic markers that distinguish the mothers of children with FAS from other women who drink in pregnancy and bear normal or nearly normal children. Treatment of women for alcoholism during pregnancy probably comes too late to prevent brain damage in affected fetuses even if the correct high-risk, alcoholic women are selected for therapy. While it would be ideal to identify and treat all alcoholic women prior to pregnancy, resources for such an effort are not available. However, each patient with FAS (as identified through a FAS diagnostic clinic) has a mother who has a proven ability to give birth to a child damaged by prenatal alcohol exposure. Focusing prevention efforts on this select and high-risk group of women could reduce the incidence of FAS births dramatically without overburdening the current health care and alcohol treatment system (Clarren and Astley, 1998).

A Cooperative Agreement with the Centers for Disease Control and Prevention (CDC) from 1992 to 1997 allowed for the development of a FAS Diagnostic Clinic at the University of Washington to: (1) assess the feasibility of using a FAS Diagnostic Clinic as a center for identifying and targeting primary prevention intervention to high-risk women; (2) generate a comprehensive, lifetime profile of their birth mothers as a first step in the development of a FAS Primary Prevention Program targeted to meet their needs; (3) identify factors that have enhanced and/or hindered the birth mothers' ability to achieve abstinence.

The methods and outcomes of this FAS diagnostic and prevention project are presented in two parts. The first report presents the objectives and methodology for the entire project and summarizes the project's success at identifying high-risk birth mothers through the diagnosis of their children (Objective I). This second report presents a lifetime profile of 80 women who gave birth to a child with FAS and identifies factors that enhanced and hindered their ability to achieve abstinence and/or practice effective family planning (Objectives II and III).

METHODS

A detailed presentation of the methods is presented in Part I of this report (Astley et. Al, 2000). Briefly, the birth mothers of children with confirmed prenatal alcohol exposure and a diagnosis of FAS or static encephalopathy were identified retrospectively and prospectively through pediatric diagnostic clinics at the University of Washington and Children's Hospital and Regional Medical Center in Seattle, Washington.

These clinics included the University of Washington FAS Diagnostic Clinic established through this Cooperative Agreement (Clarren and Astley, 1997; Clarren et. al, 2000). The diagnosis of FAS or static encephalopathy/alcohol exposed was made using the clinical gestalt guidelines published by Sokol and Clarren (1989) or the 4-digit Diagnostic Code created by Astley and Clarren (1997, 1999, 2000). Women were eligible to enroll if they gave birth to at least one child with a diagnosis of FAS or static encephalopathy as described above. They could be of any age or race and had to be a resident of Washington State at the time of study enrollment. The women participated in a four-hour structured personal interview developed to generate a lifetime, comprehensive profile of her sociodemographics, reproductive and family planning history, social and health care utilization patterns, adverse social experiences, social support network, alcohol use and treatment history, mental health and intelligence quotient. The interview included 2,044 questions. The questions focused on three time periods in the women's lives: 1) at the birth of the index child with FAS, 2) at the time of the interview and 3) over their lifetime. This study was reviewed and approved by the University of Washington Human Subjects Review Board.

Analysis

t-tests and paired *t*-tests were used to compare outcomes between two independent or paired groups respectively when outcomes were measured on continuous scales. Chi-square tests and Fisher Exact tests were used to compare outcomes between two independent groups when outcomes were measured on nominal scales. Wilcoxon Signed Rank tests and McNemar tests were used to compare proportions between two independent or paired groups respectively, when outcomes were measured on ordinal scales.

RESULTS

Identification and Enrollment of Birth Mothers

A total of 257 women were identified as potentially eligible to enroll in this study. They had given birth to one or more children with confirmed exposure to alcohol and a gestalt diagnosis of FAS (Sokol and Clarren, 1989) or a 4-Digit diagnosis of FAS or static encephalopathy/alcohol exposed (Astley and Clarren, 1997, 1999, 2000). Of the 257 mothers, 92 were confirmed to be eligible to enroll in this study, 58 were confirmed to be ineligible and the eligibility of the remaining 107 remained unknown. Of the 92 mothers confirmed to be eligible, 80 (87%) were enrolled and interviewed. A more detailed summary of identification and enrollment can be found in Part I of this series (Astley *et al*., 2000).

Representativeness of the Maternal and Patient Study Populations

The maternal population that the FAS DPN clinics will target for primary prevention efforts are the birth mothers of children with FAS and static encephalopathy who can be identified and located with reasonable effort and live within Washington State where they are eligible to receive social and health care services. This target population is defined by the eligibility criteria presented above for this study. Eighty of the 92 women (87%) confirmed to be eligible to enroll in this study were enrolled and interviewed. A more detailed summary of the representativeness of this study population is presented in Part I of this series (Astley *et al*., 2000). Based on the percent of women interviewed (87%) and the profiles of the eligible women who did (n = 80) and did not enroll (n = 12), this study population is regarded as being highly representative of the target population.

Profile of the 80 Children whose Mothers were Enrolled.

A profile of the 80 children whose mothers were enrolled in the study is presented in Part I of this series (Astley *et al*., 2000). They were predominantly Caucasian, 7.8 years of age at the time of their diagnosis with over half no longer living with their birth mother at the time of the diagnosis. Eighty-nine percent had a gestalt or 4-Digit diagnosis of FAS or AFAS, the remaining 11% had a 4-Digit diagnosis of static encephalopathy/alcohol exposed without the full FAS facial phenotype. These were the diagnostic outcomes used to determine the birth mothers enrollment eligibility.

Maternal Sociodemographic and Mental Health Profile

A comprehensive, lifetime profile of the 80 birth mothers was generated documenting their sociodemographics, social and health care utilization patterns, adverse social experiences, social support networks and mental health (Tables 1, 2, 3 and 4). Due to the volume of data collected, only selected portions of this profile are presented in this report. Briefly, these women were on average 21 years of age at the birth of their first child, 27 years of age at the birth of the index child, 35 years of age at the diagnosis of the index child and 38 years of age at the time of study enrollment. The study population was predominantly Caucasian, closely resembling the racial distribution of Washington State with a slight over-sampling of Native Americans. Their children were on average 7.8 ± 5.9 (0.1 to 24.2) years of age at the time they were diagnosed. The average maternal I.Q. was 90.0 ± 15.2. Sixty-one percent did not complete high school; 25% had some college education. Fifty-nine percent had a gross annual household income of less than $10,000 at the time of the interview; 78% were in this income bracket at the time of the index child's birth. Ninety-five percent had been physically or sexually abused during their lifetime. Ninety-six percent had one to ten mental health disorders with the most prevalent being post traumatic stress disorder (77 %) and simple phobia (44%).

Maternal Lifetime Reproductive and Family Planning Histories

Their lifetime reproductive and family planning histories are presented in Tables 5 and 6. At the time of the interview, these women had given birth to 272 children. Seventy-three percent of each woman's live births were reportedly unplanned, 76% were reportedly exposed to alcohol. Mean parity and gravity at the time of the interview was 3.4 ± 1.6 and 4.4 ± 2.1 respectively. The mean parity of the index child was 2.6 ± 1.5. Thirty-five of these women went on to have 61 additional children after the birth of their index child. These 35 birth

mothers reported that 80% of the 61 children were unplanned and 75% were exposed to alcohol. Although the study did not include gathering include outcome data on these subsequent births, it was known that a least six of these children were diagnosed with FAS. The 80 women on average reported not using any form of birth control during most (81%) of their pregnancies. When asked what form of birth control they would prefer if it were available to them free of charge, the most preferred method was Depo Provera (31.6%) followed by Norplant (16.5%), tubal ligation (13.9%) and the pill (10.1%).

Maternal Lifetime Drug and Tobacco Use

Eighty-six percent of the women reported using illicit drugs at some time in their lives, 40% reported use around the time of the birth of the index child and 9% reported current use (around the time of the interview) (Table 7). The most common drugs used were marijuana, speed/amphetamines and cocaine/crack. Eighty-four percent of the women smoked tobacco around the time of the index child's birth.

Maternal Lifetime Alcohol Use and Treatment Histories

A large volume of data collected on alcohol use and treatment, brief summaries are presented in Tables 8 and 9. Briefly, these women were on average 15 years of age when they first started drinking, between 23 and 28 years of age when they were drinking maximally, 26 years of age when they first attempted to stop drinking and 27 years of age at the birth of the index child. They reported drinking on average nine fluid ounces (or 266 ml) of alcohol per drinking occasion just before the birth of the index child**.** Almost half of the women (47%) reported drinking daily at that time. While 84% reported

Number of women identified with mental health disorders on the Quick Diagnostic Interview Schedule, age at onset of the disorder and temporal relationship of onset of disorder to onset of alcoholism are given.

they felt they had a problem with alcohol use, 94% reported they did not want to reduce their use because it helped them cope, 72% did not want to reduce because they were in an abusive relationship, and 79% reported they were too depressed to do anything about it. The four most common reasons they did not seek alcohol treatment were they did not want to give up alcohol (87%), they were afraid they would lose their kids (42%), there was no one to take care of the kids (40%) and their partner did not want them to go to treatment (39%).

Of the 80 women interviewed, 41 reported they were abstinent by the time their child was diagnosed with FAS or static encephalopathy. Abstinence was defined as "consumes no alcohol or consumes minimal quantities only on special occasions". This is comparable to the definition of abstinence proposed by Cahalan (*et al*., 1969) "drinks less than once a year or does not drink alcoholic beverages". Fifty of the 80 women reported they were currently abstinent (at the time of the interview). They had made, on average, six concerted attempts to stop drinking. Of the 80 women, 37 (46.2%) were still at risk for producing another child damaged by alcohol exposure at the time of the index child's diagnosis by virtue of still being fertile and actively drinking or at risk for drinking.

Contrasts between Women Who had and had not Achieved Abstinence.

Contrasts between the 50 women who had achieved abstinence by the time of the interview and the 25 women who were not abstinence at this time point are presented in Table 10. The women who had achieved abstinence had, on average, significantly higher I.Q.s, higher household incomes, larger more satisfactory social support networks and were more likely to report a religious affiliation. While they were equally likely to have mental health disorders, those who had achieved abstinence were more likely to have received treatment for their mental health disorder(s). Those who had achieved abstinence reported higher levels of drinking just before the birth of the index child and were more likely to have parents who had problems with alcohol use. They were comparable in race, education, employment, adverse experiences such as physical/sexual/emotional abuse, age at the interview, age at first abstinence attempt, age at first pregnancy, age at birth of index child, and age when first started drinking.

Contrasts between a Woman's Most and Least Successful Abstinence Attempts

Women were asked an identical set of questions about alcohol use and treatment during what they believed was their least successful abstinence attempt, most successful abstinence attempt and the abstinence attempt closest to the birth of the index child. Of the 31 women who were abstinent at the time of the interview and reported a most and least successful abstinence attempt, the following were found to be significantly different between the two attempts. During their most successful attempt, they were on average six years older, more likely to be worried about the impact of their alcohol use on their health, receiving more support from their family, less likely to be employed, more likely to be dependent on public assistance for an income, more likely to be seeking treatment from an agency or person outside their home, more likely to have completed an inpatient program, more likely to have participated in an aftercare program, and more likely to attribute their success in stopping drinking to their desire/readiness to stop and their religious beliefs.

Table 5. Reproductive history of the 80 birth mothers.

Characteristic	Mean	(SD)	Min. - Max.	*n*	Valid (%)
Age (years) at first pregnancy	19.6	(3.8)	12.5 - 30.0	80

[a] 1 drink = 0.5 fluid ounce = 14.8 ml absolute alcohol. Some interpreted 'occasion' to mean a multiple-day binge.

All other factors were comparable between their most and least successful sobriety attempts, including the amount and frequency they were drinking, whether or not they had a partner who was drinking, and the number of children they were caring for at the time.

DISCUSSION

The interviews revealed that this high-risk population of women was diverse in racial, educational and economic background, were often victims of abuse and were challenged by mental health issues. Despite their rather harsh psychosocial profile, many demonstrated the ability to overcome their alcohol dependence over time. Many descriptions of the female alcoholic population have appeared in the literature (Jarvis, 1992). Despite repeated attempts to capture the essence of the "female alcoholic personality syndrome" most have recognized the heterogeneity of the population (Beckman, 1984). In comparing our population to the published profiles of women alcoholics, we find many similarities and some interesting contrasts.

Mental Health

The co-occurrence of alcoholism with other mental health disorders has been widely recognized (Regier *et al.*, 1990; Sheehan, 1993). In 1997, Kessler *et al* (1997) reported on patterns and correlates of psychiatric morbidity and co-morbidity based on data from the National Co-morbidity Survey, a nationally representative household survey of 8,098 men and women between 18 and 54 years of age. Interviews were conducted face-to-face with an 83% response rate. Diagnoses were made according to DSM-III-R using a modified version of the Composite International Diagnostic Interview (WHO, 1990). Lifetime co-occurrence of mental health disorders among the subset of 299 women with diagnoses of alcohol abuse were as follows: post traumatic stress disorder (10.5%), depression (30.1%), simple phobia (28.2%), social phobia (24.1%), antisocial personality (2.1%), agoraphobia (9.3%), generalized anxiety disorder (8.4%), mania (3.8%), and panic disorder (7.3%). The proportion of women with alcohol abuse who had a first onset of a disorder prior to the onset of her alcohol abuse were as follows: post traumatic stress disorder (10.5%), depression (30.1%), simple phobia (28.2%), social phobia (24.1%), antisocial personality (2.1%), agoraphobia (9.3%), generalized anxiety disorder (8.4%), mania (3.8%), and panic disorder (7.3%). Social phobia, simple phobia, depression and drug dependence were

Age (years) at start of most successful attempt	31.4	(6.8)	19.5 - 52.2	67	

highly predictive of subsequent development of alcohol abuse in Kessler's study population. In comparison, the prevalence of mental health disorders in our population of 80 women appeared to be much greater and more likely to precede the onset of their alcohol abuse (Table 4).

Physical/Sexual Abuse

Physical and sexual abuse is prevalent among alcoholic women. Covington (1982) reports that 12% to 53% of alcoholic women report incest or other childhood sexual abuse and up to 74% report some type of childhood or adult sexual abuse. Our study revealed childhood and/or adult sexual abuse occurred in 73% of the 80 women. Almost all (95%) were sexually and/or physically abused during their lifetime. Women who suffer from abuse may become increasingly depressed, anxious, and fearful of violence in their lives (Root, 1989). Root (1989) suggests that many women who relapse following substance abuse treatment are unable to cope with ongoing physical or sexual abuse without using alcohol or other drugs. She contends that substance abuse treatment personnel need to be familiar with the syndrome of domestic violence and abuse, because intervention will be unsuccessful if issues of past and current abuse are not addressed during substance abuse treatment. Beckman (1980) reports that alcoholic women were more likely to report that they felt powerless and inadequate compared to non-alcoholic women. She goes on to state that these findings support the contention that heavy alcohol consumption is a coping mechanism likely to be used by women to relieve feelings of helplessness and powerlessness (Beckman, 1984a). The use of alcohol and other drugs has become a way for women to deal with the emotional pain resulting from earlier abuse by someone close to them, someone they trusted (Covington and Surrey, 1997). Ninety-four percent of the women in our study reported that they did not want to reduce their alcohol use because '*alcohol helped her cope*'. Seventy-two percent reported they did not want to reduce their alcohol use because 'she was in an abusive relationship' or 'she was too depressed to do anything about it' (79%).

Social Support

Social support has often been reported in the literature as an important enabling factor for reduction of alcohol dependence. In a study of 400 Anglo alcoholics in treatment for alcoholism, Beckman, (1984a) reported that females who completed treatment were more likely to have greater social support for treatment entry. The 50 women who achieved abstinence in our study population reported having significantly larger, more satisfactory social support networks than the 25 women who failed to overcome their alcohol dependence.

Table 10. Selected contrasts between the 50 women who had achieved abstinence at the time of the interview and the 25 women who had not achieved abstinence.

Their social support networks included family, friends and service providers.

Alcohol Treatment

In 1992, a survey was conducted of 79 Seattle and King County non-profit and for-profit alcohol and drug treatment agencies to assess the availability of gender specific treatment for women (Seattle-King County Task Force for Chemically Dependent Women, 1993). The agencies reported 33% of their clientele were women of whom 73% were Caucasian, 14% were African American and 5% were Native American and 73% were between 21 and 40 years of age. Eighty-four percent of the providers did not provide on-site child care, 54% did not offer medical or mental health services at the agency site and 44% did not offer on-site recovery support groups like Alcoholics Anonymous. When the providers were asked what they believed to be the major obstacles for women securing treatment, the top three barriers reported were child-care, money and social stigma. These are certainly troubling statistics in light of the data collected in our study. Ninety-six percent of the 80 women had one or more mental health disorders and the women who received mental health treatment were significantly more likely to achieve abstinence than women with mental health disorders who did not receive treatment. Sixty to 70% of the 80 women reported they were taking care of one or more children during their reported abstinence attempts. Women who achieved abstinence were significantly more likely to participate in an aftercare program like Alcoholics Anonymous. Women who had failed to achieve abstinence had significantly lower incomes.

Beckman and Amano (1984) report that although the relative success of different types of alcoholism treatment has long been debated there is some evidence that treatment programs, regardless of their orientation, produce more positive and lasting outcomes than does doing nothing for the alcohol abuser. It is interesting to note that while 39 of the 50 women who achieved abstinence in our study reported seeking help outside their home during their most successful abstinence attempt, only 31 reported being admitted to an inpatient or/or outpatient program and only 26 reported completing the program(s). Beckman and Amano go on to report that to accept help for an alcohol-related problem, a person generally first must perceive the existence of the problem and be willing to attempt to control the problem. In our study, the women who achieved abstinence were significantly more likely to report concern for their health and a desire to want to stop drinking than the women who did not achieve abstinence.

Beckman and Amaro (1984) report that characteristics related to the individual that affect the person's ability to secure, and inclination to use, services include: 1) individual predisposing factors such as age and ethnicity; 2) attitudes and

beliefs regarding alcohol, treatment and health; 3) personal enabling traits such as personality characteristics and drinking and treatment history; and 4) social enabling characteristics such as child care responsibilities, social support systems and access to financial resources. The predisposing factors of age and ethnicity are immutable. Some mutable predisposing factors such as education and income may be changed through both policy and individual efforts, while other mutable predisposing factors such as religion or marital status, are more often changed through individual decisions (Beckman, 1984). In a study of moderately drinking women entering a program for drinking reduction (Walitzer and Connors, 1997), contrasts between the 120 women who completed the treatment with the 51 women who did not complete the program were comparable to the contrasts observed in our study (Table 10), despite the marked difference in the drinking levels of the two study populations. The moderately drinking women who did not complete treatment were significantly younger, more likely to have a racial background other than Caucasian, more likely to be single or divorced, had fewer years of education and reported more drinking per day at pretreatment relative to the women who did complete the program. Several factors that significantly differentiated the women who did and did not achieve abstinence in our study are potentially mutable (e.g., income, social support network and mental health treatment).

Family Planning

Avoiding alcohol use during pregnancy is just one of two ways to prevent FAS. The other is to prevent pregnancy during alcohol use. While the former reduces health risks to both mother and child, the later is purported by some to be the more simple and immediate means to an end. Both approaches are complex and resistant to change. While society might view the alcohol use and unintended pregnancies of these women as problems in their lives, these women often perceive their alcohol use and pregnancies as partial solutions to their problems. They report that alcohol helps them cope with their often abusive and impoverished lives. Pregnancy and children not only qualify them for social and health care services they might otherwise not receive, it also fulfills an innate desire to bear and raise children. Based on the data collected in this study, it would appear that the women were more successful at avoiding alcohol use than preventing pregnancy. This could be due, in part, to the astonishing lack of access women have to contraceptives. In 1987, 22 years after the U.S. Supreme Court affirmed the legality of contraceptive use in Griswold vs. Connecticut, 57% of pregnancies nationwide were unintended (Forrest, 1994). In 1993-94 new mothers in Washington State had approximately the same frequency of unintended pregnancies resulting in a live birth as the nation as a whole: 40% in Washington compared with 39% nationwide in 1988 (PRAMS, 1996; Brown and Eisenberg, 1995). The women in our study population reported that 78% of their first live born children were the result of unintended pregnancies; 60% of them were exposed to alcohol. There are many reasons why a woman does not practice effective birth control. One reason is access to affordable birth control. In a 1998 survey, conducted by the Office of the Insurance Commissioner, to determine the level of reproductive health benefit coverage in health insurance plans marketed in Washington State, 77% of the insurance plans paid for abortions while only 30% provided coverage for contraceptives. Worse yet, the percentage of individuals actually receiving coverage was lower; four out of five women do not have coverage for contraceptives (Senn, 1998). Lack of access to birth control was not the only reason that women in our study did not use birth control. They were equally likely to report that their alcohol and drug use interfered with their use of birth control and that their partners did not want them to use birth control. Only 10% reported they felt birth control was wrong or against their religious beliefs. In fact, 78 of the 80 women reported using some form of birth control during her life (diaphragm, IUD, cervical cap, pill, Depo Provera, Norplant, condoms, rhythm method or withdrawal) suggesting that few were opposed to birth control.

*Current Status of the Washington State FAS DPN Primary Prevention Prog*ram

The FAS DPN is currently working with the State to facilitate referral of high-risk women identified through the FAS DPN to appropriate primary prevention intervention services. Through this comprehensive approach to FAS diagnosis and prevention, we hope to measurably reduce the incidence of FAS in Washington State.

Acknowledgements - We would like to thank the following individuals and agencies for their help in designing, implementing and analyzing this study: Kathy Briggs-Jones, Serena Harris, B.A., Heather Grigg, B.A., Jill Crank, Washington State Department of Health, Washington State Department of Corrections, Seattle-King County Department of Public Health and all the collateral contacts who helped us identify and enroll the birth mothers. We extend a very sincere thank you to the birth mothers that so generously and openly contributed to this project in the hopes they may help women in similar need. This study was supported by Cooperative Agreements U84/CCU-008707 and U59/CCU-006992 from the Centers for Disease Control and Prevention. Additional support was received from the Washington State Department of Social and Health Services, the Washington Chapter of the March of Dimes Birth Defects Foundation, the John B. Chavez Memorial FAS Fund and the Center on Human Development and Disability at the University of Washington.

Abstract --- The purpose of this report is to demonstrate how to measure the magnitude of expression of the FAS facial phenotype using the new 4-Digit Diagnostic Code and the previously developed D-Score and to demonstrate how these two measures of the FAS facial phenotype correlate with brain function and structure; correlations that fail to be identified by the older gestalt method of facial measurement. The D-Score and the facial component of the 4-Digit Code quantitatively measure the magnitude of expression of the FAS facial phenotype using three facial features (palpebral fissure length, philtrum smoothness and upper lip thinness). These facial measurement systems were developed by the Washington State FAS Diagnostic and Prevention Network (FASDPN) of clinics and are used to screen and diagnose the facial component of FAS for all patients evaluated in the network of clinics (1,500 to date). The 4-Digit Code is a comprehensive diagnostic system developed by the FAS DPN in 1997 to diagnose the full spectrum of outcomes among patients with prenatal alcohol exposure. The four digits reflect the magnitude of expression of the four key diagnostic features of FAS in the following order: 1) growth deficiency, 2) the FAS facial phenotype, 3) brain dysfunction, and 4) gestational alcohol exposure. The 4-Digit Code was developed to overcome the subjective, highly variable gestalt method of diagnosis that has been used as the standard to date, worldwide. Prior to the development of the 4-Digit Code, the first 445 patients evaluated in the FAS DPN were diagnosed using the gestalt method. For research purposes, their gestalt diagnoses were transformed into 4-Digit Diagnostic Codes, presenting a unique opportunity to directly compare the two diagnostic methods. When the facial phenotype was measured using the 4-Digit Code or D-Score, the magnitude of expression of the FAS facial phenotype was significantly correlated with structural, neurologic and functional measures of brain damage and the phenotype of those receiving a 4-Digit Diagnosis of FAS showed little variability. When the gestalt method of diagnosis was used, the magnitude of expression of the FAS facial phenotype did not correlate with structural, neurologic and functional measures of brain damage and the facial phenotype of those receiving a gestalt diagnosis of FAS was highly variable. The 4-Digit Code and D-Score provide more precise and accurate measures of the FAS facial phenotype and reveal important correlations with brain structure and function, suggesting that intermediate expressions of the FAS facial phenotype may serve as important risk factor for brain damage caused by prenatal alcohol exposure.

INTRODUCTION

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The syndrome has been broadly characterized by pre- and/or postnatal growth deficiency, a characteristic set of minor facial anomalies, central nervous system (CNS) dysfunction and prenatal alcohol exposure (Jones and Smith, 1973; Clarren and Smith, 1978; Rosett, 1980; Sokol and Clarren, 1989; Stratton *et al*., 1996). In 1997, a new more objective and comprehensive, case-defined method for diagnosing the full spectrum of outcomes in individuals with prenatal alcohol exposure was created called the 4-Digit Diagnostic Code (Astley & Clarren, 1997, 1999, 2000). The four digits of the diagnostic code reflect the magnitude of expression of four key diagnostic features of FAS in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) brain damage/dysfunction, and (4) gestational alcohol exposure. Each are ranked independently on a 4-point Likert scale with 4 reflecting severe expression of the feature and 1 reflecting no expression of the feature. The 4-Digit Diagnostic Code is generated by first recording key clinical data on the standardized FAS Diagnostic Evaluation Form and following specific case-definitions to generate each of the four digits (Astley and Clarren, 1999, 2000). The concept of developing a more objective diagnostic system began with the development of a more objective, empirically derived method for measuring and case-defining the FAS facial phenotype (Astley & Clarren, 1996). A discriminant analysis was used to identify the cluster of minor anomalies and their magnitude of expression that best differentiated 42 individuals with FAS from 84 matched controls without FAS. Three features were identified (reduced palpebral fissure/inner canthal distance ratio, smooth philtrum and a thin upper lip). A discriminant equation was generated from the study demonstrating that when the magnitude of expression of these three features results in a discriminant score (D-Score) ≥ 0.80, the facial phenotype was 100% sensitive and specific to FAS. The photographs used to develop this D-Score method of facial analysis were obtained from retrospective sources, thus they did not include internal measures of scale for deriving the true palpebral fissure length (PFL) and innercanthal distance (ICD). The ratio PFL/ICD served as a proxy measure of the true lengths of each feature. Later analyses of direct measures of PFL and inner canthal distance among patients seen in the FAS DPN demonstrated that the key differentiating feature was PFL, not inner canthal distance. Like the D-Score method, the 4-Digit Code uses PFL, philtrum smoothness and upper lip thinness to define the FAS facial phenotype. Unlike the D-Score, a true measure, rather than a proxy measure of PFL, is obtained by either direct measurement or placement of an internal measure of scale in the clinical photograph. The 4-Digit Code method for documenting the magnitude of expression of the FAS facial phenotype serves as both a diagnostic and screening tool.

*Author to whom correspondence should be addressed at: Children's Hospital and Medical Center, 4800 Sand Point Way NE, CH-47, Seattle, WA 98105.

The 4-Digit facial rank has and continues to be used to diagnose the facial component of the syndrome in all patients receiving a FAS diagnostic evaluation in the theWashington State FAS Diagnostic and Prevention Network of clinics (n = 1,500 to date). It is also being used to screen all children entering long term foster care in King County WA and all residents in a WA State juvenile rehabilitation facility.

This report illustrates how to measure the magnitude of expression of the FAS facial phenotype using the 4-Digit Code and D-Score and demonstrates how the 4-Digit and D-Score measures of the FAS facial phenotype correlate with brain function and structure; correlations that fail to be identified by the standard gestalt method of diagnosis and facial measurement (Rosett, 1980; Sokol & Clarren, 1989).

SUBJECTS AND METHODS

Study Population

Data for this study came from all patients evaluated in the FAS DPN who met the following inclusion criteria: 1) had a confirmed history of prenatal alcohol exposure (Alcohol 4-Digit Rank = 3 or 4) (Astley & Clarren, 2000) and 2) consented to allow the FAS DPN to use their diagnostic data for research purposes. This study was approved by the University of Washington Human Subjects Division.

FAS Facial Phenotype

Three features (palpebral fissure length, philtrum smoothness and upper lip thinness) are measured to document the magnitude of expression of the FAS facial phenotype (Astley & Clarren, 1996). All other major and minor craniofacial anomalies are measured and recorded for clinical and research purposes but are not used to rank the magnitude of expression of the FAS facial phenotype. Palpebral fissure length is the distance from the endocanthion to the exocanthion (Figure 1). The philtrum furrow is the vertical groove extending from the midline of the upper lip to the nose (Figure 2). The upper lip refers to the area demarcated by the vermilion border (Figure 2). These three features are measured directly by a physician or measured from a digital photograph using image analysis software. Palpebral fissure length is measured in mm and transformed to a standardized z-score using appropriate published normal anthropometric charts (Iosub et al., 1985; Thomas et al, 1987; Hall et al., 1989). The z-score reflects how many standard deviations above or below the population norm the patient's PFL is, based on the patient's age. The z-score is defined as the patient's PFL minus the mean PFL for the normal population divided by the standard deviation of the mean PFL for the normal population. Philtrum smoothness and upper lip thinness are measured on 5-point Likert scales using the pictorial Lip-Philtrum Guide (Figure 3) (Astley & Clarren, 2000). This method for measuring the facial phenotype directly or photographically is demonstrated on a CD-ROM with the aid of animations and video (Astley et al., 1999).

Direct Measurement of Facial Features

Palpebral fissure lengths are measured to the nearest mm with a clear plastic ruler (1 cm by 14 cm in size) held as close as possible to the eye without touching the eye or eye lashes (Figure 1). The FAS DPN chooses not to use calipers because the patients are often too young and active to cooperate safely. The individual is asked to open his/her eyes widely to allow accurate identification of the endocanthion and exocanthion landmarks. The PFL is compared to the normal PFL for age by using a racially appropriate normal chart for PFL to compute the z-score for the right and left PFLs.

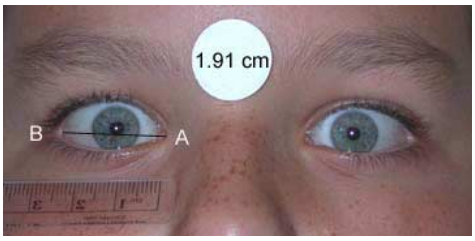

Fig. 1. Palpebral Fissure Length.

Palpebral fissure length (PFL) is measured from the endocanthion (A) to the exocanthion (B). It can be measured directly using a clear plastic cm ruler or it can be measured from a photograph with an internal measure of scale (adhesive paper sticker) placed between the eyebrows or a centimeter ruler placed below the eye.

Fig. 2 . Philtrum and Upper Lip

The philtrum is the vertical groove extending between the nose and the vermilion border of the upper lip. The smoothness of the philtrum and thinness of the upper lip (demarcated by its vermilion border) are measured by selecting the photograph from the Lip-Philtrum Guide (Figure 3) that best matches each feature independently. Upper lip thinness can also be measured from a digital photograph viewed on a computer monitor by tracing the outline of the vermilion border with a mouse and requesting image analysis software like Sigma Scan Pro to compute a measure called circularity (perimeter^2/area) (bottom photo). The thinner the upper lip, the larger the circularity (Figure 3). The circularity scores of the five lips pictured on the Lip-Philtrum Guide assist the physician in selecting the picture that best matches the patient's upper lip thinness. The lip pictured has a circularity of 40.5 and therefore would receive a rank of 1.

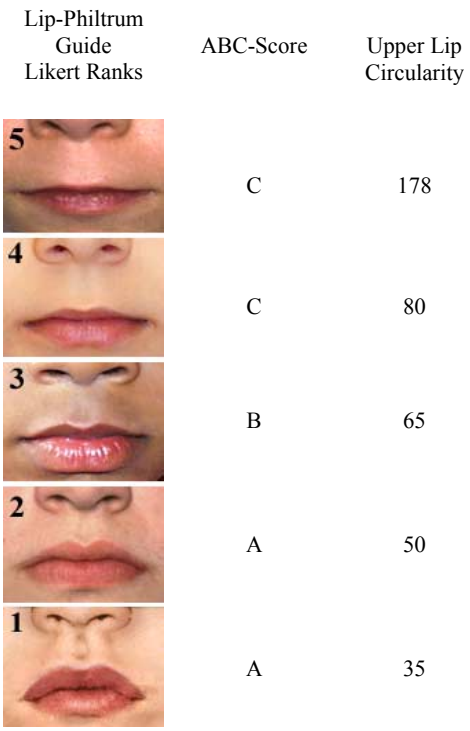

Fig 3. Lip-Philtrum Guide
Pictorial examples of the 5-point Likert scale, upper lip circularity scale and the ABC-scale used to rank upper lip thinness and philtrum smoothness. Circularity (perimeter^2/area) is a continuous measure of upper lip thinness that can be used to facilitate the ranking of upper lip thinness (Figure 2). It is important that the individual's lips are gently closed with no smile (see Figure 5).

Philtrum smoothness and upper lip thinness are measured on 5-point Likert pictorial scales by holding the Lip-Philtrum Guide next to the patient's face and assigning each feature the Likert rank of the photograph that best matches each feature (Figures 3 and 4). Philtrum smoothness and upper lip thinness are ranked independently of one another. For example a child could present with a rank 5 philtrum and rank 1 upper lip. The physician's eyes must be aligned in the patient's Frankfort Horizontal plane (demarcated by a line drawn through the patient's auditory meatus and the lowest border of the bony orbital rim) (Figures 4 and 6). If the physician's eyes are above or below this plane, the upper lip can appear thinner or thicker respectively than it truly is. The patient must have a relaxed facial expression with no smile and lips gently closed. A smile can cause the philtrum and upper lip to appear smoother and thinner than they truly are (Figure 5).

Although the innercanthal distance (R. endocanthion to L. endocanthion) is not used as a diagnostic feature of the FAS facial phenotype, it is still measured to document the presence of hypo- or hypertelorism and it is used as the denominator for the proxy measure

Fig 4. Facial Alignment and Expression

Illustration of a physician aligned in the patient's Frankfort Horizontal plane while using the Lip-Philtrum Guide to rank upper lip thinness and philtrum smoothness. The Frankfort Horizontal plane is defined by a line that passes through the patient's auditory meatus (or the upper edge of the tragus when viewed from the front, Figure 6) and the lowest border of the bony orbital rim (orbitale). The physician's eyes (or camera lens) should be directly in line with the patient's Frankfort Horizontal plane.

Fig 5. Impact of a Smile on Lip and Philtrum Measures

This is the same individual with (top photo) and without (bottom photo) a smile demonstrating how a smile can erroneously transform a deeply grooved philtrum (Likert rank = 2) and full upper lip (Likert rank = 1, lip circularity = 41) into a smooth philtrum (Likert rank = 4) and thin upper lip (Likert rank 5, lip circularity = 191) (Astley & Clarren, 1996). Circularity (perimeter^2/area) is a continuous measure of upper lip thinness that can be used to facilitate the ranking of upper lip thinness (Figures 2 and 3).

of PFL (namely PFL/ICD) used to compute the facial D-Score when a true measure of PFL is not obtainable. It is measured with a clear plastic ruler and transformed into a z-score using a racially appropriate normal chart for innercanthal distance.

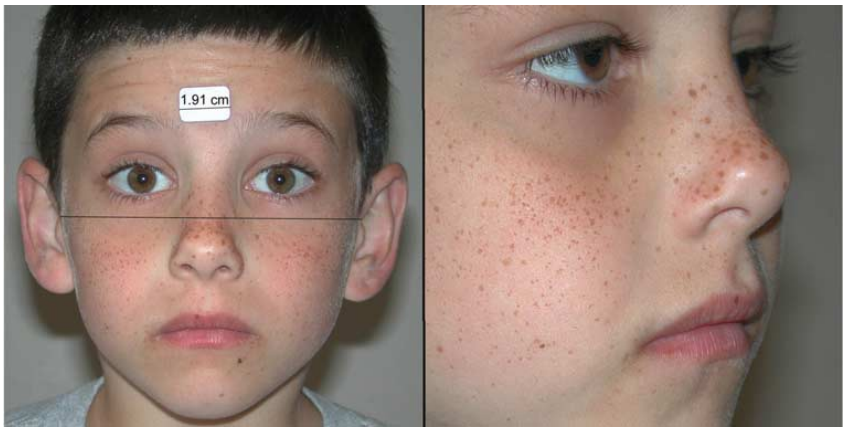

Fig. 6. Standardized Facial Photographs.
Two standardized facial photographs are obtained (frontal, ¾ view) to measure the facial phenotype of FAS. Eyes should be fully open, no eyeglasses, no smile, lips gently closed, and an internal measure of scale placed between the eyebrows. The right and left ears should be equally visible to ensure accurate measurement of the palpebral fissure lengths and innercanthal distance. An imaginary line drawn from the top of the left and right tragus should fall along the patient's lower bony orbital rims confirming the camera is aligned in the patient's Frankfort Horizontal plane (see Figure 4). The ¾ view is obtained to facilitate ranking the philtrum. It is especially important if the camera has a centrally mounted flash that can diminish the appearance of the philtrum depth in a frontal facial photograph.

Photographic Measurement of Facial Features.

An internal measure of scale is placed on the patient's forehead between their eyebrows (Figures 1 and 6). A small, adhesive paper sticker 1/2 inch to 3/4 inch in size serves well and can be purchased from an office supply store. A frontal and ¾ view photograph of the patient's face is obtained using a digital or 35 mm camera. Polaroid cameras do not provide sufficient image resolution. A close-up photo is taken such that the patient's head fills the entire frame (Figure 6). When using a digital camera, a minimum of 3-megapixel resolution is recommended. The lens of the camera is placed in-line with the patient's Frankfort Horizontal plane as described above and illustrated in Figure 4. To judge the Frankfort horizontal plane when viewing the face through the camera, an imaginary line drawn between the upper border of the left and right tragus should fall across the left and right lower bony orbital rim (Figure 6). There should also be no left-to-right rotation of the image; both ears should be equally visible in the frontal photo. The facial expression should be relaxed with no smile, lips gently closed, eyes wide open and no eyeglasses). The ¾ view is taken to facilitate ranking philtrum smoothness by purposely driving a flash of light across the philtrum to see if a shadow is cast. The ¾ view is especially important to obtain if the camera has a centrally mounted flash that can diminish the appearance of a grooved philtrum. Properly aligned facial photographs are obtained in the FAS DPN clinics with a hand-held camera and freestanding patient. Stereotaxic equipment and tripods are not necessary.

The digital image is measured using image analysis software (e.g., Sigma Scan Pro 5, 1999 of FAS DPN software to be distributed in 2001). This software allows one to enlarge the image, enhance the exposure if necessary, makes all the necessary measurements and store the data in an electronic database. If the image is obtained with a 35-mm camera, the slide, print or negative is scanned to generate a digital copy of the image. It is important to note that the resolution (or clarity) of a scanned image as small as a slide or negative may not be sufficiently high. The right and left PFLs are measured by clicking the mouse on the endocanthion and exocanthion landmarks and having Sigma Scan Pro compute the distance between the landmarks in units called pixels (or dots of light on the computer monitor). The length of the internal measure of scale (paper sticker) is also measured in units of pixels. The real size of the PFL in mm is computed from the PFL (in pixels), the length of the paper sticker (in pixels) and the real length of the paper sticker in mm using the following equation:

PFL (mm) = ((length of sticker in mm / length of sticker in pixels) x (PFL in pixels)) x1.07

If the image is rotated right or left, insert the mean PFL in pixels into the equation to compute a mean PFL in mm. The margin of eerror between this mean PFL (mm) and the true mean PFL measureed directly with calipers is less than 1%.

The 1.07 adjustment factor is included in the formula to increase the computed PFL by 7% to adjust for the foreshortening effect of measuring a facial feature that is slightly off the midline of the photograph (Farkas, 1994). This adjustment was confirmed to be accurate by comparing computed PFLs from photographs with measures obtained directly from the subjects with calipers. The computed PFL in mm is transformed into a z-score as described above to standardize it to the population norm. The PFL can also be computed by placing a clear plastic ruler directly under the eye prior to taking the facial photograph (Figure 1). The actual PFL in mm would be computed using the equation above without the adjustment factor.

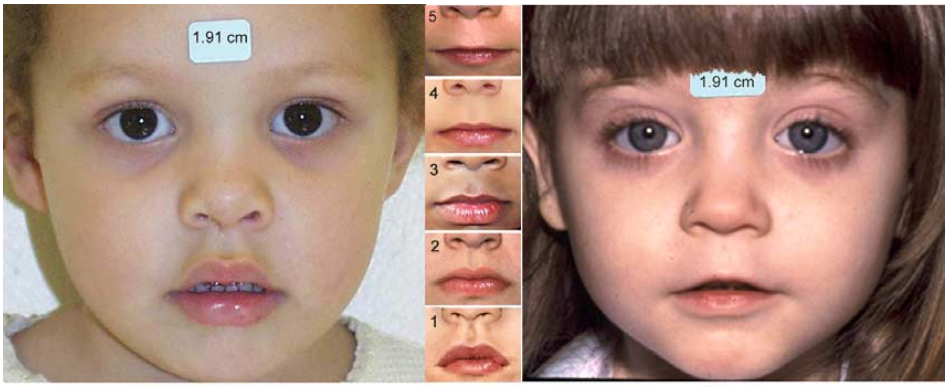

Figure 7. Facial D-Score and 4-Digit Code Rank

Example of the facial D-Scores and 4-Digit Facial Ranks of a control child and a child with the facial phenotype of FAS. The facial D-Score reflects the magnitude of expression of the FAS facial phenotype and is computed when an internal measure of scale is not in the photograph. A D-Score ≥ 0.8 is screen-positive for the face of FAS. The D-Score is computed using the palpebral fissure length/innercanthal distance ratio and the 5-point Likert ranks of philtrum smoothness and upper lip thinness using the Lip-Philtrum Guide pictured in the middle. The 4-Digit Facial rank also reflects the magnitude of expression of the FAS facial phenotype on a 4-point Likert scale. It is computed when the true PFL is available or can be computed. The first step is to generate the ABC-Score reflecting the size of the PFLs, philtrum smoothness and upper lip thinness in that order. Tables 1 and 2 are used to generate the ABC-score and transform it into the 4-Digit Facial Rank. A facial rank of 4 is face of FAS.

The real size of the ICD in mm is computed from the ICD (in pixels), the length of the paper sticker (in pixels) and the real length of the paper sticker in mm using the following equation:

ICD (mm) = (length of sticker in mm / length of sticker in pixels) x (ICD in pixels).

No adjustment factor is added to the equation because the sticker and ICD are on the midline, thus there is no foreshortening error.

Philtrum smoothness and upper lip thinness are measured using the Lip-Philtrum Guide described above. Philtrum smoothness is ranked by holding the Lip-Philtrum Guide next to the image on the computer monitor and selecting the picture that best matches the patient's philtrum. Upper lip thinness is measured by tracing the outline of the vermilion border with the mouse and having Sigma Scan Pro compute a measure called circularity (perimeter^2/area) (Figure 2). Some image analysis software programs call circularity 'compactness'. Circularity ranges from 12.8 for a circle to infinity as the circle is squashed into a line (or becomes thinner). The thinner the upper lip, the larger the circularity (Figure 3). The circularity scores of the five lips pictured on the Lip-Philtrum Guide guide the physician in selecting the picture that best matches the patient's upper lip thinness. The process of taking a facial photograph and measuring the features takes about ten minutes.

Computing the Facial D-Score

The facial D-Score is computed when a true measure of PFL cannot be obtained (e.g., home photos or retrospective photo sets that did not contain an internal measure of scale). The facial D-Score is computed using the equation:

D-score = 0.7408 – (5.7337 x (PFL / ICD)) + (1.1677 x philtrum 5-point Likert rank) + (0.1587 x upper lip 5-point Likert rank).

A facial phenotype with a D-Score ≥ 0.8 is classified as screen-positive for the facial phenotype of FAS (Figure 7). This discriminant function and cutoff value differentiated 42 patients with FAS from 84 controls with 100% sensitivity and specificity in an earlier study (Astley & Clarren, 1996).

Examples of facial D-Scores for a control child and child with the FAS facial phenotype are presented in Figure 7. The D-Score for the 2.8 year-old control child was –2.4 = 0.748 – (5.7337 x (117 pixels / 150 pixels)) + (1.1677 x 1) + (0.1587 x 1). The D-Score for the 2.1 year-old child with the FAS face was +3.2 = 0.748 – (5.7337 x (105 pixels / 143 pixels)) + (1.1677 x 5) + (0.1587 x 5).

Computing the Facial 4-Digit Code Rank

The facial 4-Digit Code rank is the most accurate diagnostic measure of the magnitude of expression of the FAS

Table 1.. 4-Digit Diagnostic Code for Facial Phenotype Rank[a]

A)

Five-Point Likert Scale for Philtrum & Lip	Z-score for mean Palpebral Fissure Length	Palpebral Fissure	Circle the ABC-Scores for: Philtrum	Upper Lip
4 or 5	≤ -2 SD	**C**	C	C
3	>-2 SD and ≤ -1 SD	B	B	**B**
1 or 2	> -1 SD	A	**A**	A

B)

4-Digit Diagnostic Code Rank*	Level of Expression of FAS Facial Phenotype	Palpebral Fissure - Philtrum - Lip ABC-Score Combinations
4	Severe	CCC
3	Moderate	CCB, CBC, BCC
2	**Mild**	CCA, CAC, CBB, CBA, **CAB**, CAA BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	Absent	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

[a]Case definitions used to define the 4-Digit Diagnostic Code ranks for FAS facial phenotype (Astley & Clarren, 2000). A. The first step in deriving the 4-Digit Code rank for the facial phenotype is to derive the facial ABC-Score. For example, if a patient's palpebral fissure lengths were > 2 SD below the norm and their philtrum and upper lip received Likert scores of 2 and 3 respectively (Figure 3), the facial phenotype would receive an ABC-Score of **CAB**. B. The final step is to convert the ABC-Score for Facial Phenotype to a 4-Digit Diagnostic Code Rank. A **CAB** score translates into a 4-Digit Diagnostic Code rank of **2.** This rank would serve as the second digit in the 4-Digit Code.

facial phenotype because it uses the actual PFL rather than the proxy measure (PFL / ICD) used by the D-Score. It can be computed from direct measures or from photographs that contain internal measures of scale. The first step in deriving the facial 4-Digit Code rank is to derive the facial ABC-Score. The magnitude of palpebral fissure length deficiency, philtrum smoothness and upper lip thinness are ranked by circling A, B, or C in each column in the ABC-Score table (Table 1a). The facial ABC-Score is converted to the facial 4-Digit Diagnostic Code Rank using Table 1b.

Examples of facial 4-Digit Code ranks for a control child and child with the FAS facial phenotype are presented in Figure 7. The control child had PFLs equal to 25 mm (z-score = 0), a rank 1 philtrum and rank 1 upper lip. These measures result in an ABC-Score of AAA and a 4-Digit facial rank of 1 (normal). The child with the FAS facial phenotype had PFLs equal to 18 mm (z-score = -4.7), a rank 5 philtrum and rank 5 upper lip. These measures result in an ABC-Score of CCC and a 4-Digit facial rank of 4 (severe). The control child's true PFLs in mm were computed from the photograph with the aid of the internal measure of scale (25 mm = ((19.1 mm / 97 pixels) x (118 pixels)) x 1.07. The PFL z-score = 0 = ((25 mm – 25 mm) / 1.31 mm) (Hall et al., 1989).

The Gestalt FAS Facial Phenotype

Prior to the development of the 4-Digit Code, all patients (n = 462) seen in the FAS DPN were diagnosed using the typical "gestalt" (Sokol & Clarren, 1989) method of diagnosis. The gestalt method uses a less specific qualitative definition for the FAS facial phenotype and records the outcome on a dichotomous scale (present/absent). As reported by Sokol and Clarren (1989) '*A characteristic face is currently qualitatively described as including short palpebral fissures, an elongated midface, a long and flattened philtrum, thin upper lip and flattened maxilla. The specific clinical features will vary with patient age'.* It is rare to find documentation in a patient's medical record or even in the medical literature as to what facial features were present when a diagnosis of FAS was given, thus, if an individual received a gestalt diagnosis of FAS, one can only infer that the FAS facial phenotype described by Sokol and Clarren (1989) was present.

Measures of Brain Function and Structure

Structural (OFC, MRI/CT/PET imaging), neurologic (seizures, cerebral palsy, etc) and functional (standardized psychometric tests of intellect, achievement, adaptation, language, neuropsychological performance, development and behavior) measures of the brain are assessed during the FASDPN diagnostic evaluation. Many of these measures are obtained from the patient's school and medical records; others are collected at the time of the patient's diagnostic evaluation. A few examples of the types of standardized psychometric tests most frequently obtained within each domain include: *Intelligence*: Wechsler Intelligence Scale for Children-3rd Edition (Wechsler, 1996) and Wechsler Adult Intelligence Scale-Revised (Wechsler, 1981), Test of Nonverbal Intelligence (Martin et. al., 1990); *Achievement*: Woodcock-Johnson Psycho-educational Battery (Woodcock & Johnson, 1990), Wide Range Achievement Test (Wilkinson, 1994); *Adaptation*: Vineland Scales of Adaptive Behavior Survey (Sparrow et. al, 1984); *Language*: Test of Word Knowledge (Wiig & Secord, 1992), Test of Auditory Comprehension of Language-Revised (Carrow-Woolfolk, 1985), Peabody Picture Vocabulary Test – Revised (Dunn & Dunn, 1981), Clinical Evaluation ofLanguage Function (Semel et. al., 2000), Test of Language Development-P:3 (Newcomer and Hammill, 2000);

Neuropsychological: Rey Complex Figure Test (Spreen & Strauss, 1998), Tests of Visual-Motor Integration (Beery, 1997), Wide Range Memory and Learning Test (Adams and Sheslow, 2000), California Verbal Learning Test-C (Delis et. al., 1994); *Infant Development*: Bayley Scales of Infant Development (Bayley, 1969), Battelle Developmental Inventory (Newborg et. al., 1984); *Behavior*: Child Behavior Check List (Achenbach, 1991), Conners Parent Rating Scale (Conners, 1985). Due to the age range of the patients and the multiple sources of data, no two patients have an identical, comprehensive set of data. To assess the correlation between the facial phenotype and brain structure and function, three types of brain outcome measures were generated from the FAS DPN clinic database. 1) When a sufficient number of patients had the same standardized assessment performed (e.g., OFC centile, Full Scale Intelligence Quotient, Quick Neurologic Screening Test (a test of soft neurologic signs), Visual Motor Integration) the standardized scores from these assessments served as outcome measures. 2) More typically the clinical data set included a broad array of standardized assessments within and across one or more of the following domains: intelligence, achievement, adaptation, language, sensory processing integration, motor skills, behavioral regulation, memory and infant development. The patient's performance across all tests in each domain was ranked on a 4-point Likert scale. The ranks were defined as follows: 0 (no tests conducted*, most likely because child was too young*) 1 (all test outcomes were in the normal range; no test score was lower than 0.9 S.D.s below the norm), 2 (one or more test outcomes were in the borderline range, between 1.0 S.D. and 1.9 S.D. below the norm, but no test was two or more S.D.s below the norm) and 3 (one or more tests were below normal, defined as two or more S.D.s below the norm). 3) Finally, the 4-point Likert Scale used by the 4-Digit Code to rank evidence of organic brain damage was used as a global composite measure of brain structure and dysfunction. The case-definitions and clinical names applied to each rank are: Rank 4 (microcephaly or abnormalities on brain images or evidence of persistent neurologic findings or an IQ <= 60); Rank 3 (performance on standardized psychometric tests > 2 SD below the norm across three or more of the following areas: sensory processing/integration, motor skills, behavioral regulation, adaptive behavior, memory, language, achievement, intelligence); Rank 2 (observational data strongly suggests the possibility of brain damage, but data does not permit a Rank 3 or 4 classification); Rank 1 (no evidence of problems likely to reflect brain damage). The FAS DPN assigns the clinical term static encephalopathy to Brain Ranks 3 and 4 and neurobehavioral disorder to Brain Rank 2. More detailed definitions of these terms are presented in Astley and Clarren (1999, 2000).

Prenatal Alcohol Exposure

All patients in this study had a confirmed history of prenatal alcohol exposure (4-Digit Alcohol Rank = 3 or 4) (Astley and Clarren, 1999, 2000). A history was considered confirmed if the birth mother reported consumption of alcohol during pregnancy, another individual directly observed the birth mother drinking during pregnancy and/or there was information available in the medical records that confirmed the birth mother had been drinking during pregnancy (e.g., blood alcohol concentrations, reported intoxicated at the time of delivery, etc). During the diagnostic evaluation, the following maternal alcohol use information is recorded on a standardized Diagnostic Evaluation Form: average and maximum number of drinks per drinking occasion just before and during pregnancy, average number of days she drank per week just before and during pregnancy, type of alcohol consumed, trimester(s) in which alcohol was consumed, was she ever diagnosed with alcoholism, did she ever receive treatment for alcoholism and finally, what was the source and reliability of the above reported information.

Statistical Analyses

Descriptive statistics were used to summarize the profile of the study population. Pearson correlation coefficients were computed to assess correlations between outcomes recorded on continuous scales. Regression analysis was used to determine if significant Pearson correlations were influenced by covariates such as age and gender. Chi-square tests were used to assess trends between outcomes recorded on nominal and ordinal scales. Oneway ANOVA with post hoc tests for linear trends was used to compare mean outcomes across three or more groups. Stepwise discriminant analysis (maximizing Wilk's lambda) was used to identify the facial feature(s) that best differentiated patients with and without FAS diagnosed using the gestalt and 4-Digit Code methods. Prior probability of FAS was set equal to the prevalence in the study samples. The probability of F to enter was 0.05, and F to remove was 0.10. The unstandardized canonical discriminant function coefficients were computed to derive the discriminant equation for calculation of each subject's discriminant score. The discriminant score was used to predict each subject's diagnostic classification (FAS, not FAS). The predicted diagnosis was compared to their actual diagnosis to compute sensitivity and specificity.

RESULTS

Sociodemographic Profile of Study Population

Of the 1,130 patients evaluated in the FAS DPN clinics through 1999, 952 (84%) had a confirmed history of prenatal alcohol exposure (4-Digit alcohol rank = 3 or 4). All had given consent to use their data for research. A brief sociodemographic profile of this study population is presented in Table 2. The population was 49% Caucasian, 44% female with an average age of 9.2 ± 6.7 S.D. years. Using the 4-Digit Diagnostic Code, 76 (8%) had a 4-Digit diagnosis of FAS or Atypical FAS (FAS without growth deficiency) and 767 (81%) had a 4-Digit diagnosis of static encephalopathy or neurobehavioral disorder without the full physical features (growth deficiency and/or facial phenotype) of FAS. A subset of 462 patients received a FAS diagnostic evaluation using the gestalt method prior to the development of the 4-Digit Code. The sociodemographic profile of this subgroup of 462 is comparable to the entire study population of 952 patients. The gestalt method of diagnosis had been carried out by one of three dysmorphologically-trained pediatricians (a dysmorphologist (SKC), a geneticist and a developmental pediatrician).

Table 2. Sociodemographic profile of patient population with confirmed prenatal alcohol exposure.

Characteristics		Entire Study Sample	Gestalt Subset

Correlations between FAS facial phenotype and brain structure/function

The magnitude of expression of the FAS facial phenotype, when measured using the D-Score and the 4-Digit Code, correlated significantly with structural, neurologic and functional measures of brain damage (Tables 3 and 4). When the magnitude of expression of the FAS facial phenotype increased, OFC percentile decreased, the Quick Neurological Screening Test standard score increased (a high score reflects neurologic dysfunction), the FSIQ decreased, and composite measures of language and early childhood development were more dysfunctional or delayed. The 4-Digit Diagnostic ranks for the magnitude of expression of the facial phenotype and evidence of brain damage (measured independently during the diagnostic evaluation) were also correlated. As the magnitude of expression of the FAS facial phenotype increased from 1 (normal) to 4 (severe FAS), the proportion of patients with evidence of organic brain damage (structural, neurological and/or functional) increased significantly. When the 4-point Likert scale for brain is collapsed into the three clinical categories (Rank 1, no evidence of brain damage; Rank 2, neurobehavioral disorder and Ranks 3 and 4, static encephalopathy) the correlation between the magnitude of expression of the facial phenotype and brain dysfunction increased. The 4-Digit and D-Score measures of the magnitude of expression of the FAS facial phenotype were not influenced by age, race or gender. In contrast to the 4-Digit and D-Score measures of the FAS facial phenotype, the gestalt measure of the FAS facial phenotype did not correlate with any measures of brain structure or function in this study population.

Correlations between FAS facial phenotype and alcohol exposure

The magnitude of expression of the FAS facial phenotype measured by the D-score and 4-Digit facial rank increased significantly with increasing number of days of maternal drinking per week both before and during pregnancy. For example, as the 4-Digit facial rank increased from 1 (normal) to 4 (severe FAS), the mean number of days per week the birth mother drank during pregnancy increased from 4.0 to 4.4 to 4.9 to 4.8 respectively ($F = 7.6$ weighted linear term, $p = 0.006$). The Pearson Correlation Coefficient between the facial D-Score and the number of days per week the birth mother drank during pregnancy was +0.11, $p = 0.009$.

Variability of the FAS facial phenotype

When patients were diagnosed using the gestalt method, the facial phenotype of those receiving a gestalt diagnosis of FAS was highly variable (Table 5). In contrast, when the same patients were diagnosed using the 4-Digit Code, the facial phenotype among those receiving a 4-Digit diagnosis of FAS showed little variability. Of the 462 patients who received diagnostic evaluations using both the gestalt and 4-Digit Code methods, 445 had sufficiently complete data sets for inclusion in the following descriptive comparison of the gestalt and 4-Digit code methods of diagnosis.When the gestalt method was used, 52 of the 445 patients (11.7%) received a diagnosis of FAS. When the 4-Digit Code method was used, 10 of the 445 patients (2.2%) received a diagnosis of FAS.

(1) 4-Digit diagnostic categories A and B (Astley & Clarren, 2000); (2) 4-Digit Diagnostic categories E-V (Astley & Clarren, 2000); (3) See Figure 3; (4) 9/14 patients ≤ 5 yrs. old; (5) all patients ≤ 5yrs. old, thus too young to confirm brain dysfunction and diagnose as FAS yet; (6) D-Score ≥ 0.8 = FAS facial phenotype; (7) increasing severity of epicanthal folds are significantly associated with decreasing age F = 8.2, p = 0.004.

Of the 52 patients who received a gestalt diagnosis of FAS, only 34% had growth deficiency (height and weight below the 10th percentile), only 27% had the full FAS facial phenotype (as defined by Rank 4 in the 4-Digit Code) and only 52% had psychometric, structural and/or neurological evidence of brain damage. In contrast 100% of the 10 patients with a 4-Digit Code of FAS had growth deficiency, the full FAS facial phenotype and evidence of brain damage as defined in the sentence above. The magnitude and frequency of expression of nine minor facial anomalies frequently reported to be associated with the gestalt FAS facial phenotype were compared between the patients who did and did not receive a diagnosis of FAS using the two diagnostic methods (Table 5). The prevalence of all other minor anomalies was relatively low. Hypertelorism (an innercanthal distance greater than 2 S.D.s above the norm), often referred to in the literature as a diagnostic feature of FAS, was not observed in any of the 52 patients with either a gestalt or 4-Digit diagnosis of FAS. The most prevalent minor anomaly in the gestalt group was small palpebral fissure lengths. When the same patients were diagnosed using the 4-Digit Code, the facial phenotype of the patients who received a diagnosis of FAS did not vary from patient to patient. All patients diagnosed with FAS had small palpebral fissures, a smooth philtrum (Rank 4 or 5) and a thin upper lip (Rank 4 or 5).

Stepwise discriminant analyses performed on the subset of patients who received both gestalt and 4-Digit diagnostic evaluations further confirmed that the FAS facial phenotype was highly variable when the gestalt method was used and showed little variability when the 4-Digit Diagnostic Code method was used. The following facial features were made available to the stepwise discriminant analyses: mean PFL z-score, innercanthal distance z-score, mean PFL/innercanthal distance ratio, lip thinness measured on 5-point Likert scale, philtrum smoothness measured on 5-point Likert rank, epicanthal folds, flat nasal bridge, hypoplastic midface, ptosis, clown eyebrows, and nose length to midface height ratio. Only patients who had all of these facial descriptors measured in their data sets were included in the analyses. Among the 431 patients who received a gestalt diagnostic evaluation, the stepwise discriminant analysis was unable to identify a pattern of facial anomalies that accurately differentiated the 52 patients who received a gestalt diagnosis of FAS from the 379 who did not receive a gestalt diagnosis of FAS. Two features did meet the stepwise entry criteria for inclusion into the discriminant equation: the PFL/innercanthal distance ratio and philtrum smoothness. These two features, however, were only able to differentiate the 52 with FAS from the 379 patients without FAS with 97.6% specificity (364 of 379 without FAS were correctly classified as not having FAS) and 37.3%

sensitivity (only 19 of the 52 with FAS were correctly classified as having FAS). In contrast, when the same patients were diagnosed using the 4-Digit Code, the discriminant analysis identified three facial features (PFL z-score, philtrum smoothness and upper lip thinness (both measured on the 5-point Likert scale from the Lip-Philtrum Guide)) as the features that differentiated the 10 patients with a 4-Digit diagnosis of FAS from the 411 patients that did not receive a 4-Digit diagnosis of FAS with 100% sensitivity and specificity.

DISCUSSION

The 4-Digit Code and D-Score methods for measuring and reporting the magnitude of expression of the FAS facial phenotype offer many advantages over the gestalt method. The use of a specifically case-defined diagnostic method that relies on objective, quantitative, higher-level measurement scales: 1) facilitates the collection of more accurate and precise outcome measures by a broader array of medical professionals, 2) establishes a common descriptive language for more clearly communicating outcomes in medical records and in the medical literature and 3) provides more power to detect clinically important associations-associations that are at risk of being missed when more subjective, qualitative, nominal measurement scales are used. Noted experts in dysmorphology and anthropometry have long stressed the importance of collecting more accurate, objective measures of facial anomalies in syndrome identification (Feingold, 1975; Farkas, 1994).

The facial anomalies used to generate the 4-Digit and D-Score measures of the FAS facial phenotype were identified by multivariate discriminant analyses and found to be highly sensitive and specific to FAS and prenatal alcohol exposure (Astley and Clarren, 1996). In contrast, the gestalt approach relies on anomaly checklists that purportedly characterize the FAS facial phenotype, leaving it up to the physician or researcher to arbitrarily select which anomalies define the phenotype, how many must be present and how severe they must be expressed (Rosett, 1980; Sokol and Clarren, 1989; Wiedemann et. al., 1989; Gorlin, 1990; Jones, 1997). This approach has lead to highly variable outcomes with no documented sensitivity or specificity to prenatal alcohol exposure (CDC, 1993; Floyd et. al., 1994). Consider the following series of studies that utilized anomaly checklists to address an important diagnostic question "Does the FAS facial phenotype diminish with age?" In a follow-up study of 54 patients Spohr and Steinhausen (1987) reported a statistically significant reduction in facial features defined as "characterizing the craniofacial dysmorphology" of FAS (epicanthal folds, blepharophimosis, ptosis, short upturned nose, high arched palate/cleft palate and retrognathia). The one feature that did not change with age was a thin upper vermilion. PFL and philtrum smoothness were not measured. In a retrospective study of 200 alcohol-exposed children Majewski (1993) reported that in elder cases the nose was no longer short and upturned, the lips were no longer thin and the chin often became rather prominent. The one feature that did not change with age was short palpebral fissure lengths. Finally, in a 10-year follow-up study of eight of the first eleven children to be diagnosed with FAS, Streissguth (et al., 1985) reported that while some craniofacial features changed with age (nasal bridges became more prominent and mandibles became relatively prognathic), other did not change with age (palpebral fissures remained short, philtrums remained hypoplastic, the vermilion border of the upper lip remained thin and the midface remained flat). From these and similar studies, the 1996 report by the Institute of Medicine concludes "*that some FAS craniofacial anomalies may be less evident at birth, become more conspicuous during early infancy and childhood, and often diminish or even disappear during adolescence and adulthood*" (Stratton et al., 1996). But most of the features that were reported to diminish with age 1) have never been confirmed to be sensitive or specific to prenatal alcohol exposure and 2) are remarkably consistent with descriptions of normal facial growth. Enlow and Hans (1996) report that when one compares the face of a normal child to that of a normal adult, the child's nose is short and upturned, the nasal bridge is low and the mandible is small and retrusively placed. Interestingly, the features that were least likely to change with age (short PFL, smooth philtrum and a thin upper lip) are the only features confirmed to be sensitive and specific to prenatal alcohol exposure in our previous (Astley and Clarren, 1996) and current studies and match the features originally identified as defining the face of FAS by David Smith back in 1979. As stated by Smith (1979) "*As far as the diagnosis is concerned, perhaps the most important point to emerge in the last few years is that the facial abnormalities seen in affected infants are the key cluster of features that tend to make FAS a clinically discernible entity. Many disorders result in mental and growth deficiency, but in FAS the deficiencies are typically present in a patient whose face has short palpebral fissures, a hypoplastic upper lip with a thinned vermilion border and a smoothed or absent philtrum. Up to now, the descriptions of the facial features of FAS that have appeared in the literature have not always emphasized the same abnormalities. This has led to some confusion, but inspection of the photographs accompanying these reports leaves no doubt about the facial similarities of FAS patients*.". While clinical judgement plays an important role in the initial identification and definition of a new syndrome, more analytic approaches to pattern recognition such as discriminant analysis, supported by objective, quantitative measures of outcome, can and should be used to hone the definition. The match between the facial features identified by our descriminant analyses and reported by Smith back in 1979 further demonstrates that the analytical approach used by the FAS DPN has succeeded in objectively case-defining not redefining the original FAS facial phenotype.

Correlations between face and brain

The correlations observed between the magnitude of expression of the FAS facial phenotype and brain structure and function: 1) further validate that short PFLs, a smooth philtrum and a thin upper lip are key diagnostic facial features, 2) are consistent with the clinical literature that midline defects can *predict* underlying brain dysfunction (DeMeyer, 1975; Astley et al., 1999) and 3) provide evidence that an intermediate expression of the FAS facial phenotype may serve as an important clinical risk factor for brain damage caused by prenatal alcohol exposure. The FAS facial features (short palpebral fissure lengths, a smooth philtrum and a thin upper lip) selected by the discriminant analyses in this study and the previous study (Astley & Clarren, 1996) are midline anomalies

derived from the anterior frontal neural crest primordia of the early forebrain (Johnston, 1975). Deficiencies in the numbers of crest cells most frequently affect development of the frontonasal derivatives and are usually associated with defective forebrain and eye development (Johnston, 1975). It has long been speculated that some extreme forms of midline facial anomalies (i.e., cyclopia, holoprosencephaly, arhinencephaly) are pathognomonic of brain malformation (DeMeyer, 1975). This speculation was further supported by the presence of a proportional increase in midventral forebrain deficiencies and the severity of facial dysmorphia in mice and a nonhuman primate with holoposencephaly, all of which were exposed to ethanol early in gestation (Sulik & Johnston, 1982, 1983; Sulik, 1984; Siebert et al., 1991). Now, two additional studies have demonstrated that much more subtle midline facial anomalies (craniofacial bony alterations in nonhuman primates and soft-tissue facial anomalies in this current human clinical population) appear to be pathognomonic of brain malformation/dysfunction (Astley & Clarren, 1999). David Smith (1979) reported similar findings "*the severity of dysmorphic features appears to be related to the degree of mental deficiency*". The dysmorphic features he was referring to were small palpebral fissures, a smooth philtrum and a thin upper lip. No other studies, to our knowledge, have reported significant linear correlations between the magnitude of expression of the FAS facial phenotype and cognitive impairment among individuals with prenatal alcohol exposure. Other clinical research teams have reported correlations between the number of physical anomalies observed over the entire body and brain dysfunction in individuals with prenatal alcohol exposure, although not all were reported to be statistically significant (Majewski, 1993; Spohr et al., 1993). No correlations were observed between the gestalt FAS facial phenotype and brain dysfunction in this study. Failure to detect statistically significant correlations between face and brain, when a gestalt approach to diagnosis was used, has also been reported by others (Graham et. al., 1988; Spohr et. al., 1993).

In summary, thousands of individuals with FAS have been identified and thousands of laboratory, clinical and population-based studies have been conducted. While these studies have greatly advanced our understanding of alcohol's teratogenic potential, advancements in the clinical and public health arenas are less impressive. To date, we still cannot derive an accurate estimate of the prevalence of FAS (Floyd et. al., 1994) nor can we document success in preventing FAS. Advancements in these two arenas are contingent upon physicians making accurate diagnoses. Accurate diagnoses require specific and objective case definitions that document the full range of outcomes associated with prenatal alcohol exposure. These definitions should be continually honed to incorporate the latest technological advances (e.g., magnetic resonance spectroscopy and functional MRI, digital image analysis, etc.) and should be guided by more sophisticated, multivariate, analytic approaches to pattern recognition.

Application of the fetal alcohol syndrome facial photographic screening tool in a foster care population

Susan J. Astley, PhD, Julie Stachowiak, RN, MN, Sterling K. Clarren, MD, and Cherie Clausen, RN, MN

We determined the prevalence of fetal alcohol syndrome (FAS) in a foster care population and evaluated the performance of the FAS Facial Photographic Screening Tool. All children enrolled in a Washington State Foster Care Passport Program were screened for three conditions: (1) the FAS facial phenotype from a photograph, (2) evidence of brain damage with prenatal alcohol exposure from their Health and Education passport, and/or (3) other syndromes identifiable from a facial photograph. Screen-positives received diagnostic evaluations at a FAS Diagnostic and Prevention Network clinic. The prevalence of FAS in this foster care population was 10 to 15/1000, or 10 to 15 times greater than in the general population. The screening tool performed with 100% sensitivity, 99.8% specificity, 85.7% predictive value positive, and 100% predictive value negative. We conclude that the foster care population is a high-risk population for FAS. The screening tool performed with very high accuracy and could be used to track FAS prevalence over time in foster care to accurately assess the effectiveness of primary prevention efforts. (J Pediatr 2002;141:712-7)

Fetal alcohol syndrome (FAS), a permanent birth defect caused by maternal consumption of alcohol during pregnancy, is characterized by growth deficiency, central nervous system dysfunction, and a unique cluster of minor facial anomalies.[1,2] FAS is the leading known cause of mental retardation in the Western world[3] and is entirely preventable.

Primary prevention of FAS and prevention of secondary disabilities (eg, school/job failure, depression, trouble with the law) among persons with FAS are paramount. With the development of the FAS Facial Photographic Screening Tool,[1,4] the creation of the FAS 4-Digit Diagnostic Code[2,5,6] and the establishment of the Washington State FAS Diagnostic and Prevention Network (FAS DPN) of clinics,[7,8] FAS screening, diagnosis and prevention are now being effectively and efficiently conducted in Washington State.

Targeting FAS prevention efforts to high-risk populations is an efficient and effective use of limited resources. Children in foster care serve as an ideal population to target. First, the risk of FAS in this population is likely to be high; as much as 75% of children in foster care have a family history of mental illness or drug or alcohol abuse.[9] Foster children comprised 2 to 5 times the normative percent of children below the 5th percentile for height and weight.[9,10] Developmental disabilities and mental health diagnoses are also disproportionately prevalent in foster children.[9,11] Second, early diagnosis helps reduce the risk of secondary disabilities.[12] Third, if a child's disabilities are fully known and disclosed at the time of placement, foster care systems will be able to establish more appropriate placements, foster/adoptive parents will be better prepared to meet their child's needs and the children are less likely to experience multiple failed placements. Finally, the population is readily accessible and thoroughly tracked.

PHN	Public health nurse

The primary objectives of this project were to: (1) screen all eligible children

in out-of-home care, enrolled in the Region 4 (King County) Foster Care Passport Program (FCPP), for the FAS facial phenotype, structural or neurologic evidence of brain damage with confirmed prenatal alcohol exposure, and/or other syndromes identifiable from a facial photograph; (2) provide all children who screen positive with comprehensive diagnostic evaluations and treatment plans through the FAS DPN of clinics; (3) determine the prevalence of FAS in this foster care population; and (4) evaluate the performance of the FAS Facial Photographic Screening Tool in a population-based sample.

METHODS

This FAS screening was a collaborative effort between the University of Washington FAS DPN, the Washington State Department of Social and Health Services (DSHS), Children's Administration, Division of Children and Family Services (DCFS), Region 4, and Public Health–Seattle and King County.

Subjects

All children who were legally dependent with the state of Washington and enrolled in the Region 4 FCPP on or after March 1, 1999 in King County, Washington, were eligible to participate in this screening. To be enrolled in the FCPP, a child had to be: (1) legally supervised by DCFS; (2) 0 to 12 years of age at the time of enrollment, but were able to remain in the program after their 12th birthday; (3) dependent; and (4) in out-of-home placement. Throughout this report, the term "foster care" will refer to children in out-of-home care that includes children in foster care or in the care of their relatives. Up to 500 children enter this FCPP annually.

To maximize the efficiency of the FAS Screening program, the screening was incorporated into an already established state program, the FCPP. The FCPP uses information regarding services already provided to children who receive Medicaid-covered health services, such as early, periodic screening, diagnosis, and treatment (EPSDT) examinations, as well as other health care information, to provide a comprehensive health picture of each enrolled child. Children who remain in out-of-home placement for 90 consecutive days are automatically referred through the DSHS information system to the FCPP. A public health nurse (PHN) and a health program assistant work as a team to seek out and gather all available health history information (from birth to present) for each child enrolled in the program. The PHN interprets and enters all information into a computerized Health and Education database. A shortened summary (a Health and Education "passport") is provided with health recommendations to the social worker and the foster parent to share with the child's health care provider(s). Each child's passport is updated every 6 months. By nesting the FAS screening into an already existing program, the screening program had access to a computer-generated eligibility list, current names and addresses of all foster parents and caseworkers, and a concise summary of the child's health/educational history. When the screening was complete, the child's screening and diagnostic outcomes, as well as their electronic facial photograph, were entered into the Health and Education Database and case file. This provided immediate and broad access to this information for future medical/social service care and placement decisions. This screening activity was approved by the Human Research Review Boards of Washington State and the University of Washington.

Enrollment

The FCPP identified all eligible children, obtained written consent from the child's legal guardian (DCFS social worker), sent the child's foster parents a letter that explained the purpose and process of the FAS screening, and sent the FAS DPN the list of all newly eligible, consented children, weekly. The FAS DPN scheduler called each foster parent to schedule a photography appointment with one of the two FAS DPN photographers.

Facial Photograph and Head Circumference

Two University of Washington students were trained to take three standardized facial photographs (frontal, ¾ view and lateral) by using a handheld, 3-megapixel, digital camera. The guidelines of Astley and Clarren[16] and the FAS Tutor CD ROM[17] were followed. The photographers were also shown how to measure the child's head circumference (occipital frontal circumference (OFC). During a 20-minute photography session at the child's foster home, the photographer took the standardized photographs, one casual portrait photograph (to give to the child as a way of thanking them and assuring them they were a fine looking child) and the OFC. The photographers transferred the photographic images and OFC measures to the University of Washington FAS DPN image analysis laboratory weekly.

A small proportion (20%) of the children had foster placements with relatives who lived outside King County or outside Washington State. These families were sent a disposable camera with a one-page pictorial instruction sheet for how to take the three standardized photographs. A stamped, addressed envelope was enclosed for them to return the camera. Parents were not requested to measure their child's OFC. We relied on OFC measures in the child's passport, when available. The FAS DPN scanned the photos to generate electronic image files. On occasion, a second camera had to be sent to the family because the lower resolution of the photos from the disposable camera were not of sufficient quality to provide an accurate screen.

Review of the Foster Care Health and Education Passport

All passports were reviewed by S. J. A. The passport was used to screen for structural or neurologic evidence of

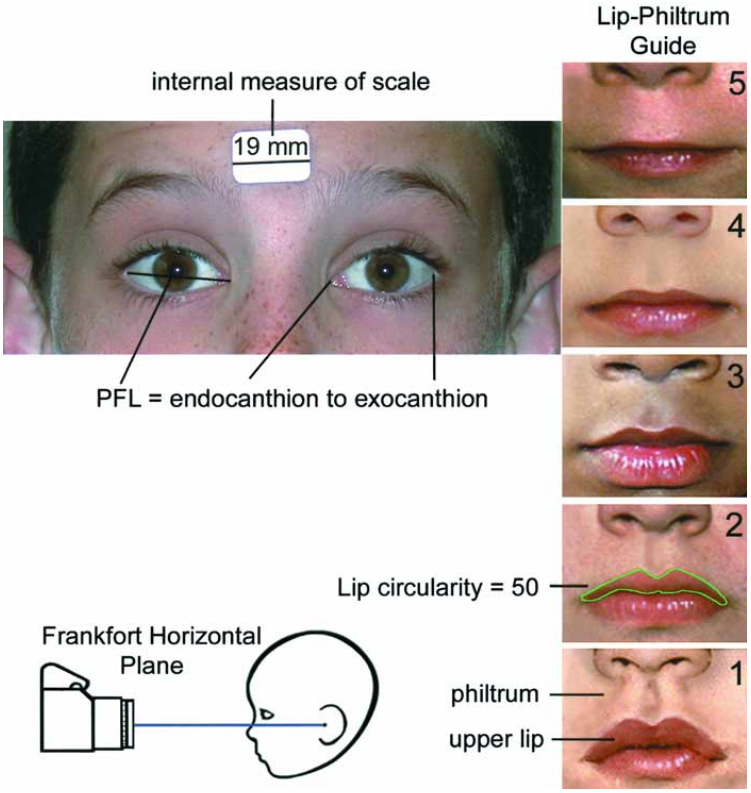

Figure. A standardized, digital, frontal facial photograph is taken while aligning the center of the camera lens in the patient's Frankfort horizontal plane (a plane extending from the patient's upper margin of the external auditory meatus [porion] through the lowest margin of the lower bony orbital rim [orbitale]). An internal measure of scale *(19 mm paper sticker)* is placed between the patient's eyebrows to serve as a ruler or internal measure of scale in the photo. Three facial features are measured: (1) the palpebral fissure length *(PFL)* or distance between the endocanthion and exocanthion landmarks, (2) philtrum smoothness, and (3) upper lip thinness. The PFL is converted to a *Z* score (or number of SD above or below the norm) by using appropriate normal anthropometric tables.[19] The philtrum is ranked using the 5-point Likert scale depicted on the Lip-Philtrum Guide. The upper lip is first outlined with the computer mouse to generate a quantitative measure of thinness called circularity (perimeter^2/area). It is then ranked on the 5-point Likert scale depicted on the Lip-Philtrum Guide by using circularity as a guide. The circularity of each upper lip pictured on the Lip-Philtrum Guide is: Rank 5 = 178, Rank 4 = 85, Rank 3 = 65, Rank 2 = 50, and Rank 1 = 35.

brain damage (seizures, microcephaly, abnormal brain magnetic resonance imaging/computed tomography/ positron emission tomography scans, neurologic disorders) and documentation of prenatal alcohol exposure, and to generate a clinical profile of the screened population. The clinical profile served to describe the study population and assess the performance of the photographic screening tool. When screening a population-based sample, one rarely gets the opportunity to assess the screen-negative subjects to confirm they were truly negative. The passports provided an invaluable opportunity to review the medical histories and prenatal exposures of all screen-negative children to determine if any of the three remaining key diagnostic features of FAS (growth deficiency, brain dysfunction, and prenatal alcohol exposure) were present in a child.

Facial Photographic Assessment

Image analysis software[18] was used to measure the magnitude of expression of the FAS facial phenotype (short palpebral fissure lengths, smooth philtrum, and thin upper lip) from the digital images (Figure). Briefly, the image is presented on a computer monitor, the three facial features are measured, and the magnitude of expression of the FAS facial phenotype is classified into one of 4 case-defined categories; normal, mild, moderate, or severe.[16] The photographs were also reviewed by a dysmorphologist for the presence of other minor and/or major anomalies that may or may not be part of another syndrome. Assessment of the photographs took approximately 10 minutes per child.

Screen-Positive Definition for FAS

A child was screened positive for FAS if all three of the following features were present in their facial photograph: (1) palpebral fissure lengths were >2 SD below the mean,[19] (2) the philtrum was smooth (Likert rank 4 or 5 on the 5-point Lip-Philtrum Guide), and (3) the vermilion border of the upper lip was thin (Likert rank 4 or 5 on the 5-point Lip-Philtrum Guide [circularity ≥75]) (Figure).[4,16] Confirmation of prenatal alcohol exposure was not required at the time of the screening because this facial phenotype is so highly specific to prenatal alcohol exposure.[4] Confirmation was sought at the time of diagnosis. This case-definition of the facial phenotype was derived analytically by Astley and Clarren[4] and matches the original 1979 definition by Smith.[20]

Screen Positive Definition for Structural or Neurologic Evidence of Brain Damage with Prenatal Alcohol Exposure

A screening tool to accurately identify persons at risk for fetal alcohol effects (FAE) does not exist because cognitive/behavioral dysfunction associated with prenatal alcohol exposure is not sufficiently specific to prenatal alcohol exposure to clinically label the outcome as a specific FAE. It is for that reason that FAE is not a medical-

ly recognized diagnosis.[21,22] The number of persons with brain damage caused by prenatal alcohol exposure who do not have FAS far exceeds the number of persons with FAS. Current medical technology simply cannot confirm that a patient's brain damage/dysfunction was caused by their prenatal alcohol exposure when the patient does not have the FAS facial phenotype. But identification and treatment of persons with brain damage does not require confirmation of etiology. Prenatal alcohol exposure and structural/neurologic evidence of brain damage are clear risk factors for brain damage/dysfunction. If prenatal alcohol exposure *and* structural or neurologic evidence of brain damage (microcephaly, seizures of unknown origin, abnormal brain image) were present, the child was screened positive for static encephalopathy/alcohol exposed. Confirmation of prenatal alcohol exposure at the time of the screening was required because a secondary goal of this study was to identify birth mothers at high risk of exposing future children to damaging levels of prenatal alcohol exposure.

Procedure Followed When a Child Screened Negative

An FAS screen-negative medical note and the child's portrait photographs were sent to the FCPP and the foster parents. The medical note included the statement that a child could still have problems related to prenatal alcohol exposure that will not show up in a facial photograph; thus if they had concerns about the child's growth or development, they should talk with the child's health care provider.

Procedure Followed When a Child Screened Positive for FAS and/or Brain Damage/Alcohol Exposed

When a child screened positive for either FAS or structural/neurologic evidence of brain damage with confirmed prenatal alcohol exposure, the following documents were sent to the FCPP: (1) a standardized screen-positive medical note, (2) an FAS DPN clinic registration packet, and (3) copies of the child's portrait photograph. The FCPP notified the social worker, entered the screen-positive results in the Health and Education database, updated the passport and health recommendations, completed the FAS DPN registration packet, and provided the social worker with an updated passport packet for the DCFS file, along with the FAS DPN registration packet. The foster parents were initially informed of the screen-positive outcome by the FCPP PHN. The foster child, accompanied by his/ her foster parents and caseworker, was subsequently scheduled for a diagnostic evaluation at the FAS DPN clinic where he/she received a comprehensive diagnostic evaluation and treatment plan by the multidisciplinary team using the 4-Digit Diagnostic Code.[2,23]

Procedure Followed When a Child Screened Positive for Other Facial Anomalies/Syndromes

When the dysmorphologist identified other minor/major craniofacial anomalies that were either consistent with another syndrome or warranted further follow-up, the child's medical record was reviewed and the child was referred to a clinical geneticist or craniofacial clinic, if appropriate. Information, in the form of a medical note, was sent from the FAS DPN to the FCPP. All information received by the FCPP was entered into the database. Updated passports and health recommendations were supplied to the foster family as well as the assigned social worker, including any recommendations for further evaluation.

Data Analysis

The prevalence of FAS (number of children with FAS/number of children screened) with 95% confidence intervals (95% CI) was computed. A binomial test was used to determine if the observed prevalence of FAS in this foster population was significantly different from the estimated prevalence of 1 to 3 per 1000 live births reported in the general population.[24]

RESULTS

Sociodemographics and Participation Rate

In this ongoing screening activity, 793 children were eligible to participate between March of 1999 and September of 2001. Of these 793 children, 592 have been screened to date, 8 had already received an FAS diagnostic evaluation before the screening program, 129 are in the process of being screened, 10 chose not to participate, and 54 left foster care before completing the screening. The diagnostic outcomes of the 8 children were combined with the screening outcomes of the 592 children to serve as the study population of 600 children for this first screening program assessment. The 600 children were on average 5.8 ± 4.1 SD years of age at the time they were screened, 48% were female, 48% were white, 32% were black, 12% were Native American, 15% had documented prenatal alcohol exposure, and 32% had documented prenatal drug exposure. The 64 children who did not participate in the screening were nearly identical in profile to the 600 who did participate. The participation rate to date is 98.6%. Only 10 families of 739 chose not to participate.

FAS Screen-Positive Outcomes

Of the first 600 children screened to date, 10 screened positive for FAS. They were 5.5 ± 3.1 years of age (range, 1.1-11.4 years), 30% female, 40% white, 20% black, and 10% Native American. Nine of the children had confirmed prenatal alcohol exposure; one, still pending review, has a family history of alcohol abuse. Four of the 10 children who screened positive for FAS had microcephaly and only one was significantly growth deficient

(height and weight <3rd percentile). Six had documented prenatal exposure to illicit drugs. Diagnostic evaluations have been conducted on 7 of the 10 children to date in this ongoing screening. Six of the seven received a diagnosis of FAS. The 7th child had the full facial features, attention deficit–hyperactivity disorder, poor adaptation skills, borderline concerns in visual-motor integration and soft neurologic signs, significant impairment in academics, and prenatal alcohol exposure. This profile fell just short of a full diagnosis of FAS using the 4-Digit Diagnostic Code. He received a diagnosis of sentinel physical findings/neurobehavioral disorder/alcohol exposed. None of these 7 children had been previously diagnosed with FAS. A one-year old child who screened positive for the FAS facial phenotype also had Down syndrome. This child was subsequently diagnosed with FAS (4-Digit Diagnostic Code 4444), presenting with height and weight <1% when plotted on a growth chart for children with Down syndrome, microcephaly and daily exposure to alcohol throughout gestation.

Estimated Prevalence of FAS

Due to the ongoing nature of this screening, 3 of 10 screen-positive children have not yet received diagnostic evaluations. Thus, the prevalence of FAS will fall between the following minimum and maximum estimates. If none of the three remaining children receive a diagnosis of FAS, the prevalence of FAS in this foster care population will be 6 of 600 or 10 of 1000 (95% CI, 5-22 per 1000). If all three receive a diagnosis of FAS, the prevalence of FAS will be 9 of 600 or 15 of 1000 (95% CI, 8-28 per 1000). Both of these FAS prevalence estimates are statistically significantly greater (binomial test: P values < .001) than the FAS prevalence estimate of 1 to 3 per 1000 live births in the general population reported by the National Institute of Alcohol Abuse and Alcoholism.[24]

Screen Positive for Structural or Neurologic Evidence of Brain Damage with Prenatal Alcohol Exposure, But Did Not Have the FAS Facial Phenotype

Fifteen (2.5%) of the 600 children screened positive for structural or neurologic evidence of brain damage with prenatal alcohol exposure, but did not have the FAS facial phenotype. They were 5.0 ± 3.6 years of age (range, 0.7-13.3 years), 47% female, 40% white, and 20% black. Three had seizure disorders of unknown origin and 12 had microcephaly. Nine of the 15 children have been diagnosed to date. All 15 currently meet the FAS DPN diagnostic criteria for static encephalopathy/alcohol exposed. Four of the 9 currently diagnosed also have growth deficiency.

Other Anomalies/Syndromes

Eight of the 600 (1.3%) children presented with other clusters of minor and/or major facial anomalies (including two with Down syndrome). They were 38% white, 38% black, 24% Native American, 63% female, and ranged in age from 0.6 to 10.1 years. All but two of the children had been previously identified and were receiving appropriate care. Two of the 8 had prenatal alcohol exposure, including one of the two with Down syndrome. The FAS facial analysis system clearly differentiated the two children with Down syndrome who did and did not have FAS.

Performance of the FAS Facial Photographic Screening Tool

Based on the seven screen-positive children with completed diagnostic evaluations and the 590 screen-negative children, the predictive value positive for the FAS photographic screening tool is 6 of 7 or 85.7%.[25] The predictive value negative for the screening tool is 590 of 590 or 100%. The sensitivity of the screening tool in this population-based sample is 6 of 6 or 100%. The specificity of the screening tool in this population-based sample is 590 of 591 or 99.8%. The accuracy of the tool is 596 of 597 or 99.8%. Unlike most population-based screening programs, this program had the unique ability to confirm that the 590 screen-negatives were true negatives. This confirmation was possible because the tool used to screen for the FAS facial phenotype is the same tool used to diagnose the facial phenotype in clinic.

DISCUSSION

This FAS screening program confirmed that foster care is a high-risk population for FAS, that screening for FAS in this population can be done accurately, efficiently, and with direct benefit to the children and their families, and that the FAS DPN Facial Photographic Screening Tool performs with high accuracy in a population-based sample.

During the course of this screening activity, several additional observations were made that further support the merits of FAS screening in a network of affiliated clinics. First, there was an unexpected opportunity to demonstrate that screening can lead to both primary and secondary prevention intervention for FAS. One child who screened positive for FAS returned to the care of their birth mother before the diagnostic evaluation. The birth mother willingly accompanied her child to the diagnostic appointment and received support and treatment referrals tailored to meet her needs as well as those of her child. Second, if a child's disabilities are fully known and disclosed at the time of placement, the risk of multiple failed placements could be reduced. This was observed in two children who screened positive for FAS, both of whom had multiple failed placements before diagnosis and have maintained a single successful placement since receipt of their diagnoses. Third, although the primary focus of this screening was on FAS, this activity led to increased awareness and understanding by foster parents and caseworkers of the risks of prenatal al-

cohol exposure among all children, not just children with the FAS facial features. This, in turn, led to an increase in appropriate referrals of children to the FAS DPN clinics who had prenatal alcohol exposure, cognitive/behavioral problems, but screened negative for FAS. Finally, the value of a national network of FAS DPN clinics was demonstrated when one child who screened positive for FAS lived 1600 miles outside Washington State, but was readily diagnosed by an affiliated FAS DPN multidisciplinary clinical team just a few miles from where the child lived.

The next step for the FAS DPN screening program will be to track the annual change in prevalence of FAS in this foster care population to assess the effectiveness of community FAS primary prevention efforts. Statewide expansion of the screening is also being explored. The screening program was both cost-effective and time efficient in large part because of nesting it into an already existing state-run program. Expansion of the screening program will be facilitated by FAS Facial Photographic Analysis software[18] developed by the FAS DPN. The software will allow the user to measure the key facial features from digital photographs and generate a hard copy or electronic outcome report within minutes.

We thank the following FAS DPN staff for their assistance on this project: Courtney Tharp, Kathleen Tharp, Jessica Liu, Joshua Hunter, Julee Myers, Jill Crank, Heather Grigg, and Kristen Daniels. We also thank James Mowrey, Adrienne Miller, and all FCPP and DCFS staff for their commitment and effort in this project. We are especially grateful to the Minnesota FAS DPN clinic team, who conducted the diagnostic evaluation on a child placed outside of Washington State. Finally, we thank the foster families who so readily assisted the FAS DPN and FCPP in the conduct of this screening.

Summary

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. It is characterised by growth deficiency, central nervous system damage/dysfunction, and a unique cluster of minor facial anomalies. To assess the effectiveness of fetal alcohol syndrome prevention efforts, one must be able to estimate accurately the prevalence of fetal alcohol syndrome over time in population-based samples. With the establishment of the Washington State Fetal Alcohol Syndrome Diagnostic and Prevention Network of clinics, the development of the Fetal Alcohol Syndrome Facial Photographic Analysis Software, the creation of the Fetal Alcohol Spectrum Disorders (FASD) 4-Digit Diagnostic Code, the establishment of the Foster Care Fetal Alcohol Syndrome Screening Program, and the collection of Pregnancy Risk Assessment Management System data on maternal use of alcohol during pregnancy, the tools, methods and infrastructure for assessing the effectiveness of fetal alcohol syndrome primary prevention efforts in Washington State are in place. A cross-sectional study was conducted to determine whether the prevalence of fetal alcohol syndrome among children in a foster care population, born between 1993 and 1998, decreased with the documented decrease in prevalence of maternal use of alcohol during pregnancy from 1993 and 1998 in Washington State.

The prevalence of maternal drinking during pregnancy in Washington State declined significantly ($P < 0.001$) from 1993 to 1998 as did the prevalence of fetal alcohol syndrome among foster children born 1993–98 ($P < 0.03$). These observations support the likelihood that fetal alcohol syndrome prevention efforts in Washington State are working successfully.

Introduction

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. It is characterised by growth deficiency, central nervous system (CNS) damage/dysfunction, and a unique cluster of minor facial anomalies.[1,2] It is also the leading known cause of mental retardation/developmental disabilities in the western world[3] and is entirely preventable. The prevalence of FAS is estimated to be 1–3 per 1000 live births[4] in the US general population, but has been documented to be as high as 15 per 1000 in some high-risk populations.[5]

To prevent FAS, maternal alcohol consumption during pregnancy must be avoided. Prevention efforts span a broad continuum from public health education and policy[6–13] to direct intervention targeted to high-risk women.[10] To assess the effectiveness of FAS prevention efforts, one must be able to estimate accurately, consistently and efficiently the prevalence of FAS over time in population-based samples. Accurate estimates of prevalence, in turn, require accurate diagnostic methods. With the establishment/development of the Washington State FAS Diagnostic and Prevention Network (FAS DPN) of clinics in 1993,[14–17] the computerised FAS Facial Photographic Analysis Software in 1995,[18–20] the FASD 4-Digit Diagnostic Code in 1997,[2,21,22] the Foster Care FAS Screening Program in 1999,[5] and ongoing collection of Pregnancy Risk Assessment Monitoring System (PRAMS) data by

 Paediatric and Perinatal Epidemiology 2004, **18,** 344–351

Washington State since 1993,[23–25] the methods and infrastructure for assessing the effectiveness of FAS primary prevention efforts through FAS screening, diagnosis and surveillance are now in place in Washington State.

The purpose of this cross-sectional study was to determine if the prevalence of FAS among children in a foster care population, born between 1993 and 1998, decreased with the documented decrease in prevalence of maternal use of alcohol during pregnancy from 1993 to 1998 in Washington State.

Methods

Prevention efforts in Washington State

Fetal alcohol spectrum disorder was identified at the University of Washington in 1970 by Ulleland and Smith[1] spawning two major clinical/research programmes, the FAS DPN[14] and the Fetal Alcohol and Drug Unit,[26] which have made significant contributions over the past three decades to screening, diagnosis, education and prevention of FASD. Washington State prevention efforts have reflected the full continuum of strategies from public health education and training[6,8,11,12,27] to direct intervention with high-risk women.[28–30] Although prevention efforts have been ongoing since the early 1970s, a substantial increase in effort began in 1992 with the implementation of FAS prevention projects sponsored by the Centers for Disease Control,[16,17,31,32] establishment of the Parent–Child Assistance Program,[29] and a legislative mandate in 1995[33] for statewide expansion of the FAS DPN and establishment of the FAS Interagency Work Group to ensure coordination of efforts across key state agencies including family advocacy groups.[34]

Surveillance of maternal drinking during pregnancy in Washington State

PRAMS is a CDC-sponsored, ongoing, population-based surveillance system designed to monitor self-reported maternal behaviours that occur before, during and after pregnancy.[23–25] Washington State is one of 31 states participating in PRAMS and the Washington State Department of Health has collected PRAMS data since June 1993. Each month, 1 in 40 live births are randomly selected from the Washington State birth certificates. Over-sampling by race other than Caucasian is conducted to increase the reliability of estimates for these racial groups. The data are then weighted to reflect the true racial profile of the state. At two to 6 months postpartum, the sampled mothers ($n = 2000$/year) are sent an explanatory letter and a self-administered PRAMS questionnaire. Non-respondents are sent a second questionnaire by mail and then multiple attempts to follow up are conducted by telephone. In the first year of data collection (1993), data were collected over 9 rather than 12 months with a response rate of 61%. For all other years, data were collected over 12 months with an average response rate of 70%.

The PRAMS questionnaire currently includes 66 questions (52 core questions and 14 state-specific questions). The core questions address obstetric history and risk factors, maternal feelings about timing of pregnancy, maternal economic status, birth control, prenatal care, folic acid awareness, prenatal behaviours and experiences (cigarette smoking, alcohol use, psychosocial stress during the 12 months prior to delivery, and physical abuse before and during pregnancy), prenatal hospitalisation, labour and delivery, and infant health. Two core questions documenting alcohol use include: 'During the 3 months before you got pregnant, how many alcoholic drinks did you have in an average week?' and 'During the last 3 months of your pregnancy, how many alcoholic drinks did you have in an average week?' Reported use of alcohol 3 months prior to pregnancy is deemed the most accurate measure of early pregnancy use because women often do not know they are pregnant until the second month and typically do not change their drinking patterns until they know they are pregnant.[35,36] A drink was defined as: one glass of wine, one wine cooler, one can or bottle of beer, one shot of liquor or one mixed drink. Women were asked to select from the following choices: I didn't drink then; 1–3 drinks per week, 4–6 drinks per week, 7–13 drinks per week, 14 or more drinks per week; I don't know.

To date, prevalence estimates for maternal use of alcohol 3 months prior to pregnancy and during the third trimester of pregnancy are available from 1993 to 1998 in Washington State from 12 388 women.[23–25]

Prevalence of FAS in a Washington State foster care population

In 1999, the FAS DPN implemented FAS screening and diagnosis of all children entering the Foster Care Passport Program (FCPP) in King County, Washington using the FAS Facial Photographic Analysis Software[5,19,20] and the FAS 4-Digit Diagnostic Code.[2,21]

Details on the performance of the screening tool and the prevalence of FAS among the first 600 children screened have been published previously.[5] Briefly, all children, who were legally dependent with the State of Washington and enrolled in the Region 4 FCPP on or after 1 March 1999 in King County, Washington were eligible to participate in the screening. To be enrolled in the FCPP, a child had to be: (a) legally supervised by the Department of Social and Family Services; (b) 0–12 years of age at the time of enrolment, but may remain in the programme after their 12th birthday; (c) dependent and (d) in out-of-home placement.

To screen for FAS, a photographer from the FAS DPN was sent to the home of the foster child to take standardised, digital facial photographs with an internal measure of scale placed in the photo. A child screened positive for FAS if they had all three of the following facial features: palpebral fissure lengths two or more standard deviations below the mean, a smooth philtrum (Likert rank 4 or 5 on the 5-point Lip-Philtrum Guide) and a thin upper lip (Likert rank 4 or 5 on the 5-point Lip-Philtrum Guide) (Fig. 1).[18–21] This case-definition for the FAS facial phenotype was derived analytically by Astley and Clarren,[18] matches the original 1979 definition by Smith,[37] and has been found to be highly sensitive and specific to FAS.[18] Image analysis software[20] developed by the FAS DPN was used to measure the magnitude of expression of the FAS facial phenotype from the digital images. This procedure is described in detail by Astley and Clarren[19] and demonstrated in a CD-ROM.[22]

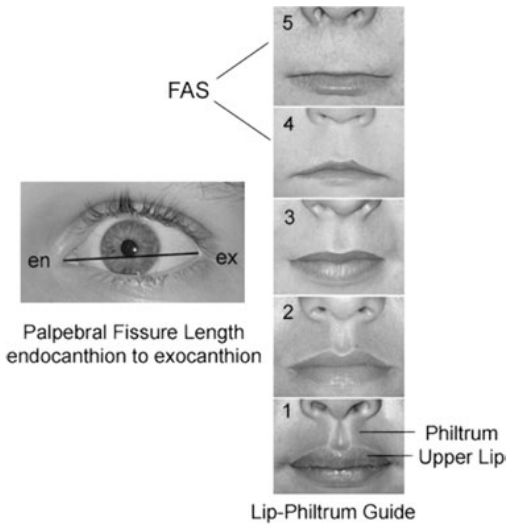

Figure 1. The three facial features of FAS include: (a) palpebral fissure lengths (the distance between the endocanthion and exocanthion landmarks) two or more S.D.s below the mean; (b) philtrum smoothness = Rank 4 or 5 on Lip-Philtrum Guide; and (c) upper lip thinness = Rank 4 or 5 on Lip-Philtrum Guide.

All children who screened positive for the FAS facial phenotype were scheduled for a diagnostic evaluation at the FAS DPN clinic where they received a comprehensive diagnostic evaluation and treatment plan by the interdisciplinary team using the 4-Digit Diagnostic Code.[2,15,21] The 4-Digit Diagnostic Code is an objective, case-defined method for diagnosing the full spectrum of outcomes associated with prenatal alcohol exposure. It was developed to increase diagnostic accuracy and reproducibility. The screening activity was approved by the Human Research Review Boards of Washington State and the University of Washington. This ongoing screening activity has demonstrated that: (1) the prevalence of FAS in this foster care population is 10–15 per 1000, (2) the screening tool performs with 100% sensitivity and 99% specificity in this population-based sample, and (3) screening can be accomplished on a near complete (98%) sample of this population.[5] The population screened ranged in age from 3 months to 15 years, was 48% female and had a racial distribution of 48% Caucasian, 32% African American and 12% Native American. The subset of five children diagnosed with FAS ranged in age from 1 to 11 years, three were female, two were Caucasian and three were African American.

Since Washington State PRAMS data documented a significant decline in maternal use of alcohol during pregnancy from 1993 to 1998, one might expect to see a decrease in the prevalence of FAS among children born in those years (1993–98). The Foster Care FAS Screening/Diagnostic Program provided a unique opportunity to assess change in prevalence of FAS over time in a high-risk population-based sample. The first step was to identify all children born from 1993 to 1998 ($n = 264$) among the first 600 children who participated in the screening programme. This was necessary because maternal use of alcohol during pregnancy from 1993 to 1998 could only affect children born in those years.

The proportion of children who were diagnosed with FAS within each of these six birth cohorts was computed. The prevalence of FAS was computed by birth cohort rather than by year of entry into foster care because the former would be far more sensitive in

documenting change. While a reduction in maternal drinking over time should result in a decrease in the prevalence of FAS among children entering foster care in each successive year, the decrease from year to year would be quite small because children entering foster care in any single year will range in age from birth up to 18 years old. For example, children entering foster care through the Foster Care Passport Program in the year 2000 will have been born across 12 different birth cohorts from 1988 to 2000. The prevalence of FAS among children entering foster care in 2000 would be influenced by the drinking patterns of their mothers from 1988 to 2000. Any reduction in drinking in the late 90s could be masked by the higher prevalence of drinking in the early 90s. Thus, to document the impact of maternal drinking on risk of FAS from year to year, the prevalence of FAS needs to be based on the year the child was born, not the year the child entered foster care.

Analysis

The chi-square test for linear trends was used to assess the change in prevalence of maternal drinking and change in prevalence of FAS from 1993 to 1998. Pearson and Spearman ρ correlation coefficients were computed to assess the correlation between prevalence of maternal drinking in early and late pregnancy and prevalence of FAS. Pearson and Spearman ρ were used when data were normally and not normally distributed respectively.

Results

Change in prevalence of alcohol use over time

Washington State PRAMS data show that the prevalence of maternal alcohol use 3 months prior to pregnancy and during the third trimester declined significantly (chi-square = 66.9, $P < 0.001$ and chi-square = 101.3, $P < 0.001$, respectively) from 1993 to 1998, exceeding the Healthy People 2010 objective of 6%[38] (Table 1, Fig. 2). This decline is most striking among the women reporting the highest levels of use (>14 drinks/week) in early pregnancy (chi-square = 64.5, $P < 0.0001$).

Change in prevalence of FAS over time

Of the first 600 children who participated in the foster care FAS Screening Program,[5] 264 were born from 1993 to 1998. Five of these 264 children screened positive and were diagnosed with FAS.[5] A diagnosis of FAS required all of the following to be present: height and weight at or below the 10th percentile; all three FAS facial features as described in Fig. 1; evidence of significant structural, neurological or functional CNS damage and a confirmed history of prenatal alcohol exposure.[2] The prevalence of FAS among these 264 foster children declined significantly (chi-square = 4.7, $P = 0.03$) across each birth cohort from 1993 to 1998. (Table 2, Fig. 2).

Table 1. Decline in the prevalence of women reporting alcohol use 3 months prior to pregnancy and in the third trimester of pregnancy in Washington State from 1993 to 1998[23–25]

		Average drinks per week

[a]Three months before pregnancy: test for linear trend from 1993 to 1998. Drinking >0 drinks/week: chi-square = 66.9, $P < 0.0001$. Drinking >14 drinks/week: chi-square = 64.5, $P < 0.0001$.
[b]Third trimester of pregnancy: test for linear trend from 1993 to 1998. Drinking >0 drinks/week: chi-square = 101.3, $P \leq 0.001$. The Healthy People 2010 objective is to reduce the prevalence of drinking during pregnancy to 6%.[38]
[c]Data were collected over 9 months in this first year with a response rate of 61%. For all other years, data were collected over 12 months with an average response rate of 70%.

Correlation between maternal drinking and FAS prevalence

The prevalence of alcohol use during pregnancy from 1993 to 1998 in this statewide sample of women was compared with the prevalence of FAS among children born between 1993 and 1998 in this King County foster care population. Despite the cross-sectional nature

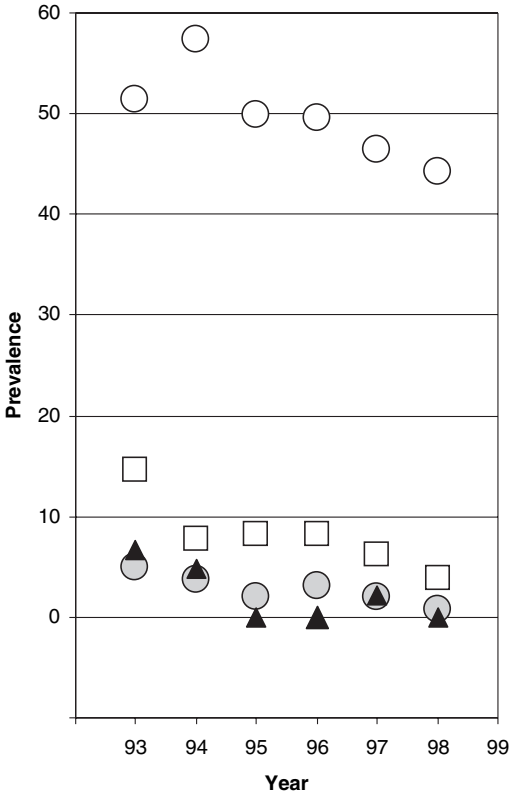

Figure 2. Decline in the prevalence of alcohol use by women in Washington State. (○) Any level of alcohol use 3 months prior to pregnancy; (□) Any level of alcohol use in the third trimester of pregnancy; (◍) Heavy alcohol use (>14 drinks/week) 3 months prior to pregnancy from 1993 to 1998;[23–25] (▲) Prevalence of FAS among children in the King County Foster Care Passport Program born from 1993 to 1998.[5]

of these data, remarkably strong correlations were observed that increased in strength as the risk in timing and level of maternal alcohol use increased. When the analysis focused on the timing of alcohol use, the decline in FAS was more strongly correlated with the decline in maternal alcohol use in early pregnancy (Pearson Correlation Coefficient = 0.61, $P = 0.200$) than in late pregnancy (Spearman's $\rho = 0.33$, $P = 0.52$). This stronger correlation between FAS and early pregnancy exposure would be expected since (1) the FAS facial features are caused by alcohol exposure in the first 8 weeks of pregnancy and (2) the PRAMS question 'How much were you drinking in the third trimester?' would fail to identify a subset of women at high risk for bearing children with FAS (namely, women who did not drink in the third trimester, but did drink heavily in early pregnancy before they knew they were pregnant). When the analysis focused on both timing and level of alcohol use, the decline in FAS was most strongly and significantly correlated with the decline in prevalence of women reporting the highest-risk drinking pattern (>14 drinks/week in early pregnancy). The Pearson Correlation Coefficient was 0.86 ($P = 0.028$). The power to detect statistically significant correlations was limited by the number of years data were available ($n = 6$). This study had 80% power to detect correlation coefficients ≥0.85, at a two-tailed alpha level of 0.05.

Discussion

PRAMS data document a significant decline in the prevalence of maternal alcohol use during pregnancy from 1993 to 1998. The FAS DPN Screening/Diagnostic Program documents a significant decline in the prevalence of FAS among foster children born between 1993 and 1998. These observations support the likelihood that FAS prevention efforts in Washington State are working successfully. While this study was not designed to determine which prevention efforts were most effective, the prevention literature strongly supports that a comprehensive approach that utilises the entire spectrum of effort from public health education to targeted intervention has the greatest impact.[10,11]

Although the declines in maternal drinking and FAS observed in this study were statistically significant, these declines are based on very subtle annual reductions (each declining by just a few percentage points per year). Detection of subtle changes in FAS prevalence requires use of diagnostic and screening methods that are specifically case-defined so that they can be

Table 2. Decline in the prevalence of FAS among 264 children in the King County Foster Care Passport Program born from 1993 to 1998

Birth cohort	Number screened	FAS prevalence[a]	FAS *n*
1993	30	6.67%	2
1994	42	4.76%	2
1995	39	0.00%	0
1996	45	0.00%	0
1997	46	2.17%	1
1998	62	0.00%	0

[a]Chi-square test for linear trend from 1993 to 1998 = 4.7, $P = 0.03$.

accurately and reproducibly administered from year to year on a complete population-based sample. Typically, FAS surveillance activities to date have been population-based and rely on records-based data abstraction to generate prevalence estimates.[39–42] The FAS DPN screening, diagnostic and surveillance programme is unique because it integrates all three of these activities, capitalising on the inherent strengths of each. For example, the FAS DPN starts by screening all children in a foster care population with a FAS screening tool that performs with 100% sensitivity and 99.8% specificity. The FAS screening tool performs with the accuracy of a diagnostic tool because it is the diagnostic tool used to measure the FAS facial phenotype. The screening activity doubles as a highly effective surveillance activity because near-complete case ascertainment (98%) is achieved. High ascertainment is accomplished because the photographic screening tool can be practically administered and is targeted to a population that is (1) specifically defined, (2) readily tracked over time, and (3) motivated to participate because of the direct benefits. All children who screen positive receive a comprehensive diagnostic evaluation by a interdisciplinary team using the *same* diagnostic method (the 4-Digit Diagnostic Code).

At the time of diagnosis, the team reviews all medical, social service and educational records available on the child in addition to obtaining measures of growth, face, brain function and alcohol exposure through caregiver interview and direct clinical evaluation of the child. In contrast, a typical surveillance programme will rely on the passive chance that: (1) a child utilises the health care system; (2) a FAS diagnostic evaluation is conducted; (3) the surveillance programme obtains a copy of the relevant medical record(s); and (4) the record contains both accurate and sufficient information to confirm the child does or does not have FAS.

In a records-based approach to surveillance, all children will not have an equal chance of being correctly identified because the diagnostic methods used will vary from child to child and the accuracy of the data in the medical record cannot be confirmed as the child is never seen directly by the surveillance programme. This will limit the ability of the programme to track subtle changes in prevalence over time. In addition, surveillance programmes that rely on record abstraction often have to rely on proxy case definitions of FAS rather than the true clinical definition because the data needed to confirm a diagnosis of FAS is often not present in the medical or psychological records.[39] The inadequacy and variability of medical record documentation of FAS is well documented in the literature[40] and has been our experience in the FAS DPN clinic for the past 12 years.

Of the first 1390 patients evaluated in the FAS DPN clinic, 91 received a diagnosis of FAS using the 4-Digit Diagnostic Code. Although 60% of these 91 patients were over the age of 5 years at the time of diagnosis, only 8 had records documenting a previous evaluation and diagnosis of FAS. These 8 patients ranged in age from 1 to 24 years old. Of the 1299 patients that did not receive a diagnosis of FAS in the FAS DPN clinic, 24 had previously been diagnosed with FAS, but neither their medical records nor direct evaluations could substantiate the diagnosis. Similar observations were made among the children enrolled in the Foster Care FAS Screening/Diagnostic Program. All 10 children who screened positive for FAS among the first 600 children enrolled had no documentation of risk of FAS in their medical, school or psychological records even though the oldest was 11 years old and most had several inches of records. All 10 children would have been missed by a records-based approach to surveillance.

Another important and unique strength of the FAS DPN approach to surveillance is the potential for direct benefit to the child and their family. Typically, surveillance programmes have no direct contact with subjects and thus, provide no direct benefit to them. In contrast, the FAS DPN program, through its initial screening and diagnostic phases, provides children who screen positive with the benefits of an accurate diagnosis and intervention plan. This can lead to improved access to services, more appropriate foster/adoptive placements and prevention of secondary disabilities.[5] The potential for direct benefit also serves as a powerful motivator for participation as demonstrated by the 98% participation rate. Maintaining a high participation rate depends in large part on the families' experiences with the screening programme. It is imperative that false-positive screening outcomes are minimised. This is achieved with the FAS Facial Photographic Analysis Software screening tool because the FAS facial phenotype is highly sensitive and specific to FAS.[5,18] Growth deficiency and cognitive/behavioural dysfunction are not specific to FAS. Screening children positive for FAS, who do not have FAS, not only costs time and money to conduct unnecessary diagnostic evaluations, but more importantly, can come at a high emotional cost to families, especially to the birth mothers.

Although the FAS DPN approach to tracking the prevalence of FAS over time has many strengths, it is important to consider what factors may affect the validity of the results presented here. Although the observed decline in FAS was statistically significant, it is important to note that the prevalence estimates within each birth cohort are limited by the small samples sizes. Two factors, however, support the validity and stability of these interim results. First, the prevalence estimates are based on near complete (98%) ascertainment of the eligible population and thus it is highly unlikely that any FAS cases were missed. Secondly, when we look forward in time to all 908 children screened to date in this ongoing screening programme, a significant decline in the prevalence of children screening positive for FAS continues to be observed across the subset of 383 children born between 1993 and 1998 (chi-square = 4.03, $P = 0.04$). For comparison, the CDC also recognised the impact of small sample sizes on the precision of prevalence estimates, thus they required a minimum of 30 respondents and a response rate of >70% before prevalence estimates could be reported from the PRAMS data.[23] These criteria were met or exceeded in this FAS prevalence study. An obvious solution to small sample sizes is to expand the screening statewide and discussions are underway to do that.

One of the key goals of surveillance is to assess the effectiveness of primary prevention. This approach to tracking the prevalence of FAS over time in a high-risk foster care population offers an interesting alternative to tracking the prevalence of FAS across an entire state population. If statewide prevention efforts and statewide reduction in maternal alcohol use are effectively reducing the prevalence of FAS in this foster care population, it would be difficult to argue that similar reductions are not also being realised across the entire general population. The same can be said for the impact of prevention efforts on the full spectrum of disorders caused by prenatal alcohol exposure. If maternal drinking during pregnancy is reduced, the full spectrum of disorders caused by that drinking will be reduced, not just the disorder called FAS.

Although there is tremendous merit and value in tracking the prevalence of individuals damaged by prenatal alcohol exposure who do not meet the diagnostic criteria for FAS, an accurate and valid screening tool to achieve this does not currently exist. Until such time, reduction in maternal drinking during pregnancy and reduction in the prevalence of FAS in foster care can serve as valid proxy measures for reduction of the full spectrum of disorders associated with prenatal alcohol exposure across the general population.

Foreword

The National Center on Birth Defects and Developmental Disabilities at the Centers for Disease Control and Prevention, in collaboration with the National Task Force on Fetal Alcohol Syndrome and Fetal Alcohol Effect, is pleased to present ***Fetal Alcohol Syndrome: Guidelines for Referral and Diagnosis.*** This document represents the deliberations of clinicians, researchers, parents, and representatives of governmental and non-governmental organizations, whose main goals were to increase the identification of individuals with fetal alcohol syndrome (FAS) using uniform criteria, and to improve the delivery of appropriate services to those individuals and their families. These new guidelines will help achieve those goals by educating medical and allied health professionals about FAS.

In 2003, we, in the FAS research and practice communities, celebrated the 30th anniversary of the first reports describing fetal alcohol syndrome. Since that time we have learned a great deal about this preventable condition. We now recognize that FAS represents the tip of the iceberg and that there is a continuum of outcomes associated with prenatal exposure to alcohol. These guidelines were undertaken, in part, as an effort to facilitate further identification, understanding, and study of all conditions resulting from prenatal exposure to alcohol. They build on previous work and incorporate important scientific and clinical knowledge that has been obtained in recent years. CDC is pleased to provide continuing support for the expansion and refinement of scientific descriptions for FAS and other disorders related to prenatal exposure to alcohol through its ongoing work with the National Task Force on Fetal Alcohol Syndrome and Fetal Alcohol Effect and the federal Interagency Coordinating Committee on Fetal Alcohol Syndrome (ICCFAS).

Preventing all adverse outcomes associated with prenatal alcohol exposure remains a primary goal of CDC, as well as the entire U.S. Department of Health and Human Services. CDC is committed to working with other federal agencies, organizations in the private sector, relevant partners, and the public to achieve this goal. Similarly, CDC is committed to enhanced early identification of individuals with FAS and related disorders to ensure their access to appropriate services. These latest guidelines for referral and diagnosis are an important step towards that goal. Together we will ensure all persons with FAS and related disorders develop optimally and reach their full potential.

José F. Cordero, M.D., M.P.H.
Assistant Surgeon General
Director
National Center on Birth Defects and Developmental Disabilities

Fetal Alcohol Syndrome: Guidelines for Referral and Diagnosis

EXECUTIVE SUMMARY

As part of the fiscal year 2002 appropriations funding legislation, the U.S. Congress mandated that the Centers for Disease Control and Prevention (CDC), acting through the National Center on Birth Defects and Developmental Disabilities (NCBDDD) Fetal Alcohol Syndrome (FAS) Prevention Team and in coordination with the National Task Force on Fetal Alcohol Syndrome and Fetal Alcohol Effect (NTFFAS/FAE), other federally funded FAS programs, and appropriate non-governmental organizations, would:

- Develop guidelines for the diagnosis of FAS and other negative birth outcomes resulting from prenatal exposure to alcohol,
- Incorporate these guidelines into curricula for medical and allied health students and practitioners, and seek to have them fully recognized by professional organizations and accrediting boards, and
- Disseminate curricula to and provide training for medical and allied health students and practitioners regarding these guidelines.

Through the coordinated efforts of CDC, the NTFFAS/FAE, and a scientific working group (SWG) of experts in FAS research, diagnosis, and treatment, the following diagnostic criteria were developed over a 2-year period:

Facial dysmorphia
Based on racial norms, individual exhibits all three characteristic facial features:

- Smooth philtrum (University of Washington Lip-Philtrum Guide rank 4 or 5)
- Thin vermillion border (University of Washington Lip-Philtrum Guide rank 4 or 5)
- Small palpebral fissures (at or below 10th percentile)

Growth problems
Confirmed prenatal or postnatal height or weight, or both, at or below the 10th percentile, documented at any one point in time (adjusted for age, sex, gestational age, and race or ethnicity).

Central Nervous System Abnormalities

I. Structural

1) Head circumference (OFC) at or below the 10th percentile adjusted for age and sex.
2) Clinically significant brain abnormalities observable through imaging.

II. Neurological
Neurological problems not due to a postnatal insult or fever, or other soft neurological signs outside normal limits.

III. Functional
Performance substantially below that expected for an individual's age, schooling, or circumstances, as evidenced by:

1. Global cognitive or intellectual deficits representing multiple domains of deficit (or significant developmental delay in younger children) with performance below the 3rd percentile (2 standard deviations below the mean for standardized testing)

or

2. Functional deficits below the 16th percentile (1 standard deviation below the mean for standardized testing) in at least three of the following domains:

a) cognitive or developmental deficits or discrepancies
b) executive functioning deficits
c) motor functioning delays
d) problems with attention or hyperactivity
e) social skills
f) other, such as sensory problems, pragmatic language problems, memory deficits, etc.

Maternal Alcohol Exposure
I. Confirmed prenatal alcohol exposure
II. Unknown prenatal alcohol exposure

Criteria for FAS Diagnosis
Requires all three of the following findings:
1. Documentation of all three facial abnormalities (smooth philtrum, thin vermillion border, and small palpebral fissures);
2. Documentation of growth deficits
3. Documentation of CNS abnormality

A primary goal of these guidelines is to provide standard diagnostic criteria for FAS so that consistency in the diagnosis can be established for clinicians, scientists, and service providers. The guidelines are based on state-of-the-art scientific research, clinical expertise, and family input regarding the physical and neuropsychological features of FAS. The SWG sought to harmonize these guidelines with other diagnostic systems currently in use in this country and others (e.g., Canada). The SWG strove to provide a balance between conservative and overly inclusive diagnostic systems. Differential diagnosis from other genetic, teratological, and behavioral disorders was emphasized.

In addition to diagnostic guidelines, guidance about medical, educational, social, and family services appropriate for individuals with FAS and their families are reviewed. Services that are applicable to all individuals with FAS and their families, as well as age-specific services, are included. Such services focus on increasing parent and professional knowledge of FAS, characteristics of the disor-

der, differences between FAS and other disorders, and appropriate techniques for parenting or educating affected individuals.

Prevention of FAS and related disorders is of tremendous public health importance. A large amount of research in recent years has enabled researchers and service providers to develop programs that are effective and targeted to specific populations for reducing the risk of an alcohol-exposed pregnancy, which prevents FAS. This research is reviewed herein and recommendations for identifying and intervening with women at risk for an alcohol-exposed pregnancy are provided.

Finally, these guidelines are not intended to be an endpoint in the discussion of diagnosing FAS. There is a great need to acquire science-based information that will facilitate diagnostic criteria for additional related disorders, such as Alcohol Related Neurodevelopmental Disorder (ARND). These guidelines conclude with a call for further research and continuous refinement of the diagnostic criteria for FAS and related conditions so that affected individuals and their families can receive important services that enable them to achieve healthy lives and reach their full potential.

x

Fetal Alcohol Syndrome: Guidelines for Referral and Diagnosis

Substantial empirical and clinical scientific evidence has shown that prenatal exposure to alcohol causes damage to the developing fetus. Such exposure is commonly cited as the leading preventable cause of birth defects and developmental disabilities (1-3). Children* exposed to alcohol during fetal development can suffer multiple effects. While the number and severity of negative effects can range from subtle to serious, the negative consequences are lifelong. The effects of prenatal exposure to alcohol and basic diagnostic features of fetal alcohol syndrome (FAS) were first described in the United States (U.S.) medical literature 30 years ago (4-8). In 1981, the U.S. Surgeon General issued a public health advisory warning that alcohol use during pregnancy could cause birth defects (9). Further, mandated labeling of alcohol products was established in 1989 (10). Despite the known adverse effects of prenatal exposure to alcohol, many children who experience these adverse effects do not receive proper diagnosis due to the absence of current diagnostic guidelines. These current guidelines, which were federally mandated of the Centers for Disease Control and Prevention (CDC) in the U.S. Department of Health and Human Services (DHHS) 2002 Appropriations Bill, seek to update and refine diagnostic and referral criteria in light of the scientific and clinical advances in the understanding of this disorder during the past 30 years.

These guidelines are organized into several sections. Background information and a history of the development of these guidelines are presented. Next, revised and refined diagnostic and referral criteria for FAS are described, including the empirical and clinical evidence that support each criterion. Comparison of these guidelines with other diagnostic methods currently in use is provided. Because diagnosis is not the endpoint for most clinicians who see children with FAS, a discussion of the essential services for affected individuals is included. Likewise, prevention of FAS by reducing the number of alcohol-exposed pregnancies is inherent in dealing with the disorder. Therefore, a discussion focused on identifying and intervening with women at risk for an alcohol-exposed pregnancy is provided. Finally, a discussion of future needs and efforts related to FAS and other prenatal alcohol-related disorders conclude this report.

BACKGROUND

Prevalence. Studies by CDC have reported FAS prevalence rates from 0.2 to 1.5 cases per 1,000 births across various populations (11-14). Other studies reflecting a variety of ascertainment methodologies have produced estimates ranging from 0.5 to 2.0 cases per 1,000 live births (15-16). Such rates are comparable with or above other common developmental disabilities such as Down syndrome or Spina Bifida (17). Using the CDC FAS estimates, among the approximately 4 million infants born each year, an estimated 1,000 to 6,000 will be born with FAS. Studies of particularly vulnerable populations yield prevalence estimates that far exceed those of other common disabilities. Disadvantaged groups, Native Americans, and other minorities have been documented to have

* Although referral and diagnosis for FAS can be made throughout the lifespan, the majority of individuals are referred and diagnosed in childhood. Thus, the terms “child” or “children” as used in these guidelines are not intended to preclude referral, assessment, and diagnosis of older individuals.

rates as high as three to five FAS affected children per 1,000 children (18-20). Available data also suggest that poverty is strongly associated with women's alcohol use before and during pregnancy, leading to an excess of children with FAS in impoverished groups (21-22).

The magnitude of the problem is even greater when the risk of FAS is considered by looking at the rate of alcohol-exposed pregnancies. In 1999, over half of all U.S. women of childbearing age reported alcohol consumption in the past month (23). The large majority of these women drank only occasionally, but 15% could have been classified as moderate or heavy drinkers (24-25). During that same period, 13% of women reported consuming five or more drinks on one occasion (binge drinking) in the past month (26). Given that nearly half of all U.S. pregnancies are unintended, and that millions of fertile women are sexually active while not using adequate contraception, an estimated 2% of women could be at risk for an alcohol-exposed pregnancy annually (27). More recently, higher rates have been found among subgroups of women, such as those treated for alcohol and drug problems, and women who have been incarcerated (28). Alcohol-related risk factors include drinking during pregnancy, pattern of alcohol use, alcohol dependence, use of multiple substances, having had a previous alcohol-exposed pregnancy, and having a partner or family member who drinks heavily (29-31). Women who receive little or no prenatal care, are unemployed, are socially transient, have lost children to foster or adoptive care because of neglect, abuse, or abandonment are more likely to have high alcohol use patterns that could affect a pregnancy (22,32). National survey data indicate that, while the percentage of women who abstain from alcohol use during pregnancy has increased slightly in recent years, 13% of women continue to use alcohol during pregnancy (26). Among pregnant women, approximately three percent report binge drinking (i.e., five or more drinks on any one occasion) or frequent drinking (i.e., seven or more drinks per week or five or more drinks on any one occasion) (1,33-34). Clearly, current prevalence rates of affected individuals and alcohol-exposed pregnancies indicate that the magnitude of the problem of FAS is a significant public health concern. However, because of the challenges of establishing accurate and timely prevalence information, the magnitude could be even greater than current data indicate.

Challenges in determining accurate prevalence. Despite the progress made over the past several decades to accurately establish and monitor the prevalence of FAS, the full magnitude of the problem is still not known. Primary care providers and others who care for children do not routinely or consistently identify individuals with FAS, which hinders efforts to account for these children in routine birth defects and developmental disabilities monitoring programs. Studies using multiple data sources (e.g., birth certificates, clinical charts, and medical records) show wide variations in identification of FAS cases depending on the population being surveyed (15,34). Four major factors lead to widespread failure to recognize FAS in primary pediatric care settings resulting in underestimates of the prevalence and impact of FAS (36-38):

- **No specific and uniformly accepted diagnostic criteria have been available.** The four broad areas of clinical features that constitute the diagnosis of FAS have remained essentially the same since first described in 1973: selected facial malformations, growth retardation, Central Nervous System (CNS) abnormalities, and maternal alcohol consumption during pregnancy. These four areas were reaffirmed in a 1996 report by the Institute of Medicine (IOM; 39-40). However, these broad areas of diagnostic criteria are not sufficiently specific to ensure diagnostic accuracy, consistency, and reliability . For example, clinicians do not have guidance about how many facial features must be present or the timing and severity of growth retardation needed to constitute

FAS diagnostic criteria. Thus, health providers are hampered in their efforts to screen and identify children with FAS.

- **FAS diagnosis is based on clinical examination of features, but not all children with FAS look or act the same.** Because each of the symptoms has a broad range of differential diagnoses, it is easy for a clinician to miss or misdiagnose FAS. Previous guidelines, including those included in the 1996 IOM report, did not account for children of different racial and ethnic groups or individuals of different ages . In addition, symptoms such as growth impairment, cognitive impairment, and learning disabilities can have a range of causes. Some of these causes or disorders have higher visibility and recognition than FAS, leading to misdiagnosis (or at least failure to include FAS in the total diagnosis). For instance, physicians are aware of the high prevalence of Attention Deficit, Hyperactivity Disorders (ADHD), but might not link attention problems to FAS. Without clear diagnostic criteria and instruction on their use, providers will continue to under-identify and under-diagnose FAS.

- **Lack of knowledge and misconceptions among primary care providers.** Many professionals believe that FAS can only occur if the mother is an alcoholic. Few know about the full range or progressive nature of the neurobehavioral symptoms that result from prenatal exposure to alcohol. Some incorrectly believe that FAS only occurs among low-income families or in Native American or other racial and ethnic minority groups (21). Better information on the impact of FAS among all populations and dissemination of race or ethnic variations in the diagnostic criteria can help clinicians understand the risk of prenatal alcohol exposure across populations. Knowledge about subpopulation variations in facial characteristics as well as growth curves for infants by gestational age also are important considerations (41).

- **Lack of diagnostic criteria to distinguish FAS from other alcohol-related conditions.** Creating and using diagnostic guidelines for FAS is a starting point for better defining the continuum of conditions related to prenatal alcohol exposure (40). FAS is a severe outcome of prenatal alcohol exposure. Other outcomes also occur and can result in major deficits. Terms such as Fetal Alcohol Effect (FAE), Alcohol-related Birth Defect (ARBD), and Alcohol-Related Neurodevelopmental Disorder (ARND) have been used to describe a spectrum of conditions related to prenatal alcohol exposure.

These four challenges indicate that what is urgently needed to advance the field of FAS diagnosis are current diagnostic guidelines based on empirical evidence as well as clinical experience. Such guidelines should be based on up-to-date scientific evidence and current clinical practices. Further, such guidelines would allow public health and service professionals to better determine the impact of FAS, and deliver needed services to affected children.

Congressional mandate. As part of the fiscal year 2002 appropriations funding legislation, Congress mandated that CDC, acting through the National Center on Birth Defects and Developmental Disabilities (NCBDDD) and in coordination with the National Task Force on Fetal Alcohol Syndrome and Fetal Alcohol Effect (NTFFAS/FAE), other federally funded FAS programs, and appropriate nongovernmental organizations, would:

- Develop guidelines for the diagnosis of FAS and other negative birth outcomes resulting from prenatal exposure to alcohol;

- Incorporate these guidelines into curricula for medical and allied health students and practitioners, and seek to have them fully recognized by professional organizations and accrediting boards; and
- Disseminate curricula to and provide training for medical and allied health students and practitioners regarding these guidelines.

Limit in scope. The mandate to CDC indicates that, in addition to guidelines for FAS, guidelines should be developed for other negative birth outcomes resulting from prenatal exposure to alcohol. However, it was subsequently determined through discussions with all interested stakeholders that the best course was to first develop guidelines for the full FAS diagnosis (see following). Then, in subsequent efforts, these guidelines could be expanded or refined to include other alcohol-related disorders. This approach was determined to provide the most timely and scientifically grounded guidelines at this time. However, this decision does not curtail ongoing efforts to define conditions beyond FAS or develop diagnostic guidelines for those conditions.

Note on terminology. Many terms are used to describe the continuum of effects that result from prenatal exposure to alcohol, including: Fetal Alcohol Effect, Alcohol-related Birth Defects, and Alcohol-Related Neurodevelopmental Disorder. A more recent term that has been introduced is Fetal Alcohol Spectrum Disorders (FASD). In April 2004, several federal agencies [(National Institutes of Health (NIH), CDC, & Substance Abuse and Mental Health Services Administration (SAMHSA)] along with experts in the field were convened at a summit sponsored by the National Organization on FAS (NOFAS) to develop a consensus definition of FASD. The resulting definition, adopted in these guidelines, is:

> *Fetal Alcohol Spectrum Disorders (FASD) is an umbrella term describing the range of effects that can occur in an individual whose mother drank alcohol during pregnancy. These effects may include physical, mental, behavioral, and/or learning disabilities with possible lifelong implications. The term FASD is not intended for use as a clinical diagnosis.*

APPROACH AND METHODS FOR DEVELOPMENT OF GUIDELINES

To meet its Congressional mandate, CDC convened an internal working group, led by staff from the FAS Prevention Team of NCBDDD, to conduct preplanning meetings to determine the best methods for development of all aspects of the guidelines: (a) general framework for referral and diagnosis, (b) development of guidelines for physical features (dysmorphia and growth) as well as exposure, and (c) development of guidance to clinicians concerning potential CNS abnormalities. Each of these aspects involved review of the literature, as well as discussions with consultants, clinicians, researchers, and parents of affected children. A description of general and specific methods of development of each aspect follows.

General review of literature. CDC staff identified various reports and documents to be used as the scientific basis for diagnostic guidelines. The science base for this work included, but was not limited to:

- Published scientific, peer-reviewed, literature on physical and neurodevelopmental effects of prenatal exposure to alcohol;
- The report of the IOM Committee to study FAS (40);
- Results from the work of the NTFFAS/FAE (42) ;
- Criteria from standard, widely used dysmorphology and neurodevelopmental textbooks or guides (40,43-44);
- Research on measuring the FAS facial phenotype (45-47);
- Reports on systems that operationally interpret the 1996 IOM criteria(48-50);
- Experience in developing a surveillance case definition for the Fetal Alcohol Syndrome Surveillance Network (FASSNET) (51);
- Ongoing state surveillance and research data, particularly work of Alaska (19,35,52), Colorado (53), New Jersey, Nevada, Washington, and the Four State FAS Consortium (consisting of North Dakota, Montana, Minnesota, and South Dakota);
- The American Academy of Pediatrics (AAP) August 2000 statements and recommendations on FAS and other effects related to maternal alcohol use (54); Position of the American Academy of Family Physicians, which refers to the AAP statement; and
- Canadian National Committee's efforts concerning standardization of guidelines for screening, diagnosis, and surveillance of FAS.

Framework. Before developing the specifics of the diagnostic and referral guidelines, CDC staff determined that it would be helpful to conceptualize the entire diagnostic and referral process encountered by affected individuals and their families. Such a framework also would assist professionals in understanding their specific role in the referral and diagnostic process, as well as guide them with next steps for each case. The framework was reviewed by health care policy consultants as well as members of the NTFFAS/FAE. Revisions were made based on their suggestions. This framework is presented in detail later in these guidelines.

Creation of the Scientific Working Group. The first step in development of the guidelines was to convene an internal CDC working group. The group consisted of members of the NCBDDD FAS prevention team, geneticists, developmental pediatricians, epidemiologists, and psychologists, as well as other allied health professionals. This internal working group developed a list of potential external experts who could be convened to develop the actual guidelines. The large external panel of experts was designated as a scientific advisory panel. From this panel, a subset of experts formed a Scientific Working Group (SWG) that delineated the specifics of the diagnostic criteria.

The external SWG convened by CDC included researchers, clinicians in general and specialty medicine, representatives from academic centers and state health agencies, as well as consumer representatives from the National Organization on FAS (NOFAS) and The Arc of the United States. The scientific advisory panel met in Atlanta, Georgia, on July 12, 2002, to begin deliberations on the proposed guidelines. At that meeting, four subgroups were created: FAS Referral and Diagnosis; ARND issues; Essential Services for Children with FAS/ARND; and Identifying and Intervening with Women at Risk for an Alcohol-Exposed Pregnancy. The subgroups met and began deliberations related to the guidelines in their respective topic areas.

A subsequent meeting of the SWG occurred on September 20, 2002, in conjunction with an NTFFAS/FAE meeting, also in Atlanta. This offered the opportunity for information sharing and feedback on progress made thus far from a range of stakeholders represented on the NTFFAS/FAE

(e.g., parents, providers, and researchers). The FAS Referral and Diagnostic subgroup and the Essential Services subgroup met to further deliberate on their recommendations. The recommendations from these two subgroups were then presented to the NTFFAS/FAE for review and input. The component of the criteria for FAS screening and diagnosis that presented the most difficulty to the FAS Referral and Diagnosis subgroup was the central nervous system (CNS)/neurobehavioral component. This group felt that members of the ARND subgroup were most qualified to develop that particular component of the criteria.

The ARND subgroup drew important information from a poll of the experts that was conducted to identify the CNS/neurobehavioral domains most affected by prenatal alcohol exposure (further description follows). Results of this poll were incorporated into the FAS Referral and Diagnosis Guidelines within the CNS/neurobehavioral component. The third meeting of the FAS Referral and Diagnosis subgroup was teleconferenced on March 11, 2003, and draft guidelines were reviewed and revised. At that time and based on review of the available scientific evidence concerning diagnosis of ARND, the scope of the guidelines was limited to FAS, with future efforts to be devoted to other prenatal alcohol-related disorders. This revised version of the diagnostic criteria was presented to and approved by the NTFFAS/FAE on March 13, 2003 with recommendations. Consensus among members of the external SWG and the NTFFAS/FAE was used to finalize each criterion of the guidelines for dysmorphology, growth, and prenatal exposure to alcohol. At the December 8 and 9, 2003, meeting of the NTFFAS/FAE, further discussions were held regarding the CNS/neurobehavioral criteria and subsequent revisions were made. Finalization of the FAS criteria was reached during a teleconference of the NTFFAS/FAE on May 13, 2004.

Highlights of deliberations of SWG: Physical criteria. The SWG concluded that a strict definition of FAS should be established first, not including diagnostic terms such as fetal alcohol effect (FAE), alcohol-related neurodevelopment disorder (ARND), and alcohol-related birth defect (ARBD) at this time because of insufficient scientific evidence on which to base diagnostic criteria for these related conditions. The SWG urged that CDC diagnostic guidelines for FAS use objective, quantitative measures to improve accuracy and reproducibility and apply specific case definitions guided by evidence-based knowledge and new technologies. The SWG also recommended use of racial and ethnic norms for facial features, head circumference (occipitofrontal circumference, OFC), and other key features when available.

During its deliberations, the SWG acknowledged the need to keep recommendations for the diagnosis of FAS relevant to practitioners working in clinical settings. Also, the SWG acknowledged differences between screening, diagnosis, surveillance, and research activities and the separate definitional needs of each of these activities. Effective tools and practical strategies for primary care settings were considered. The SWG encouraged CDC to call for action and collaboration among obstetricians, pediatricians, family practice physicians, and others providing primary care and screening services to children. The SWG also discussed the need for more data regarding the range of essential services for children who are diagnosed positive for FAS and stressed the importance of a multidisciplinary plan for care that links to the child's community healthcare provider or medical home.

Central nervous system abnormality criteria. Because the scientific evidence and professional consensus on CNS criteria are not yet at the level of specificity equal to that available for physical features, a different approach was used in developing CNS criteria. Further, it was decided that rather than

creating strict criteria for specific CNS domains and level of severity needed, more general guidelines should be described. Such general guidelines should assist the clinician in identifying areas of deficit most likely to be found with individuals who have FAS, as well as individuals with FAS who have less common types of deficits. This approach was considered optimal because a number of structures of the brain are affected versus a single, isolated structure. This generalized nature of damage from prenatal alcohol exposure can result in a wide array of neurodevelopmental outcomes.

To develop such neurodevelopmental guidelines for referral and diagnosis for FAS, the ARND/CNS subgroup polled clinicians and researchers who have extensive knowledge and experience with individuals who have FAS or other related diagnoses. These experts were individuals who specialize in neurobehavioral issues, have extensive research and clinical experience making the FAS/ARND diagnosis, and have contact with families and children with FAS. They were queried to find out what behavioral domains they encountered most frequently or were most essential for making an FAS/ARND diagnosis. Twenty-two clinicians were contacted and their responses were synthesized. The clinicians were asked to identify five areas of deficit they considered most important for diagnosis of FAS or related disorders. In addition, the clinicians were also asked to identify three to five specific behaviors that could be used as examples of each of the five areas of deficit.

The resulting guideline of neurodevelopmental features associated with FAS are presented as being as inclusive as possible, while understanding that certain areas of neurodevelopmental functions are more vulnerable to prenatal exposure to alcohol. Each domain is presented so as to include exemplars from direct observation or parent report that can be documented through standardized testing.

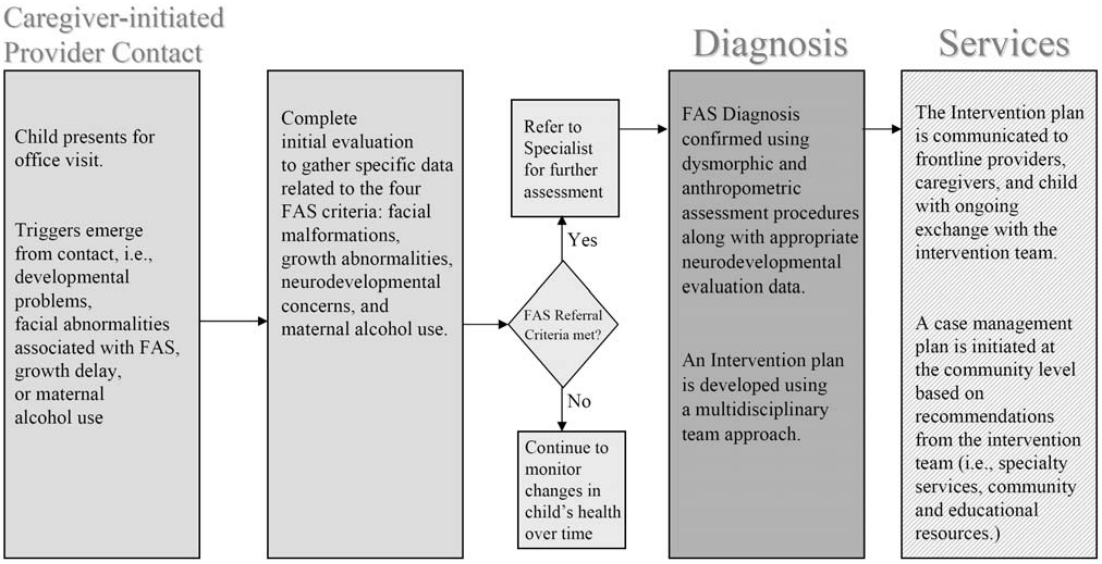
Medical diagnostic criteria are generally evaluated in two ways: (1) the criteria must be reliable and; (2) the criteria must be as valid as possible. The criteria that appear in these diagnostic guidelines meet both of these requirements. In developing these diagnostic guidelines, the SWG also considered the feasibility of applying the criteria in primary care practice and related settings where children are seen.

DIAGNOSTIC AND REFERRAL FRAMEWORK

The framework in Figure I was developed to help guide the discussions of the SWG as they deliberated on the guidelines for referral and diagnosis of FAS. The framework was developed to provide an overview of the entire identification, referral, diagnosis, and treatment process. This overview guided the SWG in identifying key points that needed to be addressed to develop specific guidelines. The framework reflects CDC's recommendation that developmental screening be implemented to improve children's health and help them reach their full potential. A discussion of the major points of the framework follows.

Initial identification. Initial recognition that a child or older individual has a potential problem can come from many sources. Often, parents notice differences between a child and his or her siblings. School systems, including Head Start and daycare staff, interact with a large number of children and often recognize when someone is having difficulty. Social service professionals, such as WIC clinic staff, social workers, and foster care agencies frequently recognize children and individuals having difficulty and needing evaluation. And finally, healthcare providers (particularly pediatricians) often are the first to screen for and detect problems; or obstetricians, who might be aware of

FIGURE 1. Framework for FAS Diagnosis and Services



a maternal substance abuse problem, might refer a newborn. Recognition of many of the problems associated with FAS is exactly the type of condition the "well child" visits to the doctor's office are meant to identify. It is assumed that triggers, such as facial abnormalities, growth delay, developmental problems, or maternal alcohol use, will emerge from the contact. Recognition of a potential problem should lead the provider, regardless of specific profession, to facilitate getting the person and his or her family to the appropriate next step.

Referral. The referral process is initiated at the point a clinician starts to have suspicions of an alcohol-related disorder for a child. This process is facilitated by thorough knowledge of the physical and neurodevelopmental domains affected in individuals with FAS, as well as characteristics that could trigger a referral. Examples of triggers are presented later, in the Referral section of these guidelines. In making a referral for a complete diagnostic evaluation for FAS, it is helpful for the referring provider to gather and document specific data related to the FAS criteria. These data will assist the provider in making the decision to diagnose the child or to refer the child to a multidisciplinary evaluation team for a confirmed diagnosis. In addition, these data could be forwarded to the multidisciplinary evaluation team to guide the diagnostic process. A complete review of systems, noting features consistent with FAS, would be most productive.

Diagnosis. At this stage, the child would be presented to a multidisciplinary team who would engage in a more thorough assessment of the child using FAS diagnostic procedures to evaluate dysmorphia and growth parameters, as well as obtain appropriate neurodevelopmental evaluation data. Once a diagnosis is made, an intervention plan would be developed using a multidisciplinary team approach. A variety of specialists could contribute to the multidisciplinary team, including dysmorphologists, developmental pediatricians, psychiatrists, psychologists, social workers, and educational specialists. Other clinicians, such as pediatricians and family practitioners, also might make the FAS diagnosis, with appropriate training in use of these guidelines. In many rural and less populated regions, these clinicians must make the diagnosis for many types of birth defects and developmental

disabilities. Many of these evaluation services are available within the community setting, for example school systems could provide neurocognitive assessments.

DIAGNOSTIC CRITERIA

Dysmorphia. Human congenital malformations are referred to as dysmorphic features or dysmorphia (55). Dysmorphia occurs when normal morphogenesis is interrupted, creating a particular feature which is shaped, sized, or positioned outside the normal range of development. Alcohol is a teratogen that results in dysmorphia through interference with nerve cell development and functioning, alterations in the ability of cells to grow and survive, increased formation of cell-damaging free radicals, altered pathways of biochemical signals within cells, and altered expression of certain genes and genetic information. In short, alcohol has been shown to interfere with fetal nerve cell development and function in a variety of ways (56-57).
