In 2011, Dr. Susan Astley wrote a chapter on Diagnosing FASD in a book entitled *Prenatal Alcohol Use and Fetal Alcohol Spectrum Disorders: Diagnosis, Assessment and New Directions in Research and Multimodal Treatment* (Astley, 2011). This chapter provided a brief overview of the discovery of FASD, diagnostic challenges, how diagnostic guidelines and clinical models have evolved over time to address these challenges, and how new technology may influence the future of FASD diagnosis. The tables below come from that chapter, and provide a side-by-side comparison of the five most commonly used diagnostic guidelines for forms of FASD; the 4-Digit Diagnostic Code (Astley, 2004b), the guidelines developed by the Centers for Disease Control and Prevention (Bertrand et al., 2004), the Canadian guidelines (Chudley et al., 2005), the revised guidelines of the Institute of Medicine (IOM) (Hoyme et al., 2005), and the original IOM guidelines (Stratton et al., 1996). Table 1 compares diagnostic criteria for FAS; Table 2, pFAS; Table 3, ARND; and Table 4, ARBD. These tables are reprinted here with the permission of the author.

It is important to note that, for the purposes of this Appendix, the 4-Digit Diagnostic Code has been translated, as best as possible, into a text (rather than numeric) format. This was done to facilitate comparison to the other guidelines that publish their diagnostic criteria in text format. Diagnostic teams should not use the textual translations of the 4-Digit Code presented in Tables 1-4 to derive a 4-Digit Code, but rather the numeric format presented in the *Diagnostic Guide for Fetal Alcohol Spectrum Disorders: The 4-Digit Diagnostic Code*, Third Edition (Astley, 2004a).

Table 1. FAS Diagnostic Criteria: Comparison Across the Five Most Current FASD Diagnostic Guidelines

	4-Digit Code (2004)	CDC (2004)	Canadian (2005)	Revised IOM (2005)	IOM (1996)
Growth	Prenatal and/ or postnatal height or weight < 10th percentile (Growth Ranks 2-4)	Prenatal and/ or postnatal height or weight < 10th percentile	At least 1 of the following: • Prenatal and/ or postnatal height or weight < 10th percentile • Weight-to-height ratio (<10th percentile)	Prenatal and/ or postnatal height or weight < 10th percentile	At least 1 of the following: • Low birth weight • Low weight for height • Decelerating weight
Face	All 3 of the following at any age: • PFL < 3rd percentile • Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5 (Face Rank 4)	All 3 of the following: • PFL < 10th percentile • Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5	All 3 of the following at any age: • PFL < 3rd percentile • Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5	2 or more of the following: • PFL < 10th percentile • Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5	Characteristic pattern that includes features such as short PFL, flat upper lip, flattened philtrum, and flat midface.
CNS	At least 1 of the following: • Structural/ Neurological: (e.g., OFC < 3rd percentile, abnormal structure, seizure disorder, hard signs) • Severe Dysfunction: (3 or more domainsa of function with impairment 2 or more SDs below the mean)	At least 1 of the following: • Structural/ Neurological: (e.g., OFC < 10th percentile, abnormal structure, seizure disorder, hard/soft signs) • Dysfunction[b]: • 3 or more domains of function with impairment 1 or more	At least 3 of the following Structure/ Neurological/ Functional domains with impairment[c]: • Hard/ soft signs, structure, cognition, communi-cation, academic achievement, memory, executive functioning, abstract reasoning, ADD,	At least 1 of the following: • Structural • OFC < 10th percentile • Abnormal structure	At least 1 of the following: • Structural/ Neurological: • Decreased cranial size at birth • Abnormal structure (e.g., microcephaly, partial/ complete agenesis of the corpus callosum, cerebellar hypoplasia) • Neurological hard/soft signs

	(CNS Rank 3 and/or 4)	SDs below the mean • Global deficit (2 or more SDs below the mean)	adaptive behavior, social skills, or communi-cation		
Alcohol	Confirmed or Unknown (Alcohol Ranks 2,3 or 4)	Confirmed or Unknown	Confirmed or Unknown	Confirmed-excessive or Unknown	Confirmed-excessive or Unknown

a. 4-Digit Code: Domains may include, but are not limited to: executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention, or activity level.
b. CDC: Performance substantially below that expected for an individual's age, schooling, or circumstances, as evidenced by: 1) Global cognitive or intellectual deficits representing multiple domains of deficit (or significant developmental delay in younger children) with performance below the 3rd percentile (2 standard deviations below the mean for standardized testing) or 2) Functional deficits below the 16th percentile (1 standard deviation below the mean for standardized testing) in at least three of the following domains: a) cognitive or developmental deficits or discrepancies b) executive functioning deficits c) motor functioning delays d) problems with attention or hyperactivity e) social skills f) other, such as sensory problems, pragmatic language problems, memory deficits, etc.
c. Canadian: Impairment indicates scores $\geq$ 2 SDs below the mean, discrepancies of 1.5-2 SDs among subtests, or $\geq$ 1 SD discrepancy between subdomains.

Table 2: Partial FAS Diagnostic Criteria: Comparison Across the Five Most Current FASD Diagnostic Guidelines

	4-Digit Code (1997-2004)	CDC[a] (2004)	Canadian (2005)	Revised IOM (2005)	IOM (1996)
Growth	Prenatal or postnatal height or weight < 10th percentile (Growth Ranks 1-4)	--	No growth deficiency	Prenatal and/or postnatal height or weight < 10th percentile	At least 1 of the following: • Low birth weight • Low weight for height • Decelerating weight
Face	All 3 of the following at any age: • PFL < 3rd percentile	--	2 of the following at any age: • PFL < 3rd percentile	2 or more of the following: • PFL < 10th percentile	Some components of the pattern of FAS characteristic facial anomalies.

Appendix E— Comparison of Current FASD Diagnostic Systems

	• Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5 (Face Ranks 3 or 4)*		• Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5	• Smooth philtrum Rank 4 or 5 • Thin upper lip • Rank 4 or 5	
CNS	At least 1 of the following: • Structural/ Neurological: (e.g., OFC < 3rd percentile, abnormal structure, seizure disorder, hard signs) • Severe Dysfunction: (3 or more domains[b] of function with impairment 2 or more SDs below the mean) (CNS Rank 3 and/or 4)	--	At least 3 of the following Structure/ Neurological/ Functional domains with significant impairment[c]: • Hard/soft signs, structure, cognition, communication, academic achievement, memory, executive functioning, abstract reasoning, ADD, adaptive behavior, social skills, or communication	At least 1 of the following: • Structural • OFC < 10th percentile • Abnormal structure • Dysfunction • Complex pattern[d] of behavior/ cognitive abnorm-alities	At least 1 of the following: • Structural/ Neurological: • Decreased cranial size at birth • Abnormal structure • Hard/soft signs • Dysfunction • Complex pattern[e] of behavior/ cognitive abnormalities
Additional Criteria	PFAS requires the CNS and Alcohol criteria to be met and allows either the Growth or the Face criteria to be relaxed just slightly. • *If the growth deficiency criteria above are met, one facial feature may be relaxed as follows: (PFL < 1 SD, or Philtrum Rank 3, or Lip Rank 3) or	--	None	PFAS requires the Face and Alcohol criteria to be met and only one of the following additional criteria: • Growth • CNS Structural • CNS dysfunction	PFAS requires the Face and Alcohol criteria to be met and only one of the following additional criteria: • Growth • CNS Structural/ Neurological • CNS dysfunction

	• If the FAS face criteria are met, growth can be relaxed to normal.				
Alcohol	Confirmed (Alcohol Ranks 3 or 4)	--	Confirmed	Confirmed-excessive or Unknown	Confirmed-excessive

a. The CDC Guidelines only address FAS.
b. 4-Digit Code: Domains may include, but are not limited to: executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention, or activity level.
c. Canadian: Impairment indicates scores ≥ 2 SDs below the mean, discrepancies of 1.5 to 2 SDs among subtests, or ≥ 1 SD discrepancy between subdomains.
d. Hoyme: Marked impairment in the performance of complex tasks (complex problem solving, planning, judgment, abstraction, metacognition, and arithmetic tasks); higher-level receptive and expressive language deficits; and disordered behavior (difficulties in personal manner, emotional lability, motor dysfunction, poor academic performance, and deficient social interaction).
e. IOM: Complex pattern of behavior or cognitive abnormalities that are inconsistent with developmental level and cannot be explained by familial background or environment alone: e.g., learning difficulties; deficits in school performance; poor impulse control; problems in social perception; deficits in higher level receptive and expressive language; poor capacity for abstraction or metacognition; specific deficits in mathematical skills; or problems in memory, attention or judgment.

Table 3. ARND (or its equivalent: Static Encephalopathy/Alcohol Exposed or Neurobehavioral Disorder/Alcohol Exposed) Diagnostic Criteria: Comparison Across the Five Most Current FASD Diagnostic Guidelines

	4-Digit Code (1997-2004)	CDC[a] (2004)	Canadian (2005)	Revised IOM (2005)	IOM (1996)
Growth	Normal to deficient (Growth Ranks 1-4)	--	No growth deficiency	No growth deficiency	No growth deficiency
Face	No more than 1 of the following: • PFL < 3rd percentile • Philtrum Rank 4 or 5 • Lip Rank 4 or 5 (Face Ranks 1-2)	--	No FAS facial phenotype	No FAS facial phenotype	Presumably no components of the pattern of FAS characteristic facial anomalies.

Appendix E— Comparison of Current FASD Diagnostic Systems

CNS	Criteria_ for "Static_ Encephalopathy" At least 1 of the following: • Structural/ Neurological: (e.g., OFC < 3rd percentile, abnormal structure, seizure disorder, hard signs) • Severe Dysfunction: (3 or more domains[b] of function with impairment 2 or more SDs below the mean) (CNS Rank 3 and/or 4) Criteria for_ "Neurobehavioral Disorder"[c] • No Structural/ Neurological abnormalities. • Moderate Dysfunction: 1-2 domains[b] of function with impairment > 1.5 SDs below the mean)	--	At least 3 of the following Structure/ Neurological/ Functional domains with significant impairment[c]: • Hard/soft signs, structure, cognition, communication, academic achievement, memory, executive functioning, abstract reasoning, ADD, adaptive behavior, social skills, or communication	At least 1 of the following: • Structural • OFC < 10th percentile • Abnormal structure • Dysfunction • Complex pattern[d] of behavior/ cognitive abnormalities	At least 1 of the following: • Structural/ Neurological: • Decreased cranial size at birth • Abnormal structure • Hard/soft signs • Dysfunction • Complex pattern[e] of behavior/cognitive abnormalities
Additional Criteria	The term ARND is not used. The following terms are used in lieu of ARND: Static Encephalopathy (Severe dysfunction) Neurobehavioral Disorder	--	--	--	--

	(Moderate dysfunction)				
Alcohol	Confirmed (Alcohol Ranks 3 or 4)	--	Confirmed	Confirmed-excessive	Confirmed-excessive

a. The CDC Guidelines only address FAS.
b. 4-Digit Code: Domains may include, but are not limited to: executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention, or activity level. MRI research confirms Neurobehavioral Disorder/Alcohol Exposed is a distinct, clinically meaningful subclassification under the umbrella of FASD [6].
c. Canadian: Impairment indicates scores ≥ 2 SDs below the mean, discrepancies of 1.5-2 SDs among subtests, or ≥ 1 SD discrepancy between subdomains.
d. Hoyme: Marked impairment in the performance of complex tasks (complex problem solving, planning, judgment, abstraction, metacognition, and arithmetic tasks); higher-level receptive and expressive language deficits; and disordered behavior (difficulties in personal manner, emotional lability, motor dysfunction, poor academic performance, and deficient social interaction).
e. IOM: Complex pattern of behavior or cognitive abnormalities that are inconsistent with developmental level and cannot be explained by familial background or environment alone: e.g., learning difficulties; deficits in school performance; poor impulse control; problems in social perception; deficits in higher level receptive and expressive language; poor capacity for abstraction or metacognition; specific deficits in mathematical skills; or problems in memory, attention or judgment.

Table 4. ARBD Diagnostic Criteria: Comparison Across the Five Most Current FASD Diagnostic Guidelines

	4-Digit Code[a] (1997-2004)	CDC[b] (2004)	Canadian[a] (2005)	Revised IOM (2005)	IOM (1996)
Growth	--	--	--	Not specified	Not specified
Face	--	--	--	2 or more of the following: • PFL < 10th percentile • Philtrum Rank 4 or 5 • Lip Rank 4 or 5	Not specified
CNS	--	--	--	Not specified	Not specified

Appendix E— Comparison of Current FASD Diagnostic Systems

Congenital Defects	--	--	--	1 or more of the following: • Cardiac: Atrial septal defects, Ventricular septal defects, Aberrant great vessels, Tetralogy of Fallot. • Skeletal: Hypoplastic nails, Shortened fifth digits, Radioulnar synostosis, Flexion contractures, Camptodactyly, Clinodactyly, Pectus excavatum and carinatum, Klippel-Feil syndrome, Hemivertebrae, Scoliosis. • Renal: Aplastic/dysplastic/hypoplastic kidneys, Horseshoe kidneys, Ureteral duplications, Hydronephrosis. • Ocular: Strabismus, Retinal vascular anomalies, Refractive problems secondary to small globes. • Auditory: Conductive hearing loss, Neurosensory hearing loss. • Other: Virtually every malformation has been described in some patient with FAS.	Congenital structural defects in 1 of the following categories, including malformations and dysplasias (if the patient displays minor anomalies only, 2 must be present): • Cardiac: Atrial septal defects, Ventricular septal defects, Aberrant great vessels, conotruncal heart defects. • Skeletal: Radioulnar synostosis, Vertebral segmentation defects, Large joint contractures, Scoliosis. • Renal: Aplastic/dysplastic/hypoplastic kidneys, "Horseshoe" kidney/ureteral duplications. • Eyes: Strabismus, Ptosis, Retinal vascular anomalies, Optic nerve hypoplasia. • Ears: Conductive hearing loss, Neurosensory hearing loss. • Minor Anomalies: Hypoplastic nails, Short fifth digits, Clinodactyly of fifth fingers, Pectus carinatum/excavatum, Camptodactyly, "Hockey stick" palmar creases, Refractive errors,

	--	--	--	The etiologic specificity of most of these anomalies to alcohol teratogenesis remains uncertain.	"Railroad track" ears.
Alcohol	--	--	--	Confirmed-excessive	Confirmed-excessive

a. The 4-Digit Code and Canadian Guidelines do not recognize ARBD as a FASD diagnostic classification.
b. The CDC Guidelines only address FAS.

Appendix F—Sample Crisis/ Safety Plan

The following is a suggested Crisis/Safety Plan that can be used with a client who has or may have an FASD, or with a family member or caregiver of the client. The plan is designed to help identify safety concerns for the client, actions that can be taken to prevent or address those concerns, and support persons that can assist.

If you have access to an electronic version of this TIP, consider printing this and the following page back-to-back as a way to reproduce the form for your use. This form has been adapted from materials in the *Families Moving Forward Program* (**http://depts.washington.edu/fmffasd/**). Check their Web site for additional resources.

Client Crisis/Safety Plan

Client's Name: _____ Date: _____

Caregiver(s): _____

Legal Guardian(s): _____

Provider/Counselor: _____

1. List the crisis or safety concerns for the client and other family members/ caregivers.

_____

_____

_____

_____

☐ *No crisis or safety concerns were identified. Clients were given appropriate resources. Item #2 below was filled out.*

2. List formal and informal supports. These can be family, friends, respite providers, social workers, community supports such as faith-based organizations (and so on). These are people available to help with crisis/ safety concerns. *(Fill out even if there are no current concerns.)*

_____

_____

_____

3. How can these support people help during a crisis?

Name: _____ Phone: _____

Action: _____

_____

Name: _____ Phone: _____

Action: _____

_____

Name: _____ Phone: _____

Action: _____

_____

Name: _____ Phone: _____

Action: _____

_____

4. Steps for the crisis plan. *(Use if safety concerns are immediate or the situation could get out of hand. Describe what might happen and what you'd do. Include phone numbers of people you would call.)*

_____

_____

_____

IF THERE IS A MEDICAL EMERGENCY, CALL 911.

5. Local Crisis Line number: _____

This is only a suggested action plan. Input from other service providers should be taken into account. This can include therapists, doctors, and emergency services.

This sample Crisis/Safety Plan was developed as part of the *Families Moving Forward Program* and adapted for this TIP with permission of the authors.

Appendix G—Services and Supports Checklist

Counselors can provide invaluable assistance to the family/caregivers of an individual who has or may have an FASD, or to their client with FASD, by helping them access appropriate services and supports. Below is a comprehensive checklist that can help a counselor and client identify what supports are needed, and choose what community resources are realistic as linkages.

If you have access to an electronic version of the TIP, consider printing this and the following page back-to-back to use with clients as an efficient worksheet. This form has been adapted from materials in the *Families Moving Forward Program* (**http://depts.washington.edu/fmffasd**). Check their Web site for more resources.

Services and Supports Checklist

Client's Name: _____ Date: _____

Which of the following would you like to look into?

Material and Financial Assistance and Resources

_____Government/financial assistance (SSI, WIC, etc.)
_____Low-cost housing
_____Adoption funding
_____Developmental disabilities funding

Information and Advocacy Resources

_____Advocacy services
_____Case management services
_____Diagnostic and evaluation services (FASD/non-FASD)
_____Guardian/future planning services
_____Information and referral services
_____Parent/family training, parenting classes
_____Legal services/assistance

Health and Mental Health Resources

_____Health/mental health care financial support
_____Medication evaluation

_____Mental health services
_____Alcohol and drug treatment/recovery programs
_____Family planning/contraceptive resources
_____Substance abuse education for children

Childcare and Respite Resources
_____In-home respite/sitter services
_____Out-of-home respite services
_____Daycare

Crisis Lines and Response Teams
_____Crisis lines/response teams
_____Crisis response teams
_____Child protective services
_____Other crisis resources

Mentor and Support Groups and Resources
_____FASD caregiver/family support groups
_____FASD self-advocacy resources
_____Birth mother network
_____Other types of support groups
_____Sibling support groups
_____Parent-to-parent support (formal and informal)
_____Mentor programs
_____Recreational activities
_____Recovery supports
_____Other support resources

Educational Services and Job Resources
_____Special education and other accommodation programs
_____School-based treatment/therapeutic services
_____Behavior management assistance
_____Tutoring
_____Educational advocacy services
_____Vocational rehabilitation
_____Vocational or job counseling/coaching

Internet and Educational Resources
_____Information on FASD and FASD supports
_____E-mail lists (for? _____)
_____Internet sites (about? _____)
_____Other brochures, books (about? _____)

OTHER
_____Juvenile justice services
_____Representative (or protective) payee services
_____ _____

This checklist was developed as part of the *Families Moving Forward Program*, and is adapted for this TIP with permission of the authors.

Appendix H—Operational Standards for Fetal Alcohol Spectrum Disorders (FASD): A Model

The state of Mississippi has developed operational standards addressing FASD that can potentially help define and inform other state reimbursement systems. The following selected standards are taken from the Mississippi Department of Mental Health's *Operational Standards for Mental Health, Intellectual/ Developmental Disabilities, and Substance Abuse Community Service Providers*, published January 2011.

- **XVI.D.1.** Fetal alcohol spectrum disorders (FASD) is an umbrella term describing the range of effects that can occur in an individual whose mother drank alcohol during pregnancy. These effects may include physical, mental, behavioral, and/or learning disabilities with possible lifelong implications. Behavioral or cognitive problems may include intellectual disability, learning disabilities, attention deficits, hyperactivity, poor impulse control, and social, language, and memory deficits. FASD occurs in about 1% of all live births, or about 450 to 500 new cases in Mississippi per year. The damage caused by prenatal alcohol exposure is permanent. The effects cannot be reversed, but many of them can be treated with the appropriate combination of interventions and support. Secondary disabilities of FASD include mental health issues (90%), school problems (60%), trouble with the law (60%) and attempted suicide (23%). Early identification and diagnosis of children with an FASD can help ensure appropriate treatment which in turn will help reduce the occurrence and impact of these secondary disabilities.
- **XVI.D.2.** Children ages birth to age 18 must be screened within six (6) months of Intake to determine if there is a need for a Fetal Alcohol Spectrum Disorders (FASD) diagnostic evaluation. Youth ages 18 to 24 may be screened for an FASD if the provider has reason to believe that there was prenatal alcohol exposure.
- **XVI.D.3.** The FASD screening tool1 will be provided by the Division of Children and Youth Services (see the DMH Record Guide). The screening may be conducted by a case manager, a therapist, or other children's mental health professional.
- **XVI.D.5.** Results of the FASD screening and FASD diagnostic evaluations, if indicated, must be reflected in the child's Individual Service Plan and/or

Case Management Service 185 Plan. If a child receives a fetal alcohol-related diagnosis, it should be recorded on the appropriate Axis.

- **XVI.D.6.** If a child's initial FASD screening result is negative and if additional information regarding maternal alcohol history is obtained that might change the results of the initial FASD screen from negative to positive for possible prenatal alcohol exposure, the result of the initial screening must be revised on the FASD Screening Form to reflect this change and a diagnostic evaluation must be sought.
- **XVI.D.7.** With consent obtained from the parent/legal guardian, children who receive a positive FASD screen should be referred to the Child Development Clinic at the University of Mississippi Medical Center or other multi-disciplinary children's clinic qualified to diagnose FASD for a diagnostic evaluation. With consent obtained from the parent/legal guardian, best practice requires a provider staff person to accompany the child and parent/guardian to the diagnostic appointment in order to participate in the child's history interview and the informational interview. If this best practice is not followed, the child's record must be documented to show the effort put forth by the staff person to attend the diagnostic appointment and the reason this did not occur. A copy of the full diagnostic report must be placed in the child's record.
- **XVI.D.8.** Treatments and interventions recommended by the FASD multi-disciplinary diagnostic team must be either provided or facilitated by the CMHC. Referral to the local MAP Team should be made when appropriate.
- **XVI.D.9.** Because children with an FASD often are not able to respond to traditional mental health services and/or treatments, children's mental health services may need to be modified in order to be more effective for children with an FASD. FASD services and service modifications must be documented in the child's record.

[1] The FASD screening tool referred to in operational standard **XVI.D.3** is available on pp. 129-131 of the *Department of Mental Health Record Guide for Mental Health, Intellectual and Developmental Disabilities, and Substance Abuse Community Providers, 2012 Revision* (**http://www.dmh.state.ms.us/pdf/DMH%20Record%20Guide%202012%20Revision.pdf**), published by the Mississippi Department of Mental Health. The tool is less extensive than the *FASD 4-Digit Code Caregiver Interview Checklist* included in Part 1, Chapter 2 of this TIP, and is intended primarily for use with children (although it is suggested for limited use with individuals ages 18-24).

Appendix I—Stakeholders Meeting Participants

Sally Anderson, Ph.D.
Special Assistant to Deputy Director, National Institute on Alcohol Abuse and Alcoholism

Jacquelyn Bertrand, Ph.D.
Behavioral Scientist, Centers for Disease Control and Prevention

Sterling K. Clarren, M.D., FAAP
Chief Executive Officer and Scientific Director, Canada NW FASD Research Network; Clinical Professor of Pediatrics, University of British Columbia; Clinical Professor of Pediatrics, University of Washington; TIP Co-Chair

Carolyn Hartness
FASD Project Specialist, Northwest Portland Area Indian Health Board

Lynne Haverkos, M.D., M.P.H.
Medical Officer, National Institute of Child Health and Human Development

John H. McGovern, M.G.A.
Senior Public Health Analyst, Health Resources and Services Administration

Sara Messelt
Executive Director, Minnesota Organization on Fetal Alcohol Syndrome

Kathleen Mitchell, M.H.S., LCADC
Vice President and National Spokesperson, National Organization on Fetal Alcohol Syndrome

Melinda M. Ohlemiller, M.A.
Chief Executive Officer, Nurses for Newborns Foundation; TIP Co-Chair

Feng Zhou, Ph.D.
Past President, FASD Study Group; Professor, Indiana University School Medicine

Center for Substance Abuse Treatment

Sharon Amatetti, M.P.H.
Public Health Analyst, Division of Services Improvement, Center for Substance Abuse Treatment

Christina Currier
Project Officer, CSAT Knowledge Application Program, Division of Services Improvement, Center for Substance Abuse Treatment

Richard T. Kopanda, M.A.
CSAT Deputy Director, Center for Substance Abuse Treatment

Linda White-Young, M.S.W., LC SW
Public Health Advisor, Division of Services Improvement, Center for Substance Abuse Treatment

Center for Substance Abuse Prevention

Jon Dunbar-Cooper, M.A., CPP
Task Order Officer, SAMHSA FASD Center for Excellence, Division of Systems Development, Center for Substance Abuse Prevention

Patricia Getty, Ph.D.
Deputy Task Order Officer, SAMHSA FASD Center for Excellence, Division of Systems Development, Center for Substance Abuse Prevention

CDR Josefine Haynes-Battle, R.N., B.S.N., M.S.N.
Past Deputy Task Order Officer, SAMHSA FASD Center for Excellence, Division of Systems Development, Center for Substance Abuse Prevention

Mike Lowther, M.A.
Acting Deputy Director, Center for Substance Abuse Prevention

Virginia Mackay-Smith, M.P.H.
Director, Division of Systems Development, Center for Substance Abuse Prevention

Center for Mental Health Services

Anna Marsh, Ph.D.
Deputy Director, Center for Mental Health Services

Deborah Stone, Ph.D.
Social Science Analyst, Center for Mental Health Services (Retired)

Appendix J—Field Reviewers

Susan Adubato, Ph.D.
Director, Northern New Jersey FAS Diagnostic Center
Director, New Jersey/North East FASD Education and Research Center, University of Medicine and Dentistry of New Jersey, New Jersey Medical School
Newark, NJ

Sally Anderson, Ph.D.
Special Assistant to Deputy Director
National Institute on Alcohol Abuse and Alcoholism
Rockville, MD

Susan Astley, Ph.D.
Professor of Epidemiology/Pediatrics, University of Washington
Director, WA State FAS Diagnostic & Prevention Network
Seattle, WA

Michael Baldwin, M.N.S.
Alaska Mental Health Trust Authority
Anchorage, AK

Jacqueline Bertrand, Ph.D.
Psychologist
Centers for Disease Control and Prevention
Atlanta, GA

Eileen B. Bisgard, J.D.
Project Director
Seventeenth Judicial FASD Project
Brighton, CO

Anthony Bullock
Hattiesburg, MS

Janet S. Burtt, M.A.
Southern California Alcohol & Drug Programs, Inc.
Downey, CA

Melissa Clarke
Lissie's Luv Yums
Great Falls, MT

Deborah E. Cohen, Ph.D.
Director, Office for Prevention of Mental Retardation and Developmental Disabilities, State of New Jersey (Retired)
Longboat Key, FL

Randolph Crawford
Norman, OK

Leah Davies
TOPDD
Austin, TX

Mary DeJoseph, D.O.
Doctor
New Jersey FASD Education and Research Center
Palmyra, NJ

Thomas Ebert, M.S.S.W., Ph.D.
ARC Community Services, Inc.
Madison, WI

Louise Floyd, R.N., D.S.N.
Team Leader/Behavioral Scientist
Fetal Alcohol Syndrome Prevention Team
National Center for Birth Defects and Developmental Disabilities
Centers for Disease Control and Prevention
Atlanta, GA

Sid Gardner, M.P.A.
President
Children and Family Futures
Irvine, CA

Julie Gelo
Trainer/Consultant/Advocate/Parent
Executive Director, NOFAS Washington
Support Person, Self Advocates with FASD in Action
Bothell, WA

Linda Grant
Evergreen Manor
Everett, WA

Therese Grant, Ph.D.
Ann Streissguth Endowed Professor in Fetal Alcohol Spectrum Disorders Director, Fetal Alcohol and Drug Unit
University of Washington School of Medicine
Seattle, WA

Cecily Hardin, M.S.W.
FASD Project Coordinator
Child Guidance Center
Jacksonville, FL

Patricia A. Harrison, Ph.D.
Research Director
Minneapolis, MN

Trisha Hinson, M.Ed., CMHT
FASD State Coordinator/Project Director
Mississippi Department of Mental Health
Brandon, MS

Sr. Johnelle Howanach
Lissie's Luv Yums
Great Falls, MT

Catherine Hutsell, M.P.H.
Health Education Specialist
FAS Prevention Team
National Center on Birth Defects and Development Disorders
Centers for Disease Control and Prevention
Atlanta, GA

Wendy O. Kalberg, M.A., CED
Senior Program Manager
UNM CASAA
Albuquerque, NM

Judith King, M.S.W., LCSW, LCADC, CPAS
Coordinator, Perinatal Addictions Prevention Project
Hudson Perinatal Consortium, Inc.
Jersey City, NJ

Suzie Kuerschner, M.Ed.
FASD Consultant and Trainer
Northwest Portland Area Indian Health Board
Rhododendron, OR

John H. McGovern, M.G.A.
Senior Public Health Analyst
Health Resources and Services Administration
Rockville, MD

Sara Messelt
Executive Director
Minnesota Organization on FAS (MOFAS)
St. Paul, MN

Violet Mitchell-Enos, M.S.W.
Scottsdale, AZ

Patricia Moran
Program Manager
White Earth Substance Abuse Program
Ponsford, MN

Jeri Museth
Wellness Coordinator, Tribal Family and Youth Services
Central Council of the Tlingit and Haida Indian Tribes of Alaska
Juneau, AK

Raquelle Myers
Santa Rosa, CA

Diane O'Connor
FASD Prevention Initiative, Research Foundation of Mental Hygiene
Support Person, Self Advocates with FASD in Action (SAFA)
Albany, NY

Heather Carmichael Olson, Ph.D.
Department of Psychiatry and Behavioral Sciences
University of Washington School of Medicine and Seattle Children's Research Institute
Seattle, WA

Carol Rangel
FASD Project Director
Division of Health and Human Services
Arkansas Division of Child and Family Services
Little Rock, AR

Jamie Reinebold, M.S.W.
Supervisor, FACES
Memorial Health System
South Bend, IN

Julia Robbins
Institute for Health and Recovery
Cambridge, MA

Paulette Romashko, M.S.W., LCSW
Director of Program Development and Evaluation
FASD Project Director
ARC Community Services, Inc.
Madison, WI

Iris Smith, Ph.D., M.P.H.
Clinical Associate Professor
Department of Behavioral Sciences and Health Education
Rollins School of Public Health
Atlanta, GA

Brenda Stoneburner, M.A., LPC
Communicable Disease Specialist
Michigan Department of Health
Bureau of Substance Abuse and Addiction
Lansing, MI

Sue Taylor, M.S.
Manager Early Childhood Services
Memorial Health System
South Ben, IN

Tracey Waller, M.B.A., RD, LD
Bellbrook, OH

Mary Kate Weber, M.P.H.
Behavioral Scientist
Fetal Alcohol Syndrome Prevention Team
National Center on Birth Defects and Developmental Disabilities
Centers for Disease Control and Prevention
Atlanta, GA

Nancy Whitney, M.S., LMHC
Clinical Director, King County Parent Child Assistant Program
University of Washington
Seattle, WA

Georgiana Wilton, Ph.D.
Associate Scientist, Family Medicine
University of Wisconsin
Madison, WI

Barbara Wybrecht, R.N.
FASD Clinical Nurse Specialist
Advocate/Trainer
Support Person, Self Advocates with FASD in Action
Grand Rapids, MI

Rob Wybrecht
Lifelong Expert on FASD
Arc of Kent County
Network Coordinator, Self Advocates with FASD in Action (SAFA)
Grand Rapids, MI

Appendix K— Acknowledgments

Numerous people contributed to the development of this TIP, including the TIP Consensus Panelists (see pp. ix-x), Stakeholder meeting attendees (see Appendix I) and field reviewers (see Appendix J).

This publication was produced under the Fetal Alcohol Spectrum Disorders (FASD) Center for Excellence contract with the Northrop Grumman Corporation, for the Substance Abuse and Mental Health Services Administration, Center for Substance Abuse Prevention.

Callie B. Gass served as the FASD Center for Excellence Project Director, and Sharon James Ackah, J.D., M.P.H., served as the Deputy Project Director. Other Northrop Grumman-FASD Center for Excellence personnel included Dan Dubovsky, M.S.W., LCSW, Senior FASD Specialist; Vinitha Meyyur, Ph.D., Senior Evaluator and TIP Task Manager; Susan Kimner, Manager for Product Development; Jason P. Merritt, M.A., Senior Writer; Barbara Kosogof, M.P.A., and Katie Chan, Health Research Analysts and Literature Review Authors; Sharon J. Lytle, Quality Assurance Editor; and Jennifer Aggelis, Graphic Designer.

CSAT TIPs and Publications Based on TIPs

What Is a TIP?

Treatment Improvement Protocols (TIPs) are the product of a systematic and innovative process that brings together clinicians, researchers, program managers, policymakers, and other Federal and non-Federal experts to reach consensus on state-of-the-art treatment practices. TIPs are developed by SAMHSA to improve the treatment capabilities of the nation's behavioral health service system.

What Is a Quick Guide?

A Quick Guide clearly and concisely presents the primary information from a TIP in a pocket-sized booklet. Each Quick Guide is divided into sections to help readers quickly locate relevant material. Some contain glossaries of terms or lists of resources. Page numbers from the original TIP are referenced so providers can refer back to the source document for more information.

What Are KAP Keys?

Also based on TIPs, KAP Keys are handy, durable tools. Keys may include assessment or screening instruments, checklists, and summaries of treatment phases. Printed on coated paper, each KAP Keys set is fastened together with a key ring and can be kept within a treatment provider's reach and consulted frequently. The Keys allow you, the busy clinician or program administrator, to locate information easily and to use this information to enhance treatment services.

Ordering Information

Publications may be ordered or downloaded for free at http://store.samhsa.gov/. To order by phone, please call 1-877-SAMHSA-7 (1-877-726-4727) (English and Español).

TWENTY YEARS OF PATIENT SURVEYS CONFIRM A FASD 4-DIGIT-CODE INTERDISCIPLINARY DIAGNOSIS AFFORDED SUBSTANTIAL ACCESS TO INTERVENTIONS THAT MET PATIENTS' NEEDS

Susan J Astley
Professor of Epidemiology and Pediatrics, University of Washington, Seattle WA

ABSTRACT

Background
2013 marks the 40th year since the term fetal alcohol syndrome (FAS) was coined at the University of Washington. In 1993, the University of Washington opened the first interdisciplinary FASD diagnostic clinic; expanded to a statewide network of clinics in 1995 (Washington State FAS Diagnostic & Prevention Network (WA FASDPN)), and introduced a new, rigorous diagnostic system, the fetal alcohol spectrum disorder (FASD) 4-Digit Diagnostic Code in 1997. The WA FASDPN mission is FASD primary and secondary prevention. Evidence of successful primary prevention (fewer alcohol-exposed pregnancies and FAS births) was documented in WA in the 1990s. Secondary prevention (reduction of disability among individuals with prenatal alcohol exposure) starts with accurate diagnoses and access to interventions that meet patients' needs.

Objective
Do patients report an FASD diagnostic evaluation affords them access to interventions that meet their needs?

Methods
Twenty years of follow-up surveys from 622 patients (birth through adult) who received an interdisciplinary FASD diagnostic evaluation at the University of Washington FASDPN using the 4-Digit Code were reviewed.

Results
Patients (99%) expressed high satisfaction in the FASD diagnostic process and outcome. Patients reported success accessing (89%) recommended interventions that met their needs (>96%). Patients with Neurobehavioral-Disorder/Alcohol-Exposed and Static-Encephalopathy/Alcohol-Exposed were as successful accessing interventions that met their needs as patients with FAS/Partial-FAS. Families of patients 0-5 years old reported the greatest access and needs met.

Conclusions
Patient surveys confirm an interdisciplinary diagnosis using the 4-Digit Code affords them substantial access to interventions that meet their needs across the spectrum of FASD diagnoses.

Key Words: *Fetal alcohol spectrum disorder (FASD), Fetal alcohol syndrome (FAS), FASD 4-Digit Diagnostic Code, Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network (WA FASDPN) Intervention*

What is FASD?
Fetal Alcohol Syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The condition is characterized by prenatal and/or postnatal growth deficiency, a unique cluster of minor facial anomalies, and central nervous system (CNS) abnormalities.[1-3] FAS is the leading known preventable cause of intellectual disabilities in the

Western World.[4] The prevalence of FAS is estimated to be 1 to 3 per 1,000 live births[5] in the general population, 10 to 15 per 1,000 in some higher-risk populations such as children residing in foster care[6,7], and 100 per 1,000 in our statewide fetal alcohol spectrum disorder (FASD) diagnostic clinics (the WA FAS Diagnostic & Prevention Network (WA FASDPN)).[8] Not all individuals damaged by prenatal alcohol exposure have FAS; the majority present with moderate to severe CNS abnormalities without the physical features. This full spectrum of adverse outcomes caused by prenatal alcohol exposure is referred to as Fetal Alcohol Spectrum Disorders (FASD). Diagnoses like FAS, Partial FAS (PFAS), Static Encephalopathy/Alcohol Exposed (SE/AE), and Neurobehavioral Disorder/Alcohol Exposed (ND/AE) fall under the umbrella of FASD.[3] The prevalence of SE/AE and ND/AE is 6-fold greater than the prevalence of FAS/PFAS in the population of individuals receiving FASD diagnostic evaluations at our statewide FASD diagnostic clinics (WA FASDPN) over the past 20 years.

The Role of an FASD Diagnostic Clinic in Primary and Secondary FASD Prevention

The year 2013 marks the 40th year since the term FAS was first coined at the University of Washington.[9] The year 2013 also marks the 20th year of the WA FASDPN diagnostic clinics.[8,10] The mission of the WA FASDPN is primary and secondary prevention of FASD through screening, diagnosis, surveillance, intervention, research, and education. In 1992, we postulated that an FASD diagnostic clinic could and should play a central role in FASD prevention; both primary prevention (reduction in prevalence of alcohol consumption during pregnancy and FASD) and secondary prevention (mitigation of disabilities among individuals with FASD). Empirical evidence now exists confirming and illustrating the central role of an FASD clinic in primary prevention of FASD.[6,11,12,7,13] The focus of the current study is the role of a FASD diagnostic clinic in secondary prevention of FASD. Secondary prevention is a level of health care that focuses on early diagnosis, use of referral services, and rapid initiation of treatment to stop the progress of disease processes or a handicapping disability.[14] In this report, the disease process or handicapping disability is FASD. As stated in the 1996 Institute of Medicine Report[5] on FASD "Children with FAS or ARND have impairments that cannot be normalized, but possibly can be improved with appropriate interventions, and they can possibly be made worse when ignored or misunderstood."

Over the past 20 years interdisciplinary FASD diagnostic clinics have opened worldwide.[2] The FASDPN has trained over 100 interdisciplinary teams in over 16 countries.[15,16] An important public health question that remains largely unanswered is "What is the direct benefit of a FASD diagnostic evaluation?" Does an FASD diagnostic evaluation lead to improved patient outcome? An important component of the FASD diagnostic process is to provide patients with a comprehensive set of intervention recommendations specific to their needs.[17-20] These recommendations are collectively generated by the interdisciplinary diagnostic team at the UW FAS DPN.[17] These recommendations include resources, referrals, and strategies that address presenting clinical concerns in areas such as health, behavior, social welfare, and education. The WA FAS DPN diagnostic teams share these intervention recommendations with caregivers at the end of the 4-hour FASD diagnostic evaluation. These recommendations are included in the patient's FASD Medical Summary Report which is submitted to their medical record. A comprehensive summary of the types and frequencies of recommendations provided to patients across all ages and FASD diagnostic classifications is presented by Jirikowic et al.[17]

Study Objectives

Over the past 20 years 2,550 patients have received an FASD diagnostic evaluation at the WA FASDPN by an interdisciplinary team using the FASD 4-Digit Diagnostic Code.[2,8] At the conclusion of their 4-hour evaluation, 78% received a diagnosis broadly under the umbrella of FASD (FAS (4%), PFAS (6%), SE/AE (24%) or ND/AE (44%)) and all received a comprehensive set of intervention recommendations. All families who attend the University of Washington FASDPN clinic receive a Patient Follow-Up Survey (Figure 1) several months after their diagnostic evaluation.

The objective of this study was to evaluate these patient surveys to answer the following questions:

1. Do families report a high level of satisfaction and confidence in the interdisciplinary FASD diagnostic process and outcome?
2. Do families report obtaining information from the FASDPN clinic they were unable to obtain elsewhere?
3. Did they find the 4-Digit Code method of diagnosis easy to understand?
4. Were families able to find/access the intervention services recommended by the clinic?
5. If they were able to access the interventions, did the interventions meet their needs?
6. Were the responses to the above questions influenced by the patient's age, diagnostic classification, or method of diagnosis (gestalt versus 4-Digit Code)?

METHODS

Interdisciplinary FASD Diagnostic Model

When the University of Washington FASD diagnostic clinic first opened in January 1993, it was the first to propose/implement an interdisciplinary approach to diagnosis[21,22] through a CDC-sponsored FAS prevention project conducted in 1992- 97.[11,12] In 1995, State legislative action (Senate Bill 5688) expanded the single clinic to a statewide network of FASD diagnostic clinics; the WA FASDPN, led by the core clinic at the University of Washington (UW). Because of the complexity and broad array of outcomes observed in individuals with prenatal alcohol exposure, an interdisciplinary team was deemed essential for an accurate and comprehensive diagnosis and intervention plan. Our interdisciplinary FASD diagnostic teams include a medical doctor, psychologist, speech language pathologist, occupational therapist, social worker, and family advocate.[2]

The patient population served by the WA FASDPN has always expressed strong preference for an evaluation that can be completed in one visit. Thus, our FASD diagnostic evaluation is conducted in one 4-hour session. In preparation for the evaluation, the patient's birth, medical, school, psychological, and social service records are collected by the clinic coordinator and pre-reviewed by the lead psychologist or social worker. On the day of the evaluation, the lead psychologist or social worker presents the patient's case history, including the outcomes of any prior medical/psychological assessments, to the team in a 30-minute case conference. While the case-conference is being conducted, the patient's growth is measured and facial photograph is taken for computerized analysis.[23] After the case-conference, the pediatrician and lead psychologist or social worker conduct an interview with the caregiver(s) while the child is assessed over a 2-hour period by the second psychologist, speech-language pathologist, and occupational therapist. The child receives a brief physical examination by the pediatrician at the end of their 2-hour assessment. The caregiver interview and child assessment sessions focus on gathering information that is needed to render an accurate diagnosis and are not already present in the child's records. The battery of assessments administered to each patient (both historically and on the day of the diagnostic evaluation) vary by patient age and area(s) of developmental concern. The team reconvenes for 1 hour to derive the FASD 4-Digit Code and generate an intervention plan. The diagnosis and intervention plan are shared with the family in the final 30 minutes of the evaluation. A single, comprehensive FASD Medical Summary Report documenting the diagnostic outcome, all data used to derive the diagnostic outcome, and intervention recommendations are submitted to the patient's medical record.

Intervention Recommendations

An important component of our FASD diagnostic process is to provide patients with a comprehensive set of intervention recommendations specific to their needs.[17,18,20] These intervention recommendations are collectively generated by the interdisciplinary diagnostic team at the completion of the 4-hour FASD diagnostic evaluation. These recommendations include resources, referrals, and strategies that address presenting clinical concerns

in areas such as health, behavior, social welfare, and education. The UW FASDPN has compiled over 200 intervention recommendations in a Microsoft Word template (each assigned a unique key code) that allows for rapid construction of individualized intervention plans by the interdisciplinary team during the course of the 4-hour diagnostic evaluation. These intervention recommendations are shared with caregivers at the end of the 4-hour diagnostic evaluation and are included in the patient's FASD Medical Summary Report that is submitted to their medical record.

A recent study published by members of the UW FASDPN diagnostic team[17] summarized the type and frequency of intervention recommendations provided to patients receiving diagnoses under the spectrum of FASD at the UW FASDPN diagnostic clinic. The focus of the study was to assess how recommendations varied by FASD diagnostic groups and selected sociodemographic characteristics (e.g., age, gender, and caregiver status). In preparation for the study, a coding system was developed to categorize the 200+ intervention recommendations into 12 sub-categories as presented in Table 1 and described more fully by Jirkowic et al.[17] Findings reported by Jirikowic et al[17] indicated that children with FASD, like children with other neurodevelopmental disabilities, have a wide range of complex and specialized needs that span across systems of care. Although FAS has historically been considered among the most severe outcomes of prenatal alcohol exposure, these data show that similar intervention recommendations and needs were seen for children across the full spectrum of diagnoses under the umbrella of FASD.

Starting in 2007, all patients evaluated in the UW FASDPN clinic have had their intervention recommendations coded in accordance with the system described above and entered into the FASDPN clinical/research database described below.

TABLE 1 Intervention recommendation categories and examples[17] (Figure 4)

Category	Examples
Family Support–Resources: Referral/ recommendations for educational materials (e.g., books, Web sites) community support groups, advocacy training, or caregiver education or support.	1. Books, Web-based resources (e.g., attachment, sleep, FASD). 2. Personal/peer support (e.g., National Organization or Fetal Alcohol Syndrome [NOFAS], grandparent support group). 3. Advocacy/education (e.g., parent advocacy group, parent education, community training). 4. Respite/self-care for caregiver.
Medical: Recommendation/referral to medical specialist or current provider for evaluation or follow-up care regarding a specific medical problem or issue.	1. Psychiatric services and/or medication management/consultation. 2. ADHD evaluation 3. Sleep evaluation 4. Vision/hearing evaluation 5. Growth 6. Neurological evaluation/consultation 7. Genetic work up or consultation
Anticipatory Guidance / Prevention: Prevention oriented recommendations based on developmental risk factors for future problems.	1. Substance abuse prevention 2. Learning problems/behavior risks (awareness of potential for school/learning difficulties and/or mental health problems). 3. Reproductive health (e.g., pregnancy and STD prevention).
Social service / Child Welfare: Resources/support for children in out of home placements, including caregiver support and funding resources.	1. Placement advocacy (e.g., stable, safe, structured, supportive home environment; movement towards long-term permanency). 2. Caregiver resources to support appropriate placements and long-term needs (e.g., adoption support, supplemental security income eligibility, family support program).

The value of a FASD diagnosis (2013)

Developmental Therapy: Referral/recommendation for occupational therapy, physical therapy, speech-language therapy, or specific therapeutic program.	1. Referral to OT 2. Referral to SLP 3. Referral to a social skills group. 4. Referral to another therapeutic program.
Education/Assessment: Referral, advocacy, or support for a specific educational program or service, psycho-educational assessment, or specific skill area that requires educational monitoring.	1. Referral/support for educational service (e.g., special education, life skills training, birth to 3 year program). 2. Monitor a specific area of performance (e.g., fine motor, language). 3. Psychoeducational–neuropsychological assessment to determine special education eligibility, re-examine individual education plan or advocate for continued eligibility.
Community-based Activities: Leisure or recreation recommendations for specific, community-based activities/programs that are prosocial, recreational, extracurricular in nature and include appropriate developmental and social supports.	1. Prosocial extracurricular/play activities (e.g., Boys and Girls Club; community social skills groups). 2. Physical/movement (e.g., noncompetitive sports; therapeutic horseback riding; Special Olympics). 3. Special interest groups (e.g., focused leisure, religious, or cultural activities). 4. Adult mentor (e.g., Big Brother/Big Sister).
Safety Awareness: Recommendations/resources to address home, school, or community safety concerns.	1. Personal ID/safety (e.g., ID bracelet, wallet card). 2. Environmental modification/supervision (e.g., alarms, line-of-sight supervision).
Mental health: Support/referral for mental health services to address individual and/or family needs around behavior, development, or mental health problem.	1. Behavioral consultation or specialist (e.g., behavior management, home-based intervention services). 2. Individual counseling 3. Family counseling 4. Case management
Adult Transition / Future Planning:	1. Vocational 2. Financial 3. Other future plan.
Accommodations: Specific adaptation or modification to environment/routine to be implemented in home, school, or other setting.	1. Behavior/emotional regulation (e.g., supports for group participation, enhancing environmental structure). 2. Communication (e.g., visual schedules, cues for social interaction). 3. Executive function, organization, memory (e.g., memory aids, checklists). 4. Sensory–motor (e.g., headphones, reducing sensory input, keyboarding). 5. Team communication (e.g., communication between home, school, and other providers).
Developmental Therapy: Referral/recommendation for occupational therapy, physical therapy, speech–language therapy, or specific therapeutic program.	1. Referral/recommendation for occupational, physical, or speech language therapy evaluation or treatment. 2. Referral to a therapeutic social skills group.
Other	1. Substance abuse recommendations supporting treatment or recovery (caregiver or patient). 2. FASD re-evaluation

Patient Follow-Up Survey

A 10-question patient follow-up survey (Figure 1) has been sent to all patients evaluated at the University of Washington FASDPN clinic since 1993. The survey is mailed approximately 3 months after the patient's FASD diagnostic evaluation and comes with a stamped, addressed return envelope to maximize participation. The family may elect to submit the survey anonymously, or they can choose to enter the patient's name on the survey. The survey queries the patient's satisfaction with the diagnostic

process; their confidence in the outcome; how successful they were at finding and accessing the interventions the diagnostic team recommended; and to what extent the interventions met their needs.

Please circle or check the most appropriate response. Additional comments are welcome. Your opinion is important to us.

1. **Patient's age.** __infant-2 years __3-5 years __6-12 years __13-18 years __19 or more years old
2. **Was the explanation of the patient's evaluation:**
   a. Easy to understand
   b. Somewhat complicated to understand
   c. Too complicated to understand
3. **How much confidence do you have in the results of the evaluation?**
   a. A lot of confidence
   b. Some confidence
   c. Very little confidence
   d. No confidence at all
4. **Did we provide you with information that you needed and were unable to get elsewhere?**
   a. Yes
   b. No
   c. Uncertain
5. **Did you feel your visit:**
   a. Took an appropriate amount of time
   b. Was too short
   c. Was too long
6. **When you left Clinic, we recommended that you contact certain people and services to help you. How successful were you at finding these people and services?**
   If you could not find the help, please explain why.
   a. Very successful
   b. Somewhat successful
   c. Had very little success
   d. Had no success at all
7. **If you were able to find the people and services we recommended to you, were they able to meet your needs?**
   If they did not meet your needs, explain why.
   a. Yes, they met all my needs.
   b. Yes, they met some of my needs.
   c. No, they met none of my needs.
   d. I was not able to find the people and services.
8. **Would you have liked the FAS Clinic to provide more help in finding community follow-up services or treatment?**
   If yes, please tell us how we could have helped.
   a. Yes
   b. No
9. **Do you have any suggestions for improving the services we provide?**
10. **Would you recommend the FAS Clinic to other families with similar needs?**
    a. Yes
    b. No

Thank you

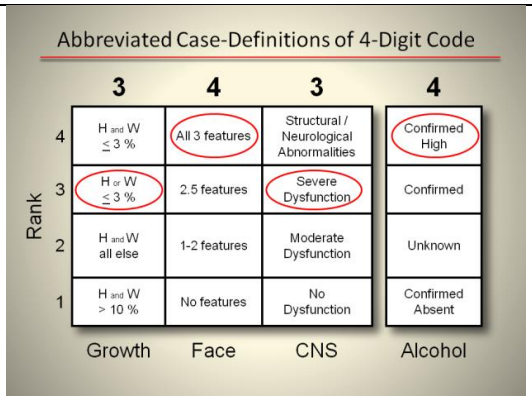
FIG. 1 Patient Follow-up Survey mailed to all patients approximately three months after their FASD diagnostic evaluation at the University of Washington FAS Diagnostic & Prevention Network clinic.

FASD Diagnostic Systems Used

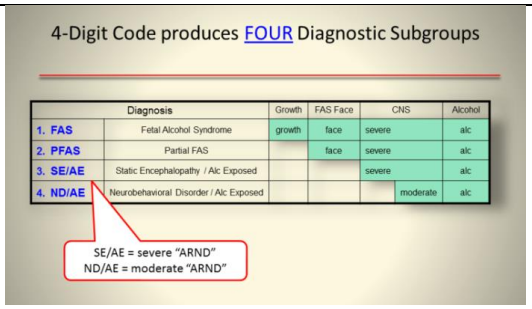
When the University of Washington FASD diagnostic clinic first opened in January 1993, the interdisciplinary team used the most current FASD diagnostic guidelines available at that time; the 1989 gestalt diagnostic criteria published by Sokol and Clarren.[24] In 1996, the Institute of Medicine (IOM) published an updated set of FASD diagnostic guidelines[5], but continued to propose a gestalt approach. The gestalt approach to diagnosis presented with many limitations.[2,10,25] The UW FASDPN created the 4-Digit Code in 1997 to overcome these limitations.[26] Thus, from 1993 through 1996, patients experienced an interdisciplinary team using a gestalt[24] approach to diagnosis. Only two FASD diagnostic classifications were rendered back then; FAS and Probable fetal alcohol effects (PFAE). PFAE was equivalent to what the IOM now calls ARND.[5] In 1997, the WA FASDPN interdisciplinary teams started using the FASD 4-Digit Diagnostic Code.[3,25] Diagnostic classifications include FAS, PFAS, SE/AE and ND/AE, as explained more fully below.

In 1997 the FASDPN switched from the gestalt[24] method of diagnosis to the FASD 4-Digit Diagnostic Code.[3,25,26] Briefly, the 4 digits of the FASD 4-Digit Code reflect the magnitude of

expression of the 4 key diagnostic features of FASD, in the following order: 1. Growth deficiency, 2. FAS facial phenotype, 3. CNS structural/functional abnormalities, and 4. Prenatal alcohol exposure (Figure 2A). The magnitude of expression of each feature is ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong "classic" presence of the FASD feature. Each Likert rank is specifically case defined. There are a total of 102 4-Digit Codes that fall broadly under the umbrella of FASD (Table 2). These codes cluster under four clinically meaningful FASD diagnostic subcategories: fetal alcohol syndrome (FAS): Diagnostic Categories A and B; Partial FAS (PFAS): Diagnostic Category C; Static Encephalopathy/Alcohol-Exposed (SE/AE): Diagnostic Categories E and F; and Neurobehavioral Disorder/Alcohol-Exposed (ND/AE): Diagnostic Categories G and H (Figure 2B). The attributes of the 4-Digit Code are summarized in Astley.[10]



A



B

FIG. 2 A. Abbreviated case-definitions of the FASD 4-Digit Code.[3] The 4-Digit Code 3434 is one of 12 Codes that fall under the diagnostic category FAS/Alcohol-Exposed (Table 2). **B**. The FASD 4-Digit Code diagnostic system produces four diagnostic subgroups under the umbrella of FASD: FAS, PFAS, SE/AE, and ND/AE.[2,8,10] The 4-Digit Code does not use the term Alcohol Related Neurodevelopmental Disorder (ARND). The terms SE/AE and ND/AE are used in place of the term ARND.

WA FASDPN Clinical/Research Database

All data collected by the WA FASDPN clinics since 1993 has been entered into an electronic clinical/research database with patient consent and Human Subjects Review Board approval.[2,10] To date, there are over 2,000 fields of information entered on over 7,000 patients requesting an evaluation and 2,550 patients who have received an evaluation to date. The majority of the data entered into the database comes from the following standardized data forms: 1) the New Patient Information Form; 2) the FASD Diagnostic Form; 3) the FAS Facial Photographic Analysis Software Report; 4) the Medical Summary that includes the Intervention Recommendations; and 5) the Patient Follow-Up

Surveys. These forms are provided in the Diagnostic Guide for FASD[3] and/or are posted on the WA FASDPN website **(www.fasdpn.org)**.

Clinical Population and Study Groups

The clinical population from which the study population was drawn is all patients (n = 2, 550) who received an interdisciplinary FASD diagnostic evaluation throughout the 20 year history of the WA FASDPN. The WA FASDPN consists of a core clinic at the University of Washington and 7 Network FASD diagnostic clinics statewide.

Of the 2,550 patients evaluated at the WA FASDPN from 1993 through 2012, 1,545 (61%) were evaluated at the University of Washington clinic. All 1,545 patients evaluated at the University of Washington clinic received patient follow-up surveys 3 months after their FASD diagnostic evaluation. Of the 1,545 patients who received surveys, 622 (40%) completed and returned the surveys. These 622 patients are the focus of this study and were divided into the following study groups to facilitate the analysis/interpretation of their survey outcomes:

The 622 patients who returned patient follow-up surveys were divided into two groups (A & B) based on the FASD diagnostic method used for their evaluation.

A. Gestalt Diagnostic Method (N = 227):

All patients evaluated from 1993 through 1996 were evaluated by the UW interdisciplinary team using a gestalt[24] method of FASD diagnosis.

Twenty-one percent of this group received a gestalt diagnosis of FAS and 60% received a diagnosis of PFAE. Group A was not further divided into the gestalt diagnostic subgroups (like Group B below) because a previous study[25,27] confirmed this gestalt approach to diagnosis led to highly variable and inaccurate diagnostic classifications. Astley[25] confirmed that 75% of the gestalt FAS diagnoses were ruled out when the individual's outcomes are retrofitted to the more rigorous criteria of the 4-Digit Code.

B. FASD 4-Digit Diagnostic Code (N = 395):

All patients evaluated from 1997 through 2012 were evaluated by an interdisciplinary team using the FASD 4-Digit Diagnostic Code.[3,25]

All patients in Group B were further subdivided into six groups based on their 4-Digit Code diagnostic outcomes. Groups B1-4 fall broadly under the umbrella of FASD. The diagnostic features specific to each group were as follows:

1. *Patients in Group B1* had a 4-Digit diagnosis of **FAS or Partial FAS (FAS/PFAS)** (e.g., 4- Digit Diagnostic Categories A,B,C: with Growth Ranks 1-4, Face Ranks 3-4, CNS Ranks 3 and/or 4, Alcohol Ranks 2-4)[3] (Figure 2). Alcohol Rank 2 (unknown exposure) could only be present if the patient had a diagnosis of full FAS because the Rank 4 FAS facial features are so specific to prenatal alcohol exposure.[6,10,28-32] In summary, patients in Group 1 had severe CNS structural and/or functional abnormalities and the full FAS facial phenotype.

2. *Patients in Group B2* had a 4-Digit diagnosis of **Static Encephalopathy / Alcohol-Exposed (SE/AE)** (e.g., 4-Digit Diagnostic Categories E,F: with Growth Ranks 1-4, Face Ranks 1-2, CNS Ranks 3 and/or 4, Alcohol Ranks 3-4).[3] In summary, patients in Group 2 had severe cognitive/behavioral dysfunction, comparable to Group 1, but did not have the FAS facial phenotype.

3. *Patients in Group B3* had a 4-Digit diagnosis of **Neurobehavioral Disorder / Alcohol-Exposed (ND/AE)** (e.g. 4-Digit Diagnostic Categories G, H: with Growth Ranks 1-4, Face Ranks 1-2, CNS Rank 2, Alcohol Ranks 3-4).[3] In summary, patients in Group 3 had prenatal alcohol exposure comparable to Groups 1 and 2, but in comparison to Groups 1 and 2 had moderate cognitive/behavioral dysfunction, and did not have the FAS facial phenotype.

4. *Patients in Group B4* had a 4-Digit diagnosis of Sentinel Physical Findings/Alcohol-Exposed or No Physical Findings or CNS Abnormalities Detected / Alcohol-Exposed **(Normal CNS/AE**) (e.g., 4-Digit Diagnostic

Categories I and J: with Growth Ranks 1-4, Face Ranks 1-4, CNS Rank 1, and Alcohol Ranks 3-4).[3] In summary, patients in Group 4 had prenatal alcohol exposure, no CNS abnormalities, and may or may not have had growth deficiency and/or FAS facial features.

5. *Patients in Group B5* do not qualify for a diagnosis under the umbrella of FASD because their prenatal alcohol exposure is unknown or confirmed absent (**Not FASD**) (e.g., 4-Digit Diagnostic Categories D, K-V).[3] In summary, patients in Group 5 may have growth, facial, and/or CNS outcomes that span the full continuum from normal to abnormal, but in the absence of prenatal alcohol exposure, their outcomes cannot be attributed to prenatal alcohol exposure. Although patients are required to have a confirmed prenatal alcohol exposure to obtain an evaluation in the UW FASDPN clinic, this subset of patients had their exposure status reclassified to unknown (Rank 2) at the time of diagnosis when further information about their exposure status became available.

6. *Patients in Group B6* submitted Patient Follow-up Surveys anonymously, thus their identity and **Diagnostic Classification** are **unknown**. Patients in this group may span the full continuum of diagnostic classifications described for Groups B1-5.

Data Analysis

This study is primarily descriptive in nature. Outcomes are summarized using means, standard deviations, and proportions (valid percentages). Chi-square statistics were used, when appropriate, to compare proportions between two or more groups. Two-tailed p-values were used with a significance level set a $p < 0.05$.

RESULTS

Clinical and Sociodemographic Profile of the WA FASDPN Patient Population

The clinical and sociodemographic profile of all 2,550 patients who received an interdisciplinary FASD diagnostic evaluation at one of the WA State WA FASDPN clinics from 1993 through 2012 is presented in Table 3. This clinical population spans the entire age range (birth to 6 yrs (33%); 6-18 yrs (62%), adults (5%)). The vast majority (76%) were in out-of-home placement at the time of their diagnostic evaluation.

Of the 2,550 WA State FASDPN patients, 1,545 (60.6%) were evaluated at the core University of Washington (UW) FASDPN clinic in Seattle, WA. These are the 1,545 patients who were mailed Follow-up Surveys over the past 20 years and are the focus of this study. This subset of 1,545 patients is highly representative of the entire WA FASDPN population. Their diagnostic profile and age distribution are near identical (within a percentage point) to the diagnostic profile and age distribution of patients evaluated across the entire WA FASDPN presented in Table 3.

The value of a FASD diagnosis (2013)

* 1) FAS/PFAS: fetal alcohol syndrome or partial FAS (4-Digit Diagnostic Categories A-C). 2) SE/AE: Static Encephalopathy/Alcohol-Exposed (4-Digit Diagnostic Categories E,F). 3) ND/AE: Neurodevelopmental Disorder/Alcohol-Exposed (4-Digit Diagnostic Categories G,H). 4) Normal CNS/AE; No Central Nervous System abnormalities/Alcohol-Exposed (4-Digit Diagnostic Categories I,J). 5) Not FASD-alcohol exposure unknown or absent (4-Digit Diagnostic Categories D,K-,V)[3].

Patient Follow-Up Surveys

Of the 1,545 Patient Follow-Up Surveys mailed out between 1993 and 2012 to patients evaluated at the UW FASDPN, 622 were completed and returned reflecting a 40% response rate. Although families were given the option to return the survey anonymously, 85% (n=527) chose to identify the name of the patient. This allowed us to connect their responses to the patient's diagnostic outcome. The 622 completed surveys are distributed equally across the 20 years (1993-2012) and reflect a patient population that is near identical to (highly representative of) the FASD diagnostic profile and age distribution of the larger patient populations from which they were pulled (the entire WA FASDPN population (n=2,550), and the subset of 1,545 from the UW FASDPN) (Tables 4 and 5). Of the 622 surveys, 277 (36%) were from patients receiving a gestalt diagnostic evaluation and 395 (64%) were from patients receiving a diagnostic evaluation using the 4-Digit Code.

Family Report of Satisfaction and Confidence

Families (n=395) reported high levels of satisfaction and confidence in the 4-Digit Code administered by the University of Washington interdisciplinary diagnostic team.[26] (Table 4).

Ninety-nine percent would recommend the Clinic to other families with similar needs. Ninety-two percent said they received information they were unable to obtain elsewhere. Eighty-three percent found the explanation of the diagnostic evaluation outcome easy to understand. Ninety-eight percent expressed confidence in the results of the evaluation. Ninety-one percent felt the single 4-hour evaluation was an appropriate length of time for the evaluation.

Measures of satisfaction and confidence were comparably high across all diagnostic sub-classifications (Tables 4, 5, Figure 3), but varied somewhat across age groups (Table 6, 7). The adult patients who returned surveys (18 individuals 19 years of age or older) were less likely to report the explanation of the diagnostic evaluation was easy to understand (53% of adults reported it was easy to understand versus 84% across all younger groups). When adults are evaluated in clinic, the results are shared back directly with the adult patient. In contrast, when children are evaluated, the results are shared with their caregiver(s). Since all 18 adult patients had moderate to severe CNS dysfunction, it is understandable why they might report it was somewhat more difficult to understand the results.

4-Digit Code Patient Follow-Up Surveys	FAS/PFAS %	SE/AE %	ND/AE %
Easy to understand	84	80	86
Confident in diagnosis	98	99	100
Provided information not received elsewhere	98	91	89
Successful at finding/accessing recommended services	90	93	90
Services met some to all of my needs	97	96	96
Would recommend clinic to other families with similar needs	100	100	100

FIG. 3 Patient follow-up surveys (n = 395) confirm families have a very high level of satisfaction and confidence in the 4-Digit Code administered by the University of Washington interdisciplinary diagnostic team. Family's whose child received a diagnosis of SE/AE or ND/AE were as likely to report successfully accessing recommended intervention services that met their needs as family's whose child received a diagnosis of FAS or FAS.

The value of a FASD diagnosis (2013)

Family Report of Access to Interventions and Needs Met by Interventions

Family's whose child received a 4-Digit Code diagnosis of SE/AE or ND/AE were as likely to report successfully accessing recommended interventions and having their needs met by the interventions as family's whose child received a diagnosis of FAS or PFAS (Table 5, Figure 3). Overall, 89% of families reported being somewhat to very successful in finding/accessing the recommended intervention services and 96% of those who found the services reported the services met some to all of their needs (Table 5). Access to interventions and having one's needs met by the interventions did not differ by diagnosis, but did differ by age (Table 7). Families of patients over 18 years of age reported less success finding and accessing recommended services and were less likely to report the interventions met their needs. A family's desire to receive more help from the Clinic to find services increased with increasing patient age.

Gestalt versus 4-Digit Code Method of Diagnosis

Among the 622 patients who returned their follow-up surveys, 227 (35%) were from patients who were diagnosed between 1993-1996 with the gestalt method of diagnosis and 395 (64%) were diagnosed between 1997 and 2012 with the 4-Digit Diagnostic Code. The survey outcomes for these two groups of patients are presented in Tables 8 and 9. Patients receiving a gestalt diagnostic evaluation were significantly less likely to report: 1) confidence in the outcome; 2) success in finding/accessing recommended intervention services, and 3) having their needs met by the services they accessed. The patient population evaluated from 1993-96, when the gestalt[24] method of diagnosis was in use, was slightly older than the patient population evaluated from 1997-2012, when the 4-Digit Code[3] method of diagnosis was used.

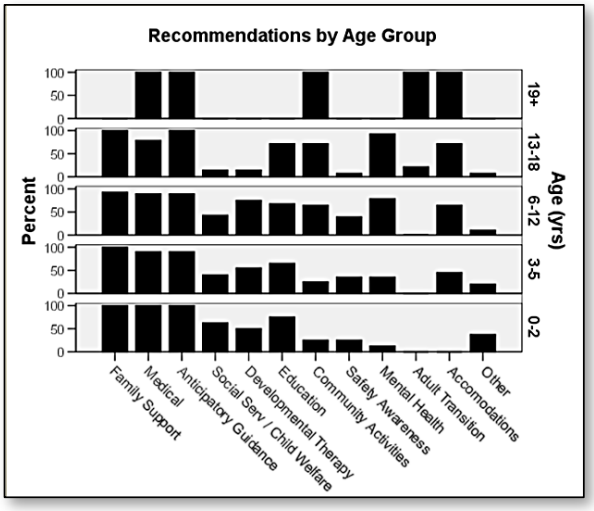
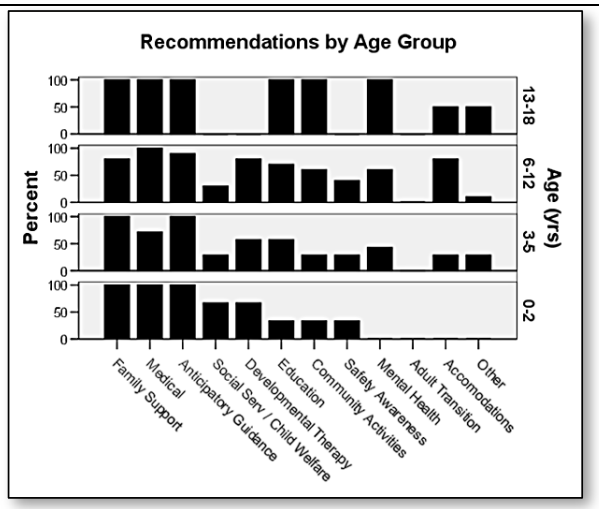
Profile of Intervention Recommendations by Age Group among Patients Diagnosed with the 4-Digit Code

Intervention recommendation profiles by age group are presented for two subsets of patients evaluated at the UW FASDPN clinic using the 4-Digit Code. Figure 4A illustrates the intervention profile for a representative sample of 170 of the 364 patients who had their interventions coded since 2007, when coding of interventions commenced at the UW FASDPN clinic. Figure 4B illustrates the intervention profile for the subset of 61 patients who returned Patient Follow-up Surveys. Both groups of patients have FASD diagnostic profiles that are comparable to (representative of) the larger population of all 395 patients diagnosed with the 4-Digit Code from which they were drawn. The diagnostic profile for the 170 patients in Figure 4A is: FAS/PFAS 15.2%, SE/AE 13.6%, ND/AE 53.0%, Normal CNS/AE 7.6%, Unknown 10.6%. The diagnostic profile for the 61 patients in Figure 4B is: FASPFAS 13.1%, SEAE 14.8, ndae 52.5, normAE 8.2%, Unknown 11.5%. These intervention profiles help put the Patient Follow-Up Surveys in perspective. When the patients were queried regarding their success at finding, accessing, and having their needs met by the interventions we recommended, the types of interventions they were pursuing are presented in Figure 4.



A



B

FIG. 4 Intevention recommendation profiles for two groups of patients who received FASD diagnostic evaluations at the Univeristy of Washington FASDPN clinic from 2007 to 2012 using the 4-Digit Code are presented. The bars represent the proportion of patients receiving each type of intervention by age group at the time of their diagnostic evaluation. **A**) Profile of intervention recommendations provided to a representative sample of 170 of the 364 patients evaluted from 2007 through 2012. **B**) Intervention profile for the 61 patients, from among the group of 170, who returned Patient Follow-up Surveys. The larger sample in Figure 4A demonstrates the profile among the subset of 61 who returned Patient Surveys is reflective of the larger population from which they were sampled. The twelve intervention subclassifications[17] are described in Table 1.

DISCUSSION

Patient follow-up surveys over 20 years illustrated the value of an interdisciplinary FASD diagnostic evaluation from an important perspective; the patient's perspective. Families (98%) expressed confidence in the interdisciplinary approach to diagnosis using the FASD 4-Digit Code with essentially all (99.5%) reporting they would recommend the diagnostic service to other families. The vast majority of families (89%) reported they were somewhat to very successful in finding/accessing the recommended intervention services and 96% of those who accessed the services reported the services met some to all of their needs. Patient reports that the recommended interventions "met some to all of their needs" is powerful qualitative evidence of intervention effectiveness and compliments the growing empirical, quantitative evidence-base on FASD intervention effectiveness.[33,34] It is important to clarify that patient outcomes over time were not directly measured in this study. When families/patients reported the interventions met some to all of their needs, the surveys did not document which specific needs were met. The intervention recommendations for each patient spanned the full continuum from services that directly addressed the patient's disabilities to services that provided caregivers with advocacy training, education, resources, even respite care (Table 1). Thus, when families report their needs were met, this is certainly a positive outcome and reflects just one of many ways to assess intervention effectiveness, but does not replace the need for more direct, empirical assessments of improved patient outcome.

The results of this study document a FASD diagnostic evaluation helped break down some of the treatment barriers and unmet needs often reported by caregivers.[35-38] Families report that these unmet needs are one of the primary reasons they are seeking an evaluation in our clinic. They typically report having received evaluations and services from a large array of providers prior to attending our clinic. Nevertheless, 92% report we provided them with information they were unable to obtain elsewhere despite the fact the clinic is located in a large metropolitan area (Seattle) with many genetic, neurodevelopmental, and psychological evaluation services available. This single 4-hour interdisciplinary evaluation appears to provide more information and access to services than the multitude of uncoordinated services the families reported accessing prior to coming to our clinic. The potential cost savings of this more efficient and more effective interdisciplinary approach to meeting these family's complex needs is enormous and will be the focus of a separate report.

Patients with Neurobehavioral Disorder/Alcohol-Exposed (ND/AE) and Static Encephalopathy/Alcohol-Exposed (SE/AE) were as successful accessing interventions that met their needs as patients with FAS or PFAS. This is in contrast to the oft stated belief that a patient will not qualify for services if the diagnosis is not FAS, PFAS or at least given a name that implies alcohol is the causal agent (e.g., Alcohol-Related Neurodevelopmental Disorder (ARND)). The FASD 4-Digit Code does not use the term Alcohol-Related Neurodevelopmental Disorder because one cannot confirm an individual's neurodevelopmental disorder is related to their prenatal alcohol exposure in the absence of the FAS facial phenotype. This study demonstrated that the diagnostic labels SE/AE and ND/AE were as effective as FAS and PFAS in providing access to intervention services. This is encouraging since individuals should qualify for services based on their disability, not on what caused their disability.

Several factors likely contributed to our patients' success in finding and accessing the recommended interventions. Access to services requires more than a diagnostic label. The diagnostic labels FAS, PFAS, SE/AE and ND/AE reveal the magnitude of disability, but do not reveal the individual's specific pattern of disability. No two individuals on the spectrum of FASD necessarily present with the same pattern of disability[8,39], and their unique pattern of disability manifests differently over their lifetime. For this reason, the most important component of the FASD interdisciplinary diagnostic evaluation is a current, comprehensive developmental /neuropsychological assessment. The outcomes of

this assessment not only help derive the diagnostic classification, but provide the core information that ultimately drives the intervention plan and qualifies an individual for services.

For a patient to derive the greatest benefit from their FASD diagnostic evaluation, they need an interdisciplinary team that can: 1) render an accurate diagnosis under the umbrella of FASD; 2) generate a comprehensive intervention plan tailored to their specific needs and circumstances; and 3) present all of this in a comprehensive medical summary report that effectively informs and educates the family and their community service providers. Over the last 20 years, the UW FASDPN interdisciplinary team has gained considerable expertise and experience in meeting the needs of this patient population. Most of the clinicians have served on the team for more than 10 years, with several having served the entire 20 years. Two factors that have contributed tremendously to the team's ability to work efficiently and effectively include: 1) their creation of an up-to-date, comprehensive list of over 200 intervention recommendations key-coded into an Intervention Plan template and 2) their creation of the FASD Medical Summary Report template. Both Microsoft Word templates are available to clinicians at no cost through the WA FASDPN. The Intervention Plan template allows the team to construct a detailed, customized list of interventions that not only meet the patient's needs, but are known to be available in the patient's community, and are likely to be financially accessible to the patient. The intervention plan spans the full continuum of patient and caregiver needs from medical, educational, placement, social service, even caregiver respite.[17] The intervention plan is printed and handed to the family at the conclusion of their 4-hour appointment. The FASD Medical Summary Report is a single, comprehensive, interdisciplinary report composed by the interdisciplinary team members. During the 4-hour appointment, team members sit at one of several computer stations, log into their report template and compose a brief report summarizing which assessments they administered, the outcomes of the assessments, and their interpretation of the outcomes. Each of these electronic reports is collected at the end of the 4-hour evaluation and inserted into the FASD Medical Summary Report template by the clinic coordinator. The FASD Medical Summary Report is complete within one hour following the 4-hour evaluation. The Intervention Plan is merged with the Medical Summary report and submitted to the patient's medical record and mailed to the patient's legal guardian within one week of their diagnostic evaluation.

The FASD Medical Summary Report is designed to both educate and inform the patient and their care providers. The content and format of this report is vital to a patient's success in accessing intervention services. A medical summary that conveys a rigorous diagnostic process and includes the assessment outcomes that ultimately drove the intervention recommendations will go far to earn the respect of the professional community. Our FASD Medical Summary Report: 1) outlines the interdisciplinary process used to derive the diagnosis, 2) describes how the 4-Digit Code measures the magnitude of impairment across the four components that characterize FASD (growth deficiency, FAS facial phenotype, CNS abnormalities, and prenatal alcohol exposure), 3) presents the patient's outcomes in each of these four areas, 4) provides a diagnostic classification with brief description, and 5) concludes with a comprehensive intervention plan. In the words of one caregiver of a 10 year old who received a diagnosis of SE/AE "*I cannot say enough good things about your services. A proper diagnosis has resulted in: change of school placement, OT/PT services provided by the school district, a referral to mental health in hopes of finding a therapist w/background in neurodevelopmental problems and patient's psychiatrist reducing his medications*".

Families of patients who were birth to 5 years of age at the time of diagnosis reported the greatest access to recommended interventions that met their needs. The WA FASDPN clinics have been accurately and effectively diagnosing individuals across the entire age span for 20 years. The youngest and oldest patients to date were 2 days old and 53 years old, respectively. One third of the WA FASDPN patient population is birth to

5.9 years of age at the time of diagnosis.[8] Their outcomes span the full continuum of FASD diagnoses. Of the 760 patients (birth to 5.9 years of age) with confirmed prenatal alcohol exposures evaluated in the first 20 years, 13% were diagnosed with FAS/PFAS; 19% with SE/AE, 51% with ND/AE; and 18% with No CNS Abnormalities/AE. Not only is an accurate FASD diagnostic evaluation possible in this young age group, but according to this study, highly beneficial. This is the age group with the greatest access to services and the greatest potential to benefit from the services.[18] This is also the age group that can lead to the most successful primary prevention efforts by reaching out to their birth mothers early in their reproductive history to prevent alcohol exposure in subsequent births.[11,12] Adult patients (19 years of age or older) reported less success (71%) finding and accessing recommended interventions relative to younger age groups (90%). Adults were also less likely (77%) to report the services met their needs compared to the younger age groups (98%). Reports of less access to and benefit from intervention services are reflective of the paucity of services available to adults with disabilities. The primary reason adult patients report seeking an FASD evaluation is the hope that the outcome will qualify them for Supplemental Security Income (SSI) or developmental disabilities assistance. Qualification for these forms of assistance in WA State is based in large part on FSIQ and adaptive behavior performance more than 2 standard deviations below the mean. Most of the adults receiving a diagnosis under the umbrella of FASD, including full FAS, do not present with FSIQs below 70. We are working with our State policy makers to address this issue.

CONCLUSION

Patient surveys over 20 years confirm an interdisciplinary diagnosis using the FASD 4-Digit Diagnostic Code provides substantial access to interventions that meet patients' needs across the full spectrum of FASD diagnoses. This is powerful evidence of the value of an FASD diagnostic evaluation.

Acknowledgments

The WA FASDPN has been supported over the past two decades by the following organizations: Centers for Disease Control and Prevention (1992-1997); Western Washington Chapter of the National March of Dimes Birth Defects Foundation (1995); Washington State Department of Social and Health Services, Division of Alcohol and Substance Abuse through the passage of Senate Bill SB5688 (1997-present); and the Chavez Memorial Fund (2002-present). Support has also received from the Center on Human Development and Disability, University of Washington since 1993 (National Institute of Child Health and Human). The creation of the FASDPN clinical dataset would not have been possible without the extensive clinical efforts and support of the interdisciplinary diagnostic teams and community health/social service agencies across WA State. And finally, special thanks are extended to the patients and their families for their benevolent contributions to the WA FASDPN dataset.

COMMENTARY Open Access

Invited commentary on Australian fetal alcohol spectrum disorder diagnostic guidelines

Susan J Astley

Abstract

The publication of Australian fetal alcohol spectrum disorder (FASD) diagnostic guidelines marks an important step forward in Australia's efforts to prevent FASD. But do we need yet another set of FASD guidelines? At the 5th International FASD Conference, the ever growing number of FASD diagnostic guidelines was identified as a core area of concern by leaders in FASD worldwide. All agreed we need to strive to adopt a single set of guidelines. It is essential that FASD diagnosis advance to incorporate new knowledge and technology. But to date, the field of FASD has seen multiple sets of guidelines published that do not address the important question-*How is the performance of these new guidelines superior to the performance of existing guidelines to warrant/justify their introduction into the medical literature*?

The Australian guidelines include FAS, PFAS and Neurodevelopmental Disorder-Alcohol Exposed (ND-AE). This latter group includes individuals with severe CNS abnormalities without the physical features of FAS. This is the group the 4-Digit-Code calls Static-Encephalopathy-Alcohol-Exposed (SE-AE). The criteria for FAS, PFAS, and ND-AE (or what the 4-Digit-Code calls SE-AE) are identical between the Australian and 4-Digit-Code guidelines with the exception of one very small, but very consequential difference in facial criteria for PFAS. The 4-Digit-Code requires a Rank 3 FAS facial phenotype for PFAS (*J Popul Ther Clin Pharmacol* **20**(3):e416–e467, 2013); the Australian guidelines relax the criteria to include the Rank 2 FAS facial phenotype. This relaxation of the criteria renders the facial phenotype NOT specific to prenatal alcohol exposure as confirmed in published empirical studies. If the facial phenotype is not specific to (caused only by) prenatal alcohol exposure one can no longer validly call the outcome PFAS. When one makes a diagnosis of FAS (full or partial), one is stating explicitly that the individual has a syndrome caused by prenatal alcohol exposure. One is also stating explicitly that the biological mother drank alcohol during pregnancy and, as a result, harmed her child. These are bold conclusions to draw and are not without medical, ethical, and even legal consequences. So the question remains-Why go against the published empirical evidence and relax the PFAS facial criteria into the normal range?

Keywords: Fetal alcohol spectrum disorders, FASD 4-digit diagnostic code

The publication of Australian fetal alcohol spectrum disorder (FASD) diagnostic guidelines [1] marks an important step forward in Australia's efforts to prevent FASD. Accurate identification of the full spectrum of outcome caused by prenatal alcohol exposure is central to FASD screening, diagnosis, intervention, surveillance, and ultimately prevention [2,3]. But do we need yet another set of FASD guidelines?

FASD diagnostic guidelines have evolved over time since the term FAS was first coined in 1973 [4]. Early guidelines were gestalt (purposely broad and conceptual) in nature and administered primarily by geneticists/dysmorphologists. The 1996 Institute of Medicine FASD guidelines [5] would be the last in this line of gestalt approaches to diagnosis. In 1997, the FASD 4-Digit-Diagnostic-Code was introduced to overcome the limitations (inaccuracies) of the gestalt method of diagnosis [6-8]. The 4-Digit-Code introduced an interdisciplinary approach guided by rigorously and empirically case-defined criteria. When the 4-Digit-Code was introduced into the medical literature, it was presented in the form of an empirical study demonstrating its superior performance to the gestalt approach it proposed to replace [7]. Over the next 17 years,

Correspondence: astley@uw.edu
FAS Diagnostic & Prevention Network, Center on Human Development and Disability, University of Washington, Box 357920, Seattle, WA 98195-7920, USA

it performance would continue to be extensively assessed (validated [2,9]) through MRI studies [10], population-based screening/surveillance studies [11-14], and patient follow-up surveys [15]. Between 2004 and 2013, five additional FASD diagnostic guidelines will be introduced into the literature [16-19]. All proposed an interdisciplinary approach using defined criteria. Most were established through a consensus process, but none had performance assessed (validated) prior to or even after publication. Most present with criteria that are marginally different from the 4-Digit-Code, but none provide empirical evidence demonstrating their superior performance relative to existing guidelines. It is essential that FASD diagnosis advance to incorporate new knowledge and technology. But to date, the field of FASD has seen multiple sets of guidelines published that do not address the important question-*How is the performance of these new guidelines superior to the performance of existing guidelines to warrant/justify their introduction into the medical literature* [2]? At the 5th International FASD Conference in 2013, the ever growing number of FASD diagnostic guidelines was identified as a core area of concern by leaders in FASD worldwide. All agreed we need to strive to adopt a single set of guidelines.

The most recent guidelines introduced into the literature are the Australian guidelines [1]. More accurately, they are consensus recommendations providing a foundation for development of Australian FASD diagnostic guidelines. The Australian guidelines adapted elements of the 4-Digit-Code and Canadian Guidelines. Let's take a closer look.

The Australian guidelines include FAS, PFAS and Neurodevelopmental Disorder-Alcohol Exposed (ND-AE). This latter group includes individuals with severe CNS abnormalities without the physical features of FAS. This is the group the 4-Digit-Code calls Static-Encephalopathy-Alcohol-Exposed (SE-AE). The Australian guidelines chose not to use the term Alcohol-Related-Neurodevelopmental-Disorder (following the 4-Digit Code and DSM-5 [20] conventions) due to the implication of causality between exposure and outcome that cannot be confirmed. The criteria for FAS, PFAS, and ND-AE (or what the 4-Digit-Code calls SE-AE) are identical between the Australian and 4-Digit-Code guidelines with the exception of one very small, but very consequential difference in facial criteria for PFAS. The 4-Digit-Code requires a Rank 3 FAS facial phenotype ("2.5" of the 3 facial features must be present) for PFAS; the Australian guidelines relax the criteria to include the Rank 2 FAS facial phenotype (2 of the 3 facial features). This relaxation of the criteria renders the facial phenotype NOT specific to prenatal alcohol exposure as confirmed in published empirical studies [2,3,21,22]. In one of those studies 25% of a group of high-functioning (mean IQ 120) children with confirmed absence of prenatal alcohol exposure presented with 2 of the 3 features. This study clearly demonstrated that the PFAS facial phenotype proposed in the Australian guidelines is not observed exclusively among children damaged by prenatal alcohol exposure. If the facial phenotype is not specific to (caused only by) prenatal alcohol exposure (and we already know the growth and CNS abnormalities are not caused only by prenatal alcohol exposure) one can no longer validly call the outcome PFAS. This problem is not resolved by requiring a confirmed prenatal alcohol exposure. The problem lies in the name (PFAS) given to the condition. When one makes a diagnosis of FAS (full or partial), one is stating explicitly that the individual has a syndrome caused by prenatal alcohol exposure. One is also stating explicitly that the biological mother drank alcohol during pregnancy and, as a result, harmed her child. These are bold conclusions to draw and are not without medical, ethical, and even legal consequences. If the growth, face and CNS criteria for PFAS are not specific to prenatal alcohol exposure, a clinical team is in no position to claim the child has a condition caused by their mother‟s alcohol use. A second problem arises with the relaxation of the facial features for PFAS into the normal range (requiring only 2 of the 3 features). If the facial criteria are relaxed, the Australian PFAS group is no longer clinically distinct from the Australian ND-AE group [2,3]. Note the only feature that distinguishes the Australian PFAS group from their ND-AE group is the facial criteria. But if the facial criteria for PFAS are relaxed into the normal range, the facial criteria are no longer clinically distinct from the facial criteria for ND-AE. If there is no clinically meaningful distinction between PFAS and ND-AE, what is the justification for creating two separate diagnostic subgroups? So the question remains-Why go against the published empirical evidence and relax the PFAS facial criteria into the normal range?

The Australian guidelines report the UW 4-Digit-Code could also be derived if desired". Unfortunately, the only issue preventing clinicians from deriving a 4-Digit-Code that would be in complete compliance with the Australian guidelines is the relaxation of the PFAS facial criteria from a Rank 3 to a Rank 2. If the Australian guidelines required a Rank 3 face for PFAS, it would not only gain the specificity required to validate the use of the term PFAS, but the 4-Digit-Codes would derive 4-Digit clinical categories (FAS, PFAS, SE-AE) that match the Australian clinical categories (FAS, PFAS, ND-AE). If the 4-Digit-Code said it was FAS, so would the Australian guidelines. If the 4-Digit-Code said it was PFAS, so would the Australian guidelines. And if the 4-Digit-Code said it was SE-AE, so would the Australian guidelines (but the Australian guidelines would simply give it a different label (ND-AE)). Individuals who present with moderate CNS dysfunction (what the 4-Digit-Code calls Neurobehavioral-Disorder-Alcohol-Exposed) would receive 4-Digit-Codes documenting

their outcomes, but in accordance with the Australian guidelines would not receive a label. This would seem a reasonable interim solution as Australians further assess how to handle this moderate end of the FASD spectrum. The authors report "*Although there is an extensive evidence base confirming prenatal alcohol exposure causes the full range of outcomes from moderate to severe CNS dysfunction and a growing evidence base documenting significant CNS structural abnormalities among alcohol-exposed individuals with moderate dysfunction; panel members identified the need for additional evidence to more fully evaluate the validity of diagnosis based on moderate CNS dysfunction*" Rendering a 4-Digit-Code would allow one to quickly apply a label retroactively in the event Australia elects to recognize (e.g., label) this moderate end of the FASD spectrum in the future.

Response

Rochelle E Watkins, Elizabeth J Elliott, Janet M Payne, Colleen M O'Leary, Jane Halliday, Jane Latimer, Amanda Wilkins, Raewyn C Mutch, James P Fitzpatrick, Heather M Jones, Lorian Hayes, Heather D'Antoine, Sue Miers, Elizabeth Russell, Lucinda Burns, Anne McKenzie, Maureen Carter, Carol Bower.

We have recently published recommendations for the diagnosis of fetal alcohol spectrum disorders (FASD) in Australia. These recommendations seek to address the known issue of underdiagnosis through supporting improved awareness of FASD and increased national capacity to respond to, and ultimately prevent, these disorders. We used an adaption approach to guideline development in recognition of existing diagnostic guidelines. Recommended national standard diagnostic criteria for Australia are based on the University of Washington (UW) 4-Digit Diagnostic Code and Canadian guidelines for FASD diagnosis. Our conclusions emphasise the importance of evaluation to improve the evidence-base for policy and practice.

In her commentary on our recommendations, Astley has raised important questions about the publication of this work, including whether we need 'yet another guideline', and expressed concern about the recommended criteria for the diagnosis of partial fetal alcohol syndrome (PFAS). Guideline development is a recognised and widely used mechanism to influence clinical practice. The lack of guidelines for diagnosis in Australia has been identified as one of the factors contributing to the underdiagnosis of FASD. We sought to establish the basis for a standard national approach to diagnosis in Australia through the adoption or adaption of existing guidelines.

Existing diagnostic guidelines lack agreement on all aspects of diagnosis, and the recommended diagnostic criteria for PFAS remain subject to debate. Although our recommended diagnostic criteria for PFAS in Australia based on the presence of 2 characteristic facial features differ from the UW guidelines, they lie within the range of criteria recommended by other guidelines. We sought peer review and publication of our findings to provide transparency and promote awareness of our work nationally and internationally. We support international collaboration to develop a common approach to diagnosis, and believe that this process will strengthen the evidence base for action globally.

Background

North America leads the world in the production of guidelines for the diagnosis of fetal alcohol spectrum disorder (FASD), and these provide a rich resource for those seeking to address and prevent the harm caused by prenatal exposure in other contexts. We recently published Australian recommendations for FASD screening and diagnosis [1] with the aim of supporting clinical decision-making to improve the identification, management and prevention of these disorders based on a standard national approach. In her commentary on our recommendations, Astley has raised some important questions about the need for these guidelines, the publication of this work and the recommended criteria for the diagnosis of partial fetal alcohol syndrome (PFAS).

National focus

The development of clinical practice guidelines has been identified as a critical activity at the national level to facilitate the delivery of effective health services [23]. The majority of published guidelines for the diagnosis of FASD were commissioned by government health agencies and motivated by concern about the impact of prenatal alcohol exposure at a national level. It is unlikely to be coincidental that North America has both published the greatest number of guidelines for diagnosis and gained recognition as leading the world in many aspects of FASD practice and research.

Guidelines are developed with the aim to influence practice. They need to be locally appropriate and integrated with strategies to facilitate their implementation. High quality guidelines developed at the international level can facilitate the development of locally appropriate guidelines for specific practice settings and, increasingly, local health providers are developing methods to integrate evidence in their own settings [24]. The need to improve service delivery and support health professionals' capacity to diagnose FASD in Australia [25,26] underpinned the Australian Government's call for development of a diagnostic instrument for Australia. The absence of guidelines for FASD diagnosis in Australia has been linked to underdiagnosis [27] and inaccurate FASD prevalence estimates [28]. The lack of a national standard approach undermines the effectiveness of interventions to educate

health professionals, increase diagnostic and management capacity, and conduct surveillance and evaluation.

Adoption or adaption

Through the development of national recommendations for FASD screening and diagnosis we aimed to improve awareness of FASD and strengthen national capacity to identify, address and prevent the harms associated with alcohol consumption in pregnancy. Four key factors framed our approach: i) that there are no international consensus criteria for diagnosis; ii) that there is variation in diagnostic practices internationally [29]; iii) that the most recent guidelines were published in 2005, and none with a published formal review; and iv) that there was little evidence to support the natural emergence of any standard national approach to diagnosis in Australia.

A range of existing guidelines have been used for diagnosis in Australia. The Institute of Medicine criteria [5] were used in the first national surveillance study in 2001 [30], the Canadian guidelines [17] were used in the first national prevalence study in 2009 [31], and the University of Washington (UW) 4-Digit Diagnostic Code [8] has been proposed for national use by authors examining the issues of diagnostic capacity and surveillance [27,28].

We used an adaption approach to development [32] in recognition of existing guidelines for diagnosis, and our work followed the accepted process of identifying whether existing guidelines would be adopted or adapted for local use [33] within a recognised research framework [34,35]. We found no clear support for the adoption of any single existing guideline [1,26]. Our recommendations have been developed to provide the foundation for a coordinated national approach to service provision, and are based on the cornerstone contributions of existing diagnostic guidelines that have helped to advance practice globally.

Process and judgement

There are considerable challenges in producing evidence-based guidelines for FASD screening and diagnosis, and disagreement between guidelines can arise for various reasons, not all of which imply that different recommendations are invalid [36]. We developed recommendations for Australia based on the deliberations of a range of stakeholders within a consensus-based approach. As is often the case in guideline development, there was a recognised need to move beyond the limited research evidence [37], and rarely 'an abundance of evidence available that leads directly to an indisputable recommendation' [38] p. 35. Recommendation development is a largely qualitative process with the need to consider multiple factors and considerable potential to encounter differences in judgement for a number of reasons, including perceptions about relevance, feasibility, risks and benefits. Panel members noted the need for additional evidence to evaluate differences in recommendations between existing guidelines, as well as the recommendations developed for Australia [1].

In the specific case of differences between the UW and Australian recommendations with respect to the facial features required for a diagnosis of PFAS, the panel recognised that the criteria for the diagnosis of PFAS remain subject to debate [39,40]. Diagnosis of disorders within the FASD spectrum is consistently challenged by an insufficient understanding of factors which contribute to individual susceptibility and phenotypic variability, and research highlights both the clinical significance of facial abnormalities [41,42] and the potential for variation in facial dysmorphology [43,44]. We support the need for further research to examine the validity of recommended diagnostic criteria for PFAS and facilitate international consensus in this area, and believe it would be premature to conclude that the diagnostic category of PFAS based on the presence of 2 facial features is invalid at this time.

Recommended facial criteria for the diagnosis of PFAS in Australia are consistent with existing guidelines [17,18], and differences in categorisation between the UW and other guidelines do not result in substantial differences in outcomes such as a diagnosis on the spectrum where one would otherwise have not been made. With reference to the potential harm caused by a diagnosis of PFAS using the recommended Australian criteria, we do not claim causation in the case of PFAS when diagnosed based on the presence of 2 characteristic facial features. The use of a non-causal assumption could be considered more conservative than assuming causation where specificity is known to be less than 100%. Contrary to Astley's comment, sufficient detail is recorded during the recommended assessment process to enable derivation of the 4-Digit Diagnostic Code despite differences between the diagnostic categories recommended in Australia and the UW guidelines. Further evaluation is critical to validating diagnostic criteria, and ensuring that the diagnostic categories used are based on meaningful distinctions across the spectrum.

We believe that our work provides a credible basis for advancing practice in Australia and, consistent with the purposes of the scientific literature and the need for transparency in recommendation development, we sought peer review and publication of a research paper which documents the methods used to develop these recommendations. If, through seeking peer review and publication to promote national and international awareness of our goals and progress, this process highlights broader issues that confront the development of FASD guidelines internationally, then we have achieved more than we had hoped.

An electronic version of this report is posted on the WA FASD-IAWG website.
http://depts.washington.edu/fasdwa/PDFs/FASD-IAWG-Dec2014-Report.pdf

EXECUTIVE SUMMARY

This report was written in response to a component of House Bill 2737 (introduced in January, 2014; did not pass) concerning Fetal Alcohol Syndrome (FAS) and Fetal Alcohol Spectrum Disorders (FASD). FAS is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. FASD is the name for the full spectrum of damage caused by prenatal alcohol exposure. FAS and FASD are 100% preventable. The purpose of this report is to describe the problem in Washington State, identify evidence-based practices for early screening, diagnosis, prevention, and intervention, and recommend policy changes.

The report draws attention to the fact that in Washington State an estimated 870 children are born with FASD each year (1% of all births), and approximately 70,000 individuals with FASD of all ages currently live here. FASD is the leading known cause of intellectual disabilities, its primary impact is on schools, foster and adoption services, the justice system, and mental health services; fewer than 10% of adults with FASD live independently or remain employed. It costs an estimated 2 million dollars in lifetime social and health care services for every child born with FASD. Annual Medicaid costs are 9 times more annually for a child with FASD compared to a child without FASD. It costs 30 times more to raise a child with FASD than to prevent FASD in the child.

The report highlights the substantial contributions made by clinicians and researchers in Washington State to developing evidence-based practices recognized and replicated globally to address FASD. These include screening, diagnosis and surveillance contributions. The University of Washington FAS Diagnostic & Prevention Network (FASDPN) clinic introduced the interdisciplinary approach to FASD diagnosis in 1992 and developed rigorous, validated tools (the FASD 4-Digit Diagnostic Code and FAS facial recognition software) to improve diagnostic accuracy. These tools and clinical model have been adopted worldwide and serve as the cornerstone for FAS screening in Washington's foster care system. FAS screening serves the dual purpose of identifying children at risk and tracking FAS prevalence over time. FAS screening has confirmed 1 out of every 100 children in Washington's foster care system has FAS. FAS screening has also confirmed the prevalence of FAS decreased significantly in Washington State as did maternal drinking during pregnancy, documenting Washington State's FASD prevention efforts are working, It "takes a village" to prevent FASD. The University of Washington FASDPN has trained thousands of healthcare, educational, correctional, and social service providers about the integral role they play in our ongoing, statewide effort to prevent FASD. The report also describes the widely-replicated, and highly successful FASD prevention model, the Parent-Child Assistance Program (PCAP). PCAP works with women who are at highest risk for delivering children with FASD, and demonstrates consistently positive research outcomes and significant cost savings for Washington State. Evidence-informed intervention best practices are also described, based on over two decades of research conducted at the University of Washington (e.g. studies of risk and protective factors for adverse life outcomes associated with FASD; the utility of

neuropsychological assessments in helping adults with FASD; Families Moving Forward with FASD, a clinician-guided intervention model meeting the needs of families affected by FASD).

Although Washington's prevention efforts are working, the State's capacity to screen, diagnose, treat, and prevent FASD falls far below the statewide need/demand for such services (e.g., the current average wait time for a family seeking a FASD diagnostic evaluation is 9 months). The report makes the following key recommendations:

Screening and Diagnosis of FASD

- Maintain current diagnostic capacity for the core University of Washington FASDPN Clinic, and if possible increase FASD diagnostic capacity through the FASDPN Network Clinics.
- Increase capacity for neuropsychological assessment of adults on Medicaid.
- Educate clinicians statewide on the importance of screening for and documenting prenatal alcohol exposure.

Prevention of FASD

- Maintain current PCAP funding in eleven counties and if possible expand PCAP to additional counties that have high rates of prenatal substance abuse, such as Thurston.
- Increase residential and outpatient substance abuse treatment capacity for pregnant and parenting women across the state.
- Increase distribution of the WA Department of Health "Substance Abuse During Pregnancy: Guidelines for Screening and Management".

Interventions for Individuals with FASD

- Reinstate funding support for community advocacy groups like NOFAS WA.
- Increase the capacity of intervention programs like Families Moving Forward.

Policy Changes to Improve FASD Identification, Prevention, and Intervention

- Explore all available opportunities to diversify funding sources, including maximizing federal Medicaid funding in order to reduce the fiscal impact on state general funds.
- Revise Developmental Disability Administration (DDA) eligibility criteria so that applicants with FASD, not just those with FAS, can be considered for eligibility under "another neurological or other condition.

INTRODUCTION

House Bill 2737 concerning Fetal Alcohol Exposure **(Appendix A)** was introduced on January 29, 2014 and was referred to Early Learning & Human Services. A public hearing in the House Committee on Early Learning & Human Services was held on February 13, 2014. This bill proposed the WA Fetal Alcohol Spectrum Disorder Interagency Work Group (FASD-IAWG) develop recommendations and provide a report by December 2014 to the appropriate committees of the legislature relating to:

- Identification of evidence-based practices for early screening and diagnosis of fetal alcohol spectrum disorders (FASD);
- Identification of evidence-based practices for prevention of FASD;
- Identification of evidence-based practices for interventions that can be used with individuals experiencing FASD; and
- Recommendations of policy changes that would improve the identification, prevention, or interventions related to FASD.

Although the bill did not pass, the FASD-IAWG made a commitment to produce the report requested in the draft legislation.

MEMBERSHIP

The Fetal Alcohol Spectrum Disorders Interagency Work Group (FASD-IAWG) was first established in 1995 through Substitute Senate Bill 5688 **(Appendix B)**. Senate Bill 5688 stipulated "*The department of social and health services, the department of health, the department of corrections, and the office of the superintendent of public instruction shall execute an interagency agreement to ensure the coordination of identification, prevention and intervention programs for children who have fetal alcohol exposure, and for women who are at high risk of having children with fetal alcohol exposure*." The FASD-IAWG has been meeting biannually since 1995. Its mission and accomplishments are presented on its website fasdwa.org. The agenda for 2014 was to develop and advance recommendations concerning FASD and summarize these recommendations in a December 2014 Report for distribution to appropriate committees of the legislature.

The 2014 FASD-IAWG is co-chaired by the FASD State Coordinator from DSHS (Sarah Pine), the director of the University of Washington Fetal Alcohol Syndrome Diagnostic and Prevention Network (Susan Astley, Ph.D.), and the director of the University of Washington Fetal Alcohol and Drug Unit (Therese Grant, Ph.D.). The Work Group includes several clinicians from the University of Washington FASD Diagnostic Clinic, the director of the University of Washington FASD Legal Issues Resource Center, a FASD Educator, the Director of NOFAS WA, and a young adult with FAS. Other members include the Assistant Secretary of DSHS/BHSIA, and representatives from DOH, DOC, and OSPI. A list of the individuals who served on this Work Group can be found in **Appendix C.**

2014 MEETINGS

The Working Group conducted meetings on the following dates:

June 12, 2014; September 15, 2014; October 29, 2014; December 1, 2014

WORK GROUP MEETING RECORDS

Please note that minutes from each meeting of the Work Group are available by contacting Sarah Pine, FASD State Coordinator.

BACKGROUND

Work Group members felt it necessary to provide the following background on fetal alcohol spectrum disorders in Washington State to serve as a basis for the recommendations which follow.

What is FAS and FASD and How is it Diagnosed?

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. FAS is characterized by growth deficiency, brain damage, and a unique cluster of facial features. Not all children exposed to and damaged by alcohol during gestation are born with FAS. Most are born with brain damage, but do not have the unique facial features of FAS. These children need the same social, educational, and healthcare services as children with FAS and far outnumber, by 10 to 1, children with FAS. The full spectrum of damage caused by prenatal alcohol exposure is called Fetal Alcohol Spectrum Disorders (FASD). There are four diagnoses under the umbrella of FASD.

Four Diagnoses under the Umbrella of FASD						
Diagnosis		Growth	FAS Face	Brain		Alcohol
1. FAS	Fetal Alcohol Syndrome	growth	face	severe		alc
2. PFAS	Partial FAS		face	severe		alc
3. SE/AE*	Static Encephalopathy / Alc Exposed			severe		alc
4. ND/AE	Neurobehavioral Disorder / Alc Exposed				moderate	alc

* Also referred to as:
- Alcohol Related Neurodevelopmental Disorder (ARND) or
- Neurodevelopmental Disorder Prenatal Alcohol Exposed (ND-PAE)

Diagnosis of FASD is conducted by an interdisciplinary team using evidence-based diagnostic guidelines. This diagnostic model was first introduced by the University of Washington in 1993 and has been adopted as best practice worldwide (SAMHSA, 2014). An interdisciplinary team of clinicians (medical doctor, psychologist, speech language pathologist, occupational therapist, social worker, and family advocate) is required to diagnosis FASD because the damage caused by prenatal alcohol exposure impacts all aspects of an individual's growth and brain development. The expertise of a medical doctor is required to assess the physical and neurological components of the disorder (i.e., growth deficits, facial anomalies, seizures). The expertise of a psychologist, speech language pathologist, and occupational therapist is required to assess the brain function component of the disorder. Deficits occur across multiple domains of brain function including attention, cognition, memory, language, and motor skills. The collective expertise of this team is also required to generate an effective, comprehensive intervention plan. The WA FASDPN conducts an FASD diagnostic evaluation in one 4-hour appointment using the FASD 4-Digit Code (Astley, 2004). The patient receives an accurate diagnosis and comprehensive intervention plan at the end of the 4-hour appointment and receives a 12-page comprehensive medical summary report the following week.

What is the Fiscal Impact of FASD on Washington State?

- It costs an estimated 2 million dollars in lifetime social and health care services for every child born with FASD (Lupton et al., 2004; Thanh & Jonsson, 2009). 870 children with FASD are born each year in Washington State (SAMHSA, 2006)
- In 2005 it cost Medicaid 9 times more in annual medical expenditures to care for a child with FASD than to care for a child without FASD ($16,782/child/year vs. $1,859/child/year) (Amendah et al., 2011). For comparison, it cost Medicaid $10,709/child/year to care for a child with Autism Spectrum Disorder.
- Washington State is the only place in the world that has successfully reduced the prevalence of maternal drinking during pregnancy statewide (14% to 4%), and documented that reduction in drinking correlated with a significant decrease in the birth rate of FAS in high-risk foster care (6% to 2%) (Astley, 2004). This was achieved within 5 years of opening two world-renowned, evidence-based programs supported in part through RCW 70.96A.500:
    1. The Fetal Alcohol Syndrome Diagnostic & Prevention Network (FASDPN)
    2. The Parent-Child Assistance Program (PCAP).
- With the combined efforts of these programs, it costs 30 times less to prevent FASD in a child, than to raise a child with FASD (Astley et al., 2000).
- Among those born with FASD, the WA FASDPN clinics have confirmed early diagnosis and a nurturing home environment significantly reduces disability and lifetime costs (Astley, 2010).

FASD Facts

- FAS was discovered in 1968 (Ulleland, 1972). Washington State is world renowned for this discovery.
- An estimated 870 children are born with FASD in Washington State each year (1% of all births).
  An estimated 70,000 individuals with FASD of all ages currently live in Washington State. (SAMHSA, 2006)
- FASD is 100% preventable. Washington State has published empirical evidence confirming its FASD prevention efforts are working. (Astley, 2004)
- FASD is the leading known cause of intellectual disabilities. (Stratton, 1996).
- FASD is not just a health care issue. Its primary impact is on schools, foster and adoption services, the justice system, and mental health services.
- Less than 10% of adults with FASD live independently or remain employed (Streissguth, Barr, Kogan, & Bookstein, 1996).
- An early accurate diagnosis, intervention, and a nurturing home environment are 3 factors empirically confirmed to substantially improve brain function and lifetime achievement among individuals with FASD (Astley, 2010; Streissguth, Barr, Kogan, & Bookstein, 1996).

What has Washington State Achieved to Date Regarding Evidence-Based and Best Practices for FASD Screening, Diagnosis, Prevention, Intervention, and Policy?

➢ EVIDENCE-BASED PRACTICES FOR EARLY SCREENING AND DIAGNOSIS OF FASD

1. **The Washington State FAS Diagnostic & Prevention Network** (fasdpn.org) is a network of interdisciplinary community-owned FASD diagnostic clinics led by the core clinical/research/training clinic at the University of Washington. The University of Washington clinic conducts 90% of the FASDPN diagnostic evaluations. The Network clinics conduct 10% of the FASDPN diagnostic evaluations. The FASDPN has been funded by the WA General Fund since 1995.

   The FASDPN was established in 1995 through enactment of RCW 70.96A.500 (Fetal Alcohol Screening and Assessment Services) **(Appendix D)**.

   > "Findings—Purpose—1995 c 54: *The legislature finds that fetal alcohol exposure is among the leading known causes of mental retardation in the children of our state. The legislature further finds that individuals with undiagnosed fetal alcohol exposure suffer substantially from secondary disabilities such as child abuse and neglect, separation from families, multiple foster placements, depression, aggression, school failure, juvenile detention, and job instability. These secondary disabilities come at a high cost to the individuals, their family, and society. The legislature finds that these problems can be reduced substantially by early diagnosis and receipt of appropriate, effective intervention*."

   The accomplishments of the FASDPN to date are described in full on its website (fasdpn.org) and briefly summarized below:

   A. **The FASDPN has provided 100% of the interdisciplinary FASD diagnostic and treatment evaluations in Washington State for the past 20 years**. The FASDPN was the first to introduce the highly effective and cost efficient interdisciplinary approach to FASD diagnosis.(Clarren & Astley, 1998; Astley, 2010). It was also the first to introduce an evidence-based FASD diagnostic system (the FASD 4-Digit Code(Astley, 2013). This FASD diagnostic model is now recognized as clinical best practice (SAMHSA, 2014) and replicated internationally.

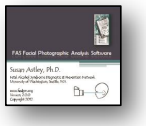
      Twenty years of FASDPN patient surveys (Astley, 2014) document:

      - 98% of families report receiving information not available to them elsewhere.
      - 89% report the diagnosis afforded them access to interventions that met their needs.
      - 100% report they would recommend the service to others.

In the words of one caregiver of a 10-year old child who received a FASD diagnosis ""*I cannot say enough good things about your services. A proper diagnosis has resulted in: change of school placement, OT/PT services provided by the school district, a referral to mental health in hopes of finding a therapist w/background in neurodevelopmental problems and patient's psychiatrist reducing his medications.*"

B. **The FASDPN provides 100% of the FAS screening and surveillance in Washington State**.

Through translational research (the rapid translation of research into clinical practice) the FASDPN created an evidence-based FAS screening tool (Astley et al., 1996, 2002) by first identifying the unique facial features of FAS and then creating FAS facial recognition software to identify these facial features from a digital photograph (Astley, 2014a). This software is now used worldwide.



The FASDPN used this facial recognition software to screen all children entering the King County Foster Care Passport Program over a 10 year period for FAS. This required nothing more than a digital facial photograph and a 5 minute computerized analysis. All children who screened positive for the FAS facial features received a full FASD diagnostic evaluation. Over 95% of the screen-positives received a diagnosis of FAS. This screening led to the discovery that one out of every 100 foster children in foster care has FAS (10 times higher than in the general population) (Astley et al., 2002).

This FAS screening program also led to the discovery that the prevalence of FAS births in Washington State decreased significantly in the same years maternal drinking during pregnancy in Washington State decreased significantly. (Astley, 2004)

The FASDPN currently provides FAS photo screening for Child Health & Education Tracking (CHET) and the Foster Care Assessment Program (FCAP).

C. **The UW FASDPN provides FASD training to hundreds of Washington State healthcare, educational, correctional, and social service providers annually**.

Training opportunities include:

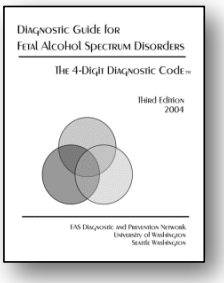
- The 1-Day Observation Training: Community professionals learn how to coordinate their efforts with the services of the FASDPN clinics to best serve individuals with FASD. These community professionals from healthcare, education, corrections, and social service are the professionals the FASDPN relies on to identify and refer individuals to the FASD clinics. They are also the professionals the FASDPN clinic will refer the patient back to for ongoing intervention services. By directly observing the FASDPN diagnostic team conduct two FASD diagnostic evaluations, their community role in this process

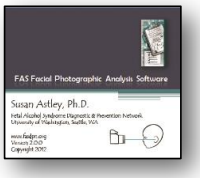
becomes crystal clear. Over 10,000 Washington State professionals have been trained to date. Training evaluations are sent monthly to the State. 100% have rated the training good to excellent.

In the words of one community professional who attended the training: "*To the inspiring FASD team members: Thank you so much for allowing me to observe your evaluations. What a treat to be able to watch in awe as each and every one of you evaluated and gained support with both child and mom with such grace and expertise. From the clinic coordinator's initial communication, to the incredible training, the lightning fast pace at which you produce those reports, the humility in delivering the diagnostic news, etc., etc.; from one outside agency, I will be happy to refer kids here (as we have in the past) and feel honored to be able to share my first-hand experience of the process! Thanks for the opportunity.*"

- Diagnostic Team Training: The UW FASDPN clinic provides diagnostic teams with instruction on how to establish an interdisciplinary FASD diagnostic clinic using the FASD 4-Digit Code. Over 150 teams have been trained worldwide including 6 in Washington State.
- FASD 4-Digit Code Online Course: The UW FASDPN clinic provides accredited online instruction for how to use the FASD 4-Digit Diagnostic Code. Over 700 professionals worldwide have completed the course. On a scale of 1 to 5, with 5 being excellent, the average score for the Online Course is 4.9.

D. **The UW FASDPN has developed the largest FASD clinical/research database and conducts translational research that has led to the development of FASD screening, surveillance, diagnostic, and intervention programs and tools used worldwide**.





Publications resulting from this research are posted on fasdpn.org.

➢ EVIDENCE-BASED PRACTICES FOR FASD PREVENTION

1. The **Parent-Child Assistance Program (PCAP)** (http://depts.washington.edu/pcapuw/) has been funded through Washington State DSHS Division of Behavioral Health and Recovery (DBHR) since 1997 by a combination of Federal Medicaid and State General Funds. PCAP:
   A. Enrolls women in Washington State who are at highest risk for delivering children with FASD: those who have an alcohol abuse problem, or who have already delivered a child with FASD.
   B. Provides intensive case management intervention to nearly 900 women and their families in eleven Washington State counties.
   C. Demonstrates consistently positive research outcomes and publishes findings in peer-reviewed journals (http://depts.washington.edu/pcapuw/).
   D. Demonstrates significant cost savings for Washington State (Casey Family Programs & Grant, 2013).
   E. Has been identified as an evidence-based practice by federal programs and clearinghouses, including the Association of Maternal and Child Health Programs (2012), the California Evidence-Based Clearinghouse for Child Welfare (2010,2013), and the Office of Juvenile Justice and Delinquency Prevention Model Program (2005, 2010).
   F. Maintains quality control and project fidelity via consistent statewide training and evaluation.
   G. Conducts research that has led to the development of screening and treatment modifications for adults with FASD that are being tested and adopted worldwide (Grant, Brown, Graham et al., 2013).
   H. Utilizes its statewide database to examine questions relevant to state child welfare policy and practices. For example, recurrent childbearing among substance-abusing mothers is a serious concern nationwide. PCAP clinical observations indicated that mothers whose children were removed from their custody often reacted by having a "replacement" baby. PCAP examined repeat alcohol/drug-exposed births among 795 clients. Consistent with our hypothesis we found that among women whose most recently delivered child had been removed from their care, the odds of having a subsequent birth increased *nearly two-fold* and the odds of having a subsequent *exposed* birth *increased three-fold*. The published paper discusses child welfare policy and practice implications and offers recommendations (Grant, Graham, Ernst et al., 2014).
   I. Utilizes its statewide database to collaborate with researchers at WSU in studying questions related to maternal substance abuse (e.g. rural/urban differences in substance abuse and mental health treatment services and outcomes; effects of contingency management on tobacco cessation recidivism.
   J. Trains and consults on the PCAP model throughout the world. In 2009 the Government of Alberta Institute of Health Economics recommended that Canada encourage programs based on the PCAP model (Institute of Health Economics, 2009). PCAP has now been replicated at forty Canadian sites with funding from provincial governments.

Mothers enrolled in PCAP are some of the highest risk women in Washington State, and they exemplify the intergenerational nature of familial substance abuse and dysfunction. *They were themselves the neglected and abused children in our communities just a decade or two ago* (Grant, Huggins, Graham et al., 2011). As children, over 90% had substance abusing parents, 63% were physically and/or sexually abused, 64% ran away from home, 30% had child welfare services involvement, and over half did not graduate from high school. As young mothers, they are likely to give their babies the same kind of upbringing they experienced as children unless we reach out with care, engagement, and intervention.

All PCAP clients have substance abuse disorders. Most are on Medicaid and have publicly funded core services available to them, but they do not tend to access these services or succeed on their own. For example, before enrollment in PCAP, 34% did not have a regular healthcare provider and 88% were not using a family planning method; 86% had previously been in inpatient or outpatient treatment (an average of three times); 43% were homeless or transient. The PCAP model, based on relational theory and motivational interviewing concepts, *offers outreach and engagement* to clients from trained, supervised case managers who provide support, structured goal setting, and consistent coaching (Grant, Ernst, & Streissguth, 1999). PCAP case managers are realistic role models who inspire hope—many are in long-term recovery and have overcome difficult life circumstances similar to those experienced by clients.

The PCAP approach makes a difference to clients:

- *"There were times when I felt like I was going to relapse and my case manager would be there for me, and she'd keep checking on me and I'd get through it. I've learned so much about myself and being responsible again and being a good mother. It was all what she taught me—she changed my life for me."*
- *"She helped me establish goals; she's helped me achieve my goals. She's taught me responsibility, dependability. After three years of working with her, I see myself as a strong, independent woman."*
- *"Before PCAP I never thought about goals. They showed me the right direction. They showed me that I am responsible. That no matter who I am or what I do, I am somebody. It is never too late."*

➢ EVIDENCE-BASED AND BEST PRACTICES FOR FASD INTERVENTION

1. **The Substance Abuse and Mental Health Services Administration (SAMHSA)** most recent Treatment Improvement Protocol (TIP) #58 is entitled "Addressing Fetal Alcohol Spectrum Disorders" (SAMHSA, 2014). Members of the University of Washington FADU and FASDPN programs, as well as members of the IAWG were coauthors of this document. FASD programs developed in Washington State are referenced throughout the TIP. It offers best-practices guidelines based on an evidence base of scientific research findings and clinical practice theory and principles. The TIP provides: 1) appropriate counseling methods for behavioral health practitioners; 2) support for program administrators to implement recommendations; and 3) an in-depth literature review.

2. **NOFAS WA** (nofaswa.org). Substitute Senate Bill 5688 also stipulated "*The interagency agreement shall provide a process for community advocacy groups to participate in the review and development of identification, prevention, and intervention programs administered or contracted for by the agencies executing this agreement*." NOFAS WA is a nonprofit 501(C) (3) family advocacy program established in 2003. NOFAS WA is an alliance of families and professionals supporting individuals with FASD, the families that care for them, and the systems that serve them. It hosts programs like FASt Friends, Teen Group, Family Camp, Trainings, and Conferences to empower families to succeed. NOFAS WA is an affiliate of the National Organization of Fetal Alcohol Syndrome. NOFAS Washington State received periodic funding support from the State prior to 2008 for targeted activities like Family Camp.

3. **Families Moving Forward with FASD** (http://depts.washington.edu/fmffasd/). Intervention services guided by clinicians with expertise/experience in FASD best meet the needs of families. Evidence-based programs like the University of Washington Families Moving Forward (FMF) with FASD provide this clinician training and parent support (Bertrand, 2009).

4. **Families confirm access to effective intervention starts with an accurate FASD diagnosis**. Twenty years of patient surveys confirm the FASDPN's interdisciplinary approach to diagnosis using the 4-Digit Code afforded them substantial access to community-based interventions that met their needs (Astley, 2014). For a patient to derive the greatest benefit from their FASD diagnostic evaluation, they need an interdisciplinary team that can: 1) render an accurate diagnosis under the umbrella of FASD; 2) generate a comprehensive intervention plan tailored to their specific needs and circumstances; and 3) present all of this in a comprehensive medical summary report that effectively informs and educates the family and their community service providers. In one 4-hour FASD evaluation, the patient is evaluated by a pediatrician, psychologist, speech language pathologist, and occupational therapist. Patients reported this single 4-hour assessment provided them with more information and access to

services than the multitude of uncoordinated services the families reported accessing prior to coming to the FASDPN clinic.

5. **UW Fetal Alcohol and Drug Unit researchers have developed practices effective with people who have FASD and published these in peer-reviewed papers**:
   - In 1992-1996 the Centers for Disease Control and Prevention (CDC) funded Dr. Ann Streissguth to study the occurrence and range of adverse effects of FASD across the lifespan. The study documented risk and protective factors among 451 individuals diagnosed with an FASD (age range 6 to 51 years).

     The Final report and the 2004 published paper continue to be cited worldwide as the most definitive sources of information on this topic. (Streissguth et al., 1996, 2004)

   - People with FASD are at high risk for substance abuse problems. Using the PCAP database, UW researchers conducted the first study of substance abuse treatment participation among people with FASD compared to those without FASD (Grant, Brown, Graham & Ernst, 2014). Findings: women with FASD were less likely to attend and complete inpatient and outpatient treatment; those with FASD were more likely to complete treatment within a residential versus outpatient setting. Detailed recommendations were developed for treatment accommodations to address impairments in FASD (Grant, Brown, Dubovsky, & Ries, 2013).
   - UW researchers developed and tested a 27-item Life History Screen interview protocol (LHS) to screen individuals at treatment intake for characteristics typically found in FASD in order to inform assessments and treatment planning (Grant, Brown, Graham, et al., 2013). Findings: the LHS shows promise as an efficient self-report screen for identifying possible FASD. Researchers in Canada and Germany are now conducting government-funded studies to further develop psychometric properties of the LHS.
   - People with FASD have 5 times greater risk for suicide attempt than those in the general population. UW researchers described clinical profiles of a sample of people with FASD, identified suicide risk and protective factors, and made recommendations for reducing suicide attempt among people with FASD (Huggins et al., 2008).
   - People with FASD are at high risk for criminal justice system involvement. UW researchers have developed detailed strategies for assessing prenatal alcohol exposure in legal settings (Brown et al., accepted).
   - Early intervention can reduce the likelihood that people with FASD will have adverse lifelong effects. UW researchers described how neonatal cranial ultrasound results led to an early FAS diagnosis and successful intervention in an infant whose mother was enrolled in PCAP (Grant, Bookstein, Whitney, & Streissguth, 2006).
   - UW researchers described the neuropsychological assessments administered to PCAP clients who have FASD, and illustrated how results have been used to help multidisciplinary teams respond effectively to affected individuals (Sparrow et al., 2013).

➢ POLICIES THAT IMPROVED FASD IDENTIFICATION, PREVENTION, AND INTERVENTION.

1. Washington State was the first to discover FAS in 1968. In 1973 the University of Washington introduced the term FAS into the medical literature. These actions paved the way for the following national public health policies:

   A. In 1981, The FDA posted the first **Surgeon General's Advisory on Alcohol and Pregnancy**: "*According to the Surgeon General, Women should not drink alcoholic beverages during pregnancy because of the risk of birth defects*".

   B. In 1988 the **Alcohol Beverage Labeling Act** was enacted. "*Government Warning: (1) According to the surgeon general, women should not drink alcoholic beverages during pregnancy because of the risk of birth defects. (2) Consumption of alcoholic beverages impairs our ability to drive a car or operate heavy machinery, and may cause health problems.*"

2. In 1992, Washington State was the first state to establish the position of "**FAS State Coordinator**". In 2003, SAMHSA expanded this to the National Association of FASD State Coordinators (SAMHSA 2003, 2014).

3. In 1992, the University of Washington opened the **first interdisciplinary FASD diagnostic clinic** (Clarren & Astley, 1998). In 1997 the UW went on create the **first case-defined FASD diagnostic system** (the FASD 4-Digit Diagnostic Code) (Astley & Clarren, 1997). This interdisciplinary approach to FASD diagnosis using rigorous case-defined guidelines is now regarded as clinical best practice worldwide (SAMHSA, 2014).

4. In 1993, Washington State enacted RCW 66.16.110 **Birth Defects from Alcohol-Warning Signs**. *The board shall cause to be posted in conspicuous places, in a number determined by the board, within each state liquor store, notices in print not less than one inch high warning persons that consumption of alcohol shortly before conception or during pregnancy may cause birth defects, including fetal alcohol syndrome and fetal alcohol effects*.

5. In 1995 Washington State was the **first to establish a statewide network of clinics** (the WA FAS Diagnostic & Prevention Network) through Senate Bill 5688. This Senate Bill served as the template for legislatures nationwide to establish statewide FASD diagnostic networks.

6. **The FASD Interagency Work Group** (fasdwa.org). In 1995, the FASD-IAWG was established through Senate Bill 5688 to ensure coordination of DSHS, DOH, DOC, OSPI, and UW programs for individuals impacted by FASD and women at risk of bearing children with FASD. In 2004 the IAWG composed and posted on its website a comprehensive historical record of all programs and policies related to FASD implemented in Washington State.

7. In 1998, Washington State enacted RCW 13.34.805: **Drug-Affected and Alcohol-Affected Infants – Comprehensive Plan**. *The Department of Health and the Department of Social and*

Health Services shall develop a comprehensive plan for providing services to mother who (a) have delivered a drug or alcohol exposed or affected infant, and (b) meet the definition of at-risk eligible persons in RCW 74.09.790 and who have a child up to three years of age. The services to be provided by the plan will include those defined in RCW 74.09.790. The plan shall provide for the coordination of services through community-based programs and among: (i) The department; (ii) the departments' divisions; and (iii) other state agencies. The plan shall include recommendations to the legislature for implementing the plan and any alternative methods for addressing the needs of these mothers and their children

8. In 2004, Governor Locke proclaimed September 9th as" **FASD Awareness Day"**. First recognized in 1999, International FASD Awareness Day helps raise awareness about the range of conditions that can result from alcohol use during pregnancy. September 9, 2004 was enacted as National FASD Day by the 108th congress of the U.S.

CURRENT CHALLENGES AND RECOMMENDED SOLUTIONS

Washington State is the leader in the field of FASD, being the first to discover FASD, and the first to develop evidence-based tools and programs for the screening, diagnosis, intervention, and prevention of FASD. Although Washington State's prevention efforts are working, the State's capacity to screen, diagnose, treat, and prevent FASD falls far below the statewide need/demand for such services. Our recommendations below focus primarily on increasing the capacity of our evidence-based screening, diagnosis, intervention, and prevention efforts.

A. Screening and Diagnosis of FASD

1. **Challenge**: Washington State's FASD diagnostic capacity does not meet diagnostic demand. An estimated 870 children with FASD are born each year in Washington State. At 2014 funding levels, the WA FASDPN is funded to conduct only 110 diagnostic evaluations per year. The average wait time for a family seeking a FASD diagnostic evaluation is 9 months. For children birth to three years of age, this translates into lost opportunities for early intervention.

   Solution: Maintain current FASD diagnostic capacity at the core University of Washington FASDPN Clinic, and if possible increase FASD diagnostic capacity through the FASDPN Network Clinics. Doubling statewide capacity would reduce average wait time to 4.5 months.

   Cost: A FASD diagnostic evaluation at the FASDPN costs $2,900. Doubling diagnostic capacity would cost $319,000 (110 x $2,900).

   Cost Savings: *Each $2,900 evaluation conducted by the FASD saves $4,900 in ineffective diagnostic evaluations*. Twenty years of patient records confirm that patients with prenatal alcohol exposure seek out an FASD evaluation by any means possible (Astley, 2014). A 4-hour interdisciplinary FASD diagnostic evaluation conducted by a pediatrician, psychologist, speech language pathologist, occupational therapist,

social worker and family advocate at the FASDPN costs $2,900. The cost of this evaluation (4 hours with an interdisciplinary, and 3-days effort by the clinic coordinator who schedules the appointment, collects all historical records (birth, school, medical, placement) that contain vital information required to derive the FASD diagnosis, and constructs the 12-page template medical summary report) is $2,900. A family seeking a diagnosis by scheduling four separate, uncoordinated evaluations with these same clinicians would cost over $7,800. The former results in an accurate FASD diagnosis and effective intervention plan. The latter does not. This interdisciplinary approach of FASD diagnosis is recognized as best practice nationwide (SAMHSA, 2014). An early accurate FASD diagnosis reduces the lifetime cost of an individual's FASD disability by hundreds of thousands of dollars (Olson et al., 2007; Astley, 2010). The benefit (HeraldNet, 12/24/14) to the individual and their family is immeasurable.

2. **Challenge**: A comprehensive neuropsychological assessment is an important component of a FASD diagnostic evaluation and is essential to informing effective treatment and service delivery. Children and adolescents referred to the FASD diagnostic clinics often have these assessments conducted by the schools and shared with the clinics. The FASD clinics collect these existing records to reduce the time and cost of the FASD evaluation. Adults referred to the clinics rarely have this data in their records. Most adults seeking an FASD diagnostic evaluation are on Medicaid and most neuropsychologists do not accept Medicaid payment. Therefore most adults seeking an FASD diagnostic evaluation do not have affordable access to adult neuropsychological evaluation services. This can prevent them from receiving a FASD diagnostic evaluation.

   Solution: Increase capacity for neuropsychological assessment of adults on Medicaid.

   Cost of Medicaid reimbursement: approximately $720 per neuropsychological assessment. Actual cost per assessment: approximately $1,700 to $2,500, often not fully covered by insurance.

3. **Challenge**: Programs working with at-risk children are not screening effectively for prenatal alcohol exposure. Clinicians are more likely to screen for illicit drug use during pregnancy than alcohol use, even though alcohol is more harmful to the developing fetus.

   Solution: Educate clinicians statewide on the importance of screening for and documenting prenatal alcohol exposure. Documentation of prenatal alcohol exposure serves to identify at-risk children that require close developmental monitoring. The 1-Day Training at the UW FASDPN clinic provides this training.

   Cost: Doubling diagnostic capacity doubles the number of 1-Day Training sessions available at no additional cost. The training sessions at the UW FASDPN take place

during each FASD diagnostic evaluation and are conducted by the team already assembled to conduct the diagnostic evaluation.

B. Prevention of FASD

1. **Challenge**: The State First Steps Database (2010) identified at least 2,606 alcohol and drug-abusing pregnant or postpartum women (PPW) with Medicaid births. PCAP has the capacity to serve approximately 900 (35%) of these women. Approximately 1,700 women who are eligible for PCAP are not being served. Most PCAP sites have waiting lists.

   Solution: Maintain current PCAP funding in eleven counties and if possible expand PCAP to additional counties that have high rates of prenatal substance abuse, such as Thurston.

   PCAP Cost: Approximately $5200 per client per year including direct services to families, and training and evaluation by the University of Washington. The cost of a full site serving approximately 100 women (e.g. in Thurston County) is $520,000 per year. It is not reasonable or cost effective to operate PCAP in remote counties where need is low, but statewide cost to serve even half of the eligible women not being served (approximately 850) is $4.42 million per year.

   Cost Savings (Casey Family Programs & Grant, 2013):

   - *Fewer substance exposed births*. At exit from PCAP, 79% of moms are no longer at risk for delivering another alcohol/drug affected infant because they are in successful recovery or are using family planning on a regular basis. The estimated total lifetime cost for every infant born with Fetal Alcohol Syndrome (FAS) is $2 million. **PCAP data show over $20 million in lifetime cost savings** because of effective intervention among the PCAP mothers who were former binge drinkers.
   - *Reduced dependence on child welfare*. Children of mothers in PCAP who were in out-of-home care and reunified at PCAP exit had a shorter length-of-stay (3.8 months), on average, than Washington's statewide average (20.4 months). For each successful reunification, **savings of over $21,000 per child can be realized**.
   - *Reduced dependence on public assistance.* From 2007 to 2012, Temporary Assistance for Needy Families (TANF) was the main source of income for 61% of women entering PCAP compared to only 31% at exit.
   - *Increased employment.* From 2007 to 2012, employment was the main source of income for 3% percent of women entering PCAP, compared to 27% at exit, resulting in greater tax revenue from increased earnings.

2. **Challenge**: Women with alcohol abuse disorders need high-quality treatment, and those with more severe substance abuse or cognitive problems need residential treatment. In Washington State there are only 156 state-funded PPW residential treatment beds, with only 130 slots for childcare.

Solution: Increase PPW residential and outpatient substance abuse treatment capacity across the state.

Cost: In 2013 the average cost was $7,545 per client for residential treatment services and $1,274 per client for outpatient treatment.

Cost Savings Increasingly strong evidence finds that treatment pays for itself (Center for Substance Abuse Treatment, 2002). Every $1 invested yields a return of between $4 and $7 in reduced drug-related crime, criminal justice costs, and theft. Savings can exceed costs by 12 to 1 when health care savings are included. Among pregnant women who are treated, newborns weigh more, have greater gestational age, are less likely to require care in the neonatal intensive care unit (NICU), and have shorter NICU stays if admitted. Residential and combined residential-outpatient treatment appear to be the most cost effective treatment modalities

3. **Challenge**: FASDs are preventable, and health care providers are in an ideal position to screen women for alcohol use and risk for becoming pregnant. Most health care providers do not discuss FASD prevention with women.

   Solution: The Washington State Department of Health has developed comprehensive recommendations and guidelines, entitled "Substance Abuse During Pregnancy: Guidelines for Screening and Management" (WA DOH, 2013). These guidelines need to be more widely distributed to healthcare providers throughout the state via no-cost websites and list serves.

   Cost: The Guidelines can be promoted and distributed throughout the state at little cost via current health care and substance abuse websites and list serves.

Interventions for Individuals with FASD

1. **Challenge**: Families are the primary support structure for children and adults in Washington State living with FASD. Family advocacy is vital for supporting these families. NOFAS WA hosts programs like FASt Friends, Teen Group, Family Camp, Trainings, and Conferences to empower families to succeed. NOFAS WA is a nonprofit that struggles to keep its programs open.

   Solution: Reinstate funding support for community advocacy groups like NOFAS WA.

   In 1995, Senate Bill 5688 stipulated the participation of community advocacy groups. DSHS provided $100,000/year support for community advocacy programs between 1995 and 2008. Families would benefit greatly if this support was reinstated.

2. **Challenge**: Intervention services guided by clinicians with expertise/experience in FASD best meet the needs of families. Evidence-based programs like Families Moving Forward (FMF) with FASD provide this clinician training and parent support. The current capacity of programs like FMF is too low to meet statewide demand.

   Solution: Increase the capacity of programs like FMF.

D. Policy Changes to Improve FASD Identification, Prevention, and Intervention

1. **Challenge**: FASD diagnostic and prevention efforts in Washington State are limited by their heavy reliance on State General Funds. More specifically:

   A. FASD diagnostic capacity through the FASDPN clinics is limited in Washington State because over 70% of patients seeking a diagnostic evaluation are on Medicaid (Astley, 2010) and Medicaid and/or private insurance alone covers less than one third of the cost of a diagnosis. This is not unique to Washington State. In a formal study conducted by the University of Alaska Anchorage in 2004 (BHRS, 2004), the average cost of conducting a FASD diagnosis in the State of Alaska using the University of Washington interdisciplinary model was $4,821. Only $1,076 could be billed to and collected from Medicaid and/or private insurance. Recognizing that Medicaid and/or insurance alone did not cover the full cost of a diagnosis, Alaska established a Provider Agreement payment of $3,000 per FASD diagnosis to assist interdisciplinary teams in recovering the cost of a diagnosis in their community (State of Alaska, 2012). Washington State established a similar provider agreement in 2007. The cost of a FASD evaluation in Washington State is approximately $2,900. The WA FASDPN clinics receive $2,000 per evaluation from State General Funds to offset what cannot be reimbursed through Medicaid and/or private insurance.

   B. FASD prevention efforts through PCAP have been funded through WA DSHS Division of Behavioral Health and Recovery (DBHR) since 1997 by a combination of Federal Medicaid and State General Funds.

      Solution: Explore all available opportunities to diversify funding sources, including maximizing federal Medicaid funding in order to reduce the fiscal impact on state general funds. **Update:** Discussions are currently underway with members of IAWG and key State Agency personnel to address this issue.

2. **Challenge**: Many patients with FASD are unable to access existing effective interventions recommended by the FASDPN clinics. These interventions include services for cognitive, behavioral, language, and motor sensory impairments. Qualifying for services through the DDA (Developmental Disability Administration) can be an important first step in obtaining services and supports.

Solution: Revise DDA eligibility criteria so that applicants with FASD, not just those with FAS, can be considered for eligibility under "*another neurological or other condition*. **Update**: Members of the IAWG have been working effectually for the past six months to formulate these revisions. We are pleased to report the revisions are near completion with a projected implementation date of early 2015, pending approval.

APPENDIX A

H-3637.2

HOUSE BILL 2737

State of Washington 63rd Legislature 2014 Regular Session

By Representatives Kagi, Sawyer, Smith, Ryu, Gregerson, Goodman, and Freeman

Read first time 01/29/14. Referred to Committee on Early Learning & Human Services.

AN ACT Relating to fetal alcohol exposure; amending RCW 70.96A.510; adding new sections to chapter 66.28 RCW; and creating a new section.

BE IT ENACTED BY THE LEGISLATURE OF THE STATE OF WASHINGTON:

NEW SECTION. **Sec. 1.** (1) The legislature finds that fetal alcohol exposure can cause serious mental and physical disorders and disabilities in children. These disorders are preventable if a mother does not drink during pregnancy. With the advent of private alcohol retailers, there is now increased access to alcohol. The legislature intends to require signage warning women about the dangers of fetal alcohol exposure in all stores selling alcohol.

(2) The legislature further finds that by collecting evidence-based practices around the identification, prevention, and interventions for fetal alcohol spectrum disorders, the number of affected individuals can decrease and those who are affected can improve their lives. Finally, by convening a work group of stakeholders, the legislature can become better informed about steps that can be taken to appropriately address fetal alcohol exposure.

NEW SECTION. **Sec. 2.** A new section is added to chapter 66.28 RCW to read as follows:

(1) At a minimum, premises that serve alcohol for on-premises consumption, grocery store licensees, beer and wine specialty shop licensees, breweries, wineries, and taverns shall post in a conspicuous place easily seen by patrons a printed sign at least eighteen inches by twenty-four inches in size, with letters at least two inches high, warning that consumption of alcohol during pregnancy can cause birth defects.

(2) This section does not apply to self-service minibars in hotel guest rooms.

NEW SECTION. **Sec. 3.** A new section is added to chapter 66.28 RCW to read as follows:

The board shall have the authority to adopt rules to carry out section 2 of this act in a manner that will increase the visibility of signage. The contents of section 2 of this act provide the minimum requirements regarding warning that consumption of alcohol during pregnancy can cause birth defects, but the board may adopt additional rules beyond those minimum requirements to ensure that customers observe these warnings.

Sec. 4. RCW 70.96A.510 and 1995 c 54 s 3 are each amended to read as follows:

(1) The department of social and health services, the department of health, the department of corrections, and the office of the superintendent of public instruction shall execute an interagency agreement to ensure the coordination of identification, prevention, and intervention programs for ((~~children)~~) individuals who have fetal alcohol exposure, and for women who are at high risk of having children with fetal alcohol exposure.

The interagency agreement shall provide a process for community advocacy groups to participate in the review and development of identification, prevention, and intervention programs administered or contracted for by the agencies executing this agreement.

(2) The interagency agreement shall provide for a work group cochaired by the department of social and health services, the University of Washington fetal alcohol syndrome diagnostic and

prevention network, and the University of Washington fetal alcohol and drug unit to address fetal alcohol exposure issues related to identification, prevention, and intervention. This work group shall include the department of health, the department of corrections, the office of the superintendent of public instruction, and other interested organizations identified by the department of social and health services, the University of Washington fetal alcohol syndrome diagnostic and prevention network, and the University of Washington fetal alcohol and drug unit.

(3) By December 1, 2014, the work group shall develop recommendations and provide a report to the appropriate committees of the legislature relating to:

(a) Identification of evidence-based practices for early screening and diagnosis of fetal alcohol spectrum disorders;

(b) Identification of evidence-based practices for prevention of fetal alcohol spectrum disorders;

(c) Identification of evidence-based practices for interventions that can be used with individuals experiencing fetal alcohol spectrum disorders; and

(d) Recommendations of policy changes that would improve the identification, prevention, or interventions related to fetal alcohol spectrum disorders.

APPENDIX B

CERTIFICATION OF ENROLLMENT

SUBSTITUTE SENATE BILL 5688

Chapter 54, Laws of 1995

54th Legislature
1995 Regular Session

Fetal alcohol exposure prevention

EFFECTIVE DATE: 7/23/95

Passed by the Senate March 13, 1995
YEAS 48 NAYS 0

JOEL PRITCHARD
President of the Senate

Passed by the House April 5, 1995
YEAS 95 NAYS 0

CLYDE BALLARD
Speaker of the House of Representatives

Approved April 17, 1995

MIKE LOWRY
Governor of the State of Washington

CERTIFICATE

I, Marty Brown, Secretary of the Senate of the State of Washington, do hereby certify that the attached is **SUBSTITUTE SENATE BILL 5688** as passed by the Senate and the House of Representative on the dates hereon set forth.

MARTY BROWN
Secretary

FILED

April 17, 1995 – 3:45 p.m.

Secretary of State
State of Washington

SUBSTITUTE SENATE BILL 5688

Passed Legislature - 1995 Regular Session

State of Washington **54th Legislature** **1995 Regular Session**

By Senate Committee on Human Services and Corrections (originally sponsored by Senators Hargrove, Long, Franklin, Rasmussen, C. Anderson, Kohl, Prentice, McAuliffe, Fairley, Drew, Smith, Heavey, Sheldon, Wojahn, Bauer and Winsley)

Read first time 03/01/95.

AN ACT Relating to fetal alcohol exposure; adding new sections to chapter 70.96A RCW; and crating new sections.

BE IT ENACTED BY THE LEGISLATURE OF THE STATE OF WASHINGTON:

NEW SECTION. **Sec. 1.** The legislature finds that fetal alcohol exposure is among the leading known causes of mental retardation in the children of our state. The legislature further finds that individuals with undiagnosed fetal alcohol exposure suffer substantially from secondary disabilities such as child abuse and neglect, separation from families, multiple foster placements, depression, aggression, school failure, juvenile detention, and job instability. These secondary disabilities come at a high cost to the individuals, their family, and society. The legislature finds that these problems can be reduced substantially by early diagnosis and receipt of appropriate, effective intervention.

The purpose of this act is to support current public and private efforts directed at the early identification of and intervention into the problems associated with fetal alcohol exposure through the creation of a fetal alcohol exposure clinical network.

p. 1 SSB 5688.SL

NEW SECTION. **Sec.2.** A new section is added to chapter 70.96A RCW to read as follows:

(1) The department shall contract with the University of Washington fetal alcohol syndrome clinic to provide fetal alcohol exposure screening and assessment services. The University indirect charges shall not exceed ten percent of the total contract amount. The contract shall require the University of Washington fetal alcohol syndrome clinic to provide the following services:

(a) Training for health care staff in community-based fetal alcohol exposure clinics to ensure the accurate diagnosis of individuals with fetal alcohol exposure and the development and implementation of appropriate service referral plans;

(b) Development of written or visual educational materials for the individuals diagnosed with fetal alcohol exposure and their families or caregivers;

(c) Systematic information retrieval from each community clinic to (i) maintain diagnostic accuracy and reliability across all community clinics, (ii) facilitate the development of effective and efficient screening tools for population-based identification of individuals with fetal alcohol exposure, (iii) facilitate identification of the most clinically efficacious and cost-effective educational, social, vocational, and health service interventions for individuals with fetal alcohol exposure;

(d) Based on available funds, establishment of a network of community-based fetal alcohol exposure clinics across the state to meet the demand for fetal alcohol exposure diagnostic and referral services; and

(e) Preparation of an annual report for submission to the department of health, the department of social and health services, the department of corrections, and the office of the superintendent of public instruction which includes the information retrieved under subsection (1) (c) of this section.

(2) The department shall submit to the legislature, by January 1, 1996, a copy of the governor's fetal alcohol syndrome advisory board report.

NEW SECTION. **Sec. 3.** A new section is added to chapter 70.96A RCW to read as follows:

The department of social and health services, the department of health, the department of corrections, and the office of the superintendent of public instruction shall execute an interagency agreement to ensure the coordination of identification, prevention and intervention programs for children who have fetal alcohol exposure, and for women who are at high risk of having children with fetal alcohol exposure.

The interagency agreement shall provide a process for community advocacy groups to participate in the review and development of identification,prevention, and intervention programs administered or contracted for by the agencies executing this agreement.

NEW SECTION. **Sec.4.** If specific funding for the purposes of this act referencing this act by bill number is not provided by June30, 1995, in the omnibus appropriations act, this act is null and void.

Passed the Senate March 13, 1995.
Passed the House April 5, 1995.
Approved by the Governor April 17, 1995.
Filed in Office of Secretary of State April 17, 1995

RCW 70.96A.500

Fetal alcohol screening and assessment services.

The department shall contract with the University of Washington fetal alcohol syndrome clinic to provide fetal alcohol exposure screening and assessment services. The University indirect charges shall not exceed ten percent of the total contract amount. The contract shall require the University of Washington fetal alcohol syndrome clinic to provide the following services:

(1) Training for health care staff in community-based fetal alcohol exposure clinics to ensure the accurate diagnosis of individuals with fetal alcohol exposure and the development and implementation of appropriate service referral plans;
(2) Development of written or visual educational materials for the individuals diagnosed with fetal alcohol exposure and their families or caregivers;
(3) Systematic information retrieval from each community clinic to (a) maintain diagnostic accuracy and reliability across all community clinics, (b) facilitate the development of effective and efficient screening tools for population-based identification of individuals with fetal alcohol exposure, (c) facilitate identification of the most clinically efficacious and cost-effective educational, social, vocational, and health service interventions for individuals with fetal alcohol exposure;
(4) Based on available funds, establishment of a network of community-based fetal alcohol exposure clinics across the state to meet the demand for fetal alcohol exposure diagnostic and referral services; and
(5) Preparation of an annual report for submission to the department of health, the department of social and health services, the department of corrections, and the office of the superintendent of public instruction which includes the information retrieved under subsection (3) of this section.

[1998 c 245 § 136; 1995 c 54 § 2.]

Notes:

Findings – Purpose – 1995 c 54: "The legislature finds that fetal alcohol exposure is among the leading known causes of mental retardation in the children of our state. The legislature further finds that individuals with undiagnosed fetal alcohol exposure suffer substantially from secondary disabilities such as child abuse and neglect, separation from families, multiple foster placements, depression, aggression, school failure, juvenile detention, and job instability. These secondary disabilities come at a high cost to the individuals, their family, and society. The legislature finds that these problems can be reduced substantially by early diagnosis and receipt of appropriate, effective intervention.

The purpose of this act is to support current public and private efforts directed at the early identification of and intervention into the problems associated with fetal alcohol exposure through the creation of a fetal alcohol exposure clinical network." [1995 c 54 § 1.]

PALPEBRAL FISSURE LENGTH MEASUREMENT: ACCURACY OF THE FAS FACIAL PHOTOGRAPHIC ANALYSIS SOFTWARE AND INACCURACY OF THE RULER

Susan J. Astley

Professor of Epidemiology and Pediatrics, University of Washington, Seattle WA

ABSTRACT

Background
Accurate fetal alcohol spectrum disorder diagnoses require accurate facial measurement. The Fetal Alcohol Syndrome (FAS) Facial Photographic Analysis Software was developed to overcome measurement error known to occur with ruler measurement of the PFL. Recent publications have queried the Software's accuracy.

Objectives
1) Demonstrate the Software's ability to accurately measure a PFL from a 2-dimensional digital facial photograph. 2) Demonstrate the frequency and magnitude of error when the PFL is measured directly by clinicians using a ruler.

Methods
Objective 1: PFLs of mannequins were measured using the Software and a sliding digital caliper, with the latter serving as the gold-standard accurate measure. Mannequins allowed the caliper prongs to be placed directly on the landmarks that define the PFL. Objective 2: PFLs of 1,027 patients evaluated at the University of Washington FAS Diagnostic & Prevention Network were measured with the Software and directly by one or two clinicians using a ruler.

Results
Objective 1: The Software derived PFLs that were identical to or within 0.2 mm of the caliper measures. Objective 2: There was tremendous inter-rater variability in PFLs measured by clinicians using a hand held ruler. Seventy-seven percent of patients had their PFLs measured incorrectly (greater than 1 mm error) by at least one of the two clinicians using a ruler.

Conclusion
The FAS Facial Photographic Analysis Software measures the PFL with the same accuracy as a sliding digital caliper, as it was programmed to do. Direct measurement of the PFL with a ruler is very prone to error.

Key Words: *Fetal alcohol spectrum disorders, palpebral fissure length, FASD 4-Digit Diagnostic Code, WA State Fetal Alcohol Syndrome Diagnostic & Prevention Network*

FAS is a birth defect syndrome caused by maternal use of alcohol during pregnancy. FAS is characterized by growth deficiency, a unique cluster of minor facial anomalies and central nervous system (CNS) structural, neurological and/or functional abnormalities.[1]

The three diagnostic facial features of FAS as defined by the FASD 4-Digit Diagnostic Code[2] are: small palpebral fissure lengths (2 or more standard deviations below the mean), a smooth philtrum (Rank 4 or 5 on the University of Washington Lip-Philtrum Guide), and thin upper lip philtrum (Rank 4 or 5 on the University of Washington Lip-Philtrum Guide).

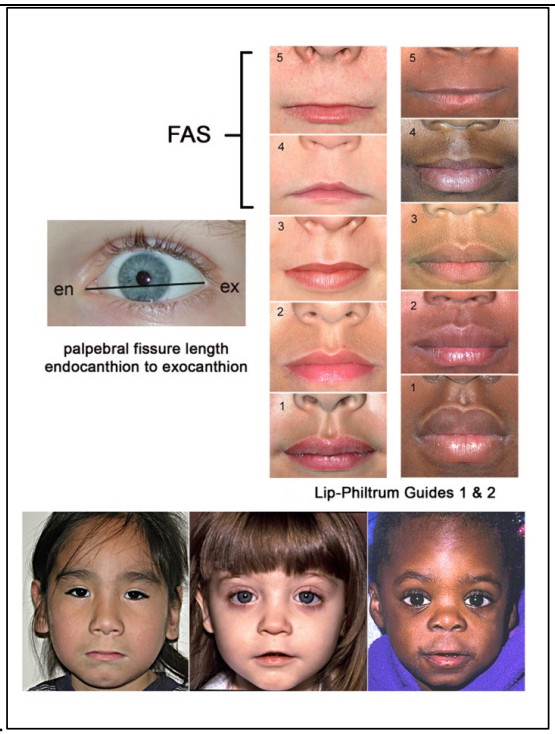

FIG. 1 The three diagnostic facial features of FAS as defined by the FASD 4-Digit Diagnostic Code[2] include: 1) short palpebral fissure lengths (2 or more standard deviations below the mean), 2) A smooth philtrum (Rank 4 or 5 on the Lip-Philtrum Guide), and 3) a thin upper lip (Rank 4 or 5 on the Lip-Philtrum Guide). Lip-Philtrum Guides 1 and 2 are used to rank upper lip thinness and philtrum smoothness. The philtrum is the vertical groove between the nose and upper lip. The guides reflect the full range of lip and philtrum shapes with Rank 3 representing the population mean. Ranks 4 and 5 reflect the thin lip and smooth philtrum that characterize the FAS facial phenotype. Guide 1 is used for Caucasians and all other races with lips like Caucasians. Guide 2 is used for African Americans and all other races with lips as full as African Americans. Examples of the FAS facial phenotype across three races: Native American, Caucasian, and African American.

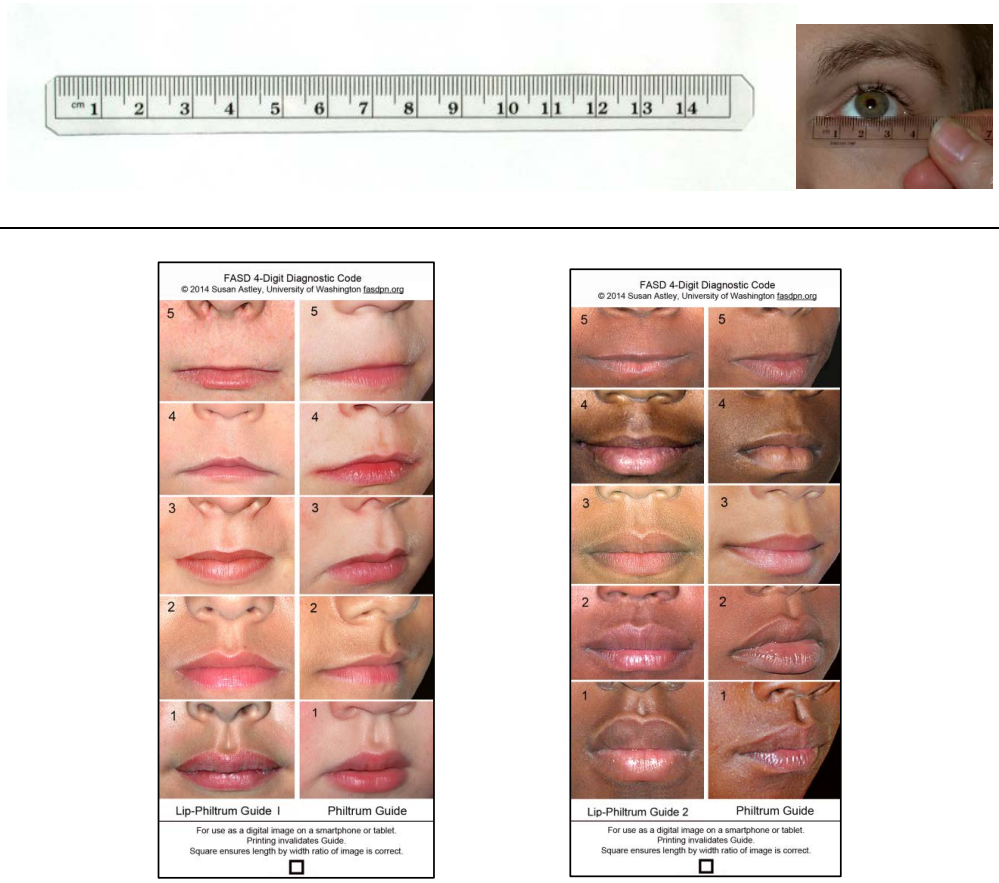

FIG. 2 The University of Washington FAS Diagnostic & Prevention Network (FAS DPN) created Lip-Philtrum Guides 1 and 2 for ranking upper lip thinness and philtrum smoothness and a 15 cm clear plastic ruler with rounded corners for safe measurement of the palpebral fissure.

In 1997, the University of Washington Fetal Alcohol Syndrome Diagnostic & Prevention Network (FAS DPN)[3] developed tools to more accurately measure the facial features of FAS. These tools included Lip-Philtrum Guides 1 and 2 to measure lip thinness and philtrum smoothness and a 15 cm clear plastic ruler with rounded corners to measure the PFL (Figure 2). The Lip-Philtrum Guides improved the accuracy and reproducibility of lip and philtrum measures by introducing pictorial scales that case-defined and rank-ordered lip thinness and philtrum smoothness.[4] The 15 mm clear plastic ruler was an improvement over the foot-long wooden ruler or soft tape measure observed to be used by some clinicians. Despite these improvements, facial

measures were still prone to error. Selecting the correct 5-point rank for lip thinness and philtrum smoothness could prove difficult if the subject's features fell close to the transition between two ranks. And measuring a PFL with a ruler poses many challenges. An accurate measure requires the clinician to place the ruler very close to the open eye and align themselves first with one corner of the patient's eye and then the other corner of the eye to avoid parallax errors. Young patients are often reluctant to allow a clinician to do this and may be unable to sit still enough to allow this measure to be obtained safely and accurately. A 1 mm error in measurement translates into almost 1 SD of error on the PFL growth chart[5], thus there is little room for error. Animations depicting these errors are presented on the FAS DPN website. With the advent of digital photography and computerized image analysis, the University of Washington developed the FAS Facial Photographic Analysis Software in 2003[6] (upgraded in 2012[7]) that allowed the clinician to more accurately measure facial features from 2 dimensional (2D) digital facial photographs (Fig. 3).

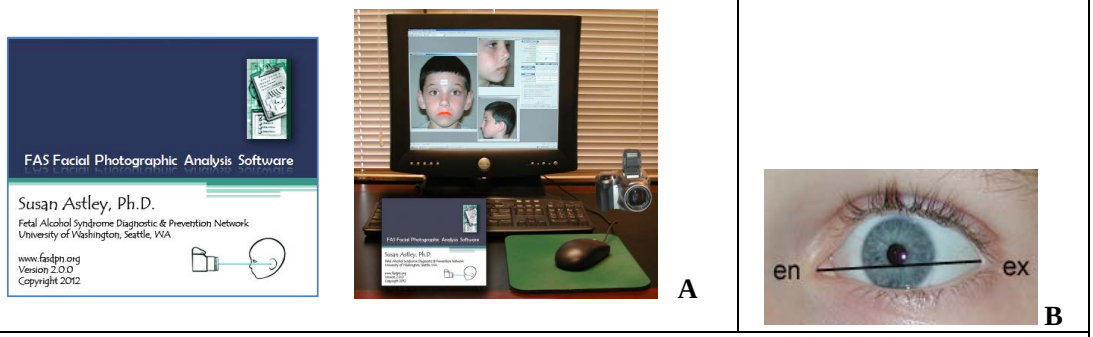

FIG. 3 A) The FAS Facial Photographic Analysis Software[7] allows a clinician to accurately measure the facial features of FAS from a 2D digital facial photograph. **B)** To measure the palpebral fissure length (PFL) the User clicks the mouse on the endocanthion and exocanthion landmarks of the eye. The Software computes the PFL in mm and reports how many standard deviations above or below the mean it is by looking it up on PFL normal growth chart.

The Software was specifically designed to overcome the error often observed when PFLs were measured with a handheld ruler.[8,9] The Software was programmed to measure a PFL with the accuracy of a sliding digital caliper (the gold standard). When used in accordance with the *Software's Manual of Instructions*, the Software generates accurate measures. The Software is programmed to generate accurate measures of the PFL, innercanthal distance, and lip circularity from a 2D image of a 3D object when the digital images meet the specifications (resolution, alignment, facial expression, etc) specified in the Instruction Manual. Throughout this publication, all reference to the "Software" refers to Version 1.0[6] or Version 2.0[7], as both use the same methods for measuring the FAS facial features. The upgrade in Version 2.0 simply provided Users with access to additional PFL normal growth charts.

There has been some confusion lately in the published literature as to the Software's ability to accurately measure a PFL from a 2D photograph. Two studies have reported on the discordance of ruler, caliper, and Software measures of the PFL. One study concluded that their Software measures were often smaller than their ruler measures.[10-11] The other study concluded

their Software measures were comparable to their ruler measures, but shorter than their caliper measures.[12] Since neither study included a gold-standard measurement of the PFL, neither study could comment on the accuracy of any of the three methods of measurement. If the Software measures tended to be smaller than the ruler and caliper measures, were the Software measures correct and the ruler and caliper measures overestimated the true PFL? Or were the Software measures incorrect and the Software underestimated the true PFL? The purpose of this study was to answer these questions.

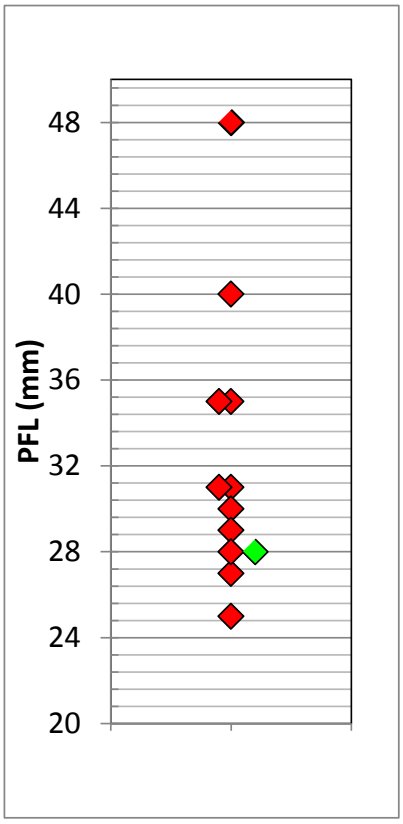
OBJECTIVES

The objectives of this study were:

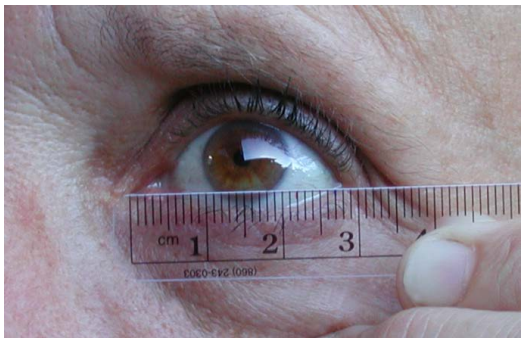
1. To demonstrate the ability of the FAS Facial Photographic Analysis Software's to accurately measure a PFL from a 2-dimensional digital facial photograph. The PFL is the distance between the endocanthion and exocanthion landmarks (Fig 2).
2. To demonstrate the frequency and magnitude of error when PFLs are measured directly by clinicians using a ruler.

It is important to clarify that this study is not assessing the accuracy of the Software for the first time, but rather demonstrating the accuracy of the Software. The accuracy of the Software was assessed and confirmed prior to its release in 2003. The Software was developed to overcome the high frequency of error known to occur when the PFL is measured directly using a ruler (Fig. 4).

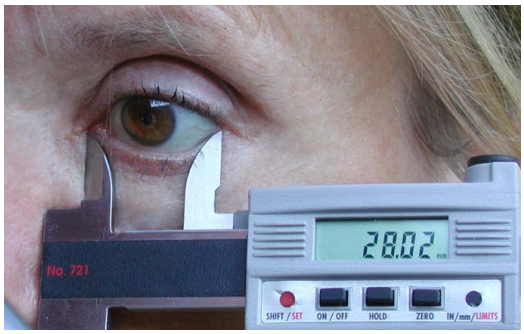
Although a demonstration of the Software's PFL measurement accuracy is posted on the FAS DPN website and the website cautions clinicians about the risk of error associated with ruler measurement of the PFL[1], neither of these topics have been comprehensively addressed by the FAS DPN in the published literature. With recent inquiry into which method of PFL measurement is most accurate (ruler, caliper, or Software)[10,11] a clear demonstration of the Software's accuracy and the ruler's inaccuracy is warranted to help guide clinicians in their choice of method.



A.



B.



C

FIG. 4 **A**. The inherent inaccuracy of measuring a PFL with a ruler was demonstrated in an exercise in which the author's left PFL was measured by 11 clinicians using a ruler. Although measurement of a PFL with a ruler may seem straightforward (**B**), the clinicians' measures ranged from 25 mm to 48 mm (red diamonds). **C**. The true PFL was 28.02 mm (green diamond) as demonstrated with a sliding digital caliper placed directly on the endocanthion and exocanthion landmarks. USE OF A CALIPER IN THIS WAY IS VERY DANGEROUS AND SHOULD NEVER BE DONE WITH A PATIENT.

TABLE 1 Software and caliper measures of the palpebral fissure lengths (PFL) from eight mannequins and one human subject.

OFC: occipital frontal circumference. mm: millimeters

METHODS

Objective 1: Software Accuracy

***Mannequin Heads*:** Eight life-size mannequin heads representing males and females across the lifespan (infant, child, adult) were used (Table 1). The head circumferences of the mannequins ranged from 39 to 54.5 mm, reflective of normal head circumferences for individuals infant through adult. Three mannequin heads were made from plastic and had eyes clearly painted on the face. Their PFLs were measured with calipers to be 11.8 mm, 17.8 mm, and 19.0 mm. Five mannequins were made from white Styrofoam and had facial features formed into the Styrofoam, but did not have eyes painted on the face. To accommodate this, a black, fine-tip felt marker was used to place small dots on each of the five mannequins to represent the endocanthion and exocanthion landmarks for the right and left palpebral fissure lengths. The five Styrofoam mannequins came with a variety of eye sizes ranging from 22 to 30 mm, thus the landmarks were placed to create PFLs of exactly 22, 25, 26, 28 and 30 mm, purposely spanning a range of PFL that would be observed in infants, children and adults.[5]

Caliper Measures of PFLs: The right and left PFLs were measured with a sliding digital caliper (Fig 4, Table 1). The prongs of the caliper were placed directly on the endocanthion and exocanthion landmarks of the palpebral fissure to obtain an exact (gold standard) measure of the PFL. A caliper can only serve as a gold standard of accurate measurement if the prongs of the caliper can be placed directly in contact with the 2 points in space being measured. A photograph was taken of each caliper measure to document the reading on the caliper. Human subjects were not used in this study because the gold standard measure of the PFL requires placing the prongs of the caliper directly on the endocanthion and exocanthion landmarks; a procedure that cannot be safely conducted with a human.

Facial Photograph: A frontal facial photograph of each mannequin head was obtained in accordance with the FAS Facial Photographic Analysis Software Version 2.0 Instruction Manual.[7] Briefly, a ¾ inch (19.05 mm) round paper sticker was placed between the eyebrows to serve an internal unit of measure in the digital image (Fig. 5, Table 1). A 5-megapixel digital camera was held 4 feet from the mannequin. The zoom feature was used to zoom in on the face until the head filled the camera frame (Table 1). Care was taken to obtain a frontal photograph with no vertical (tipped up or down) or horizontal (turned right or left) rotation.

To achieve this, the camera was held in the mannequin's Frankfort horizontal plane (the plane that runs through the external ear canals and the lower borders of the bony orbital rims) (Fig. 5). The camera was also aligned such that the right and left ears were equally visible. This camera alignment procedure is demonstrated in an animation posted on the FASDPN website.

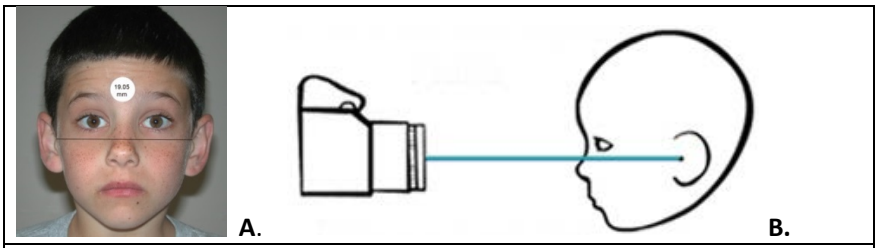

FIG. 5 A) Example of a properly aligned facial photograph. The camera is aligned in the subject's Frankfort horizontal plane (**B**. the plane (blue line) that runs through the external auditory canals and the lower borders of the bony orbital rims). When the camera is held in the subject's Frankfort horizontal plane, a line drawn between the right and left auditory canals on the facial photograph would fall along the lower boney orbital rims.

Software Measures of PFLs: Each facial image was imported into the Software for analysis. All analyses were conducted by the author. In accordance with the Software Instruction Manual, the Software's zoom feature was used to enlarge the image so the eyes and sticker covered the full width of the computer monitor (Table 1). This affords more accurate measures. To establish the measurement scale in the photo, the diameter of the paper sticker was measured. Distance in a digital image is measured in units called pixels. Pixels are the little dots of light that make up the image displayed on a computer screen. The diameter of the sticker in pixels was measured using the "single distance" tool. With the mouse the User selects the tool and clicks on the right edge of the sticker and then the left edge, bisecting the circle. This procedure establishes how many pixels is equivalent to 19.05 mm in the digital image. Next, the 3-distance tool was used to measure the right PFL, inner canthal distance (the distance between the eyes), and left PFL. With the mouse, the User selects the tool and clicks on the right exocanthion, right endocanthion, left endocanthion, and left exocanthion, in that order. In so doing, the Software records the right PFL, inner canthal distance, and left PFL in pixels. The Software then converts these three measures from pixels to mm using the pixel- to-mm conversion ratio established from measuring the diameter of the paper sticker.

***Data Analysis*:** All data was entered into SPSS[13] for analysis. The caliper measure of the PFL served as the gold standard in this study. If the Software was generating an accurate measure of the PFL, the Software measure should match the caliper measure. The Software measure of each PFL was subtracted from the caliper measure of the PFL to assess the Software's measurement accuracy. If the Software was generating an accurate measure of the PFL, the Software measure should match the caliper measure (the difference between the two measures would be zero). A negative outcome would document the Software underestimated the PFL. A positive outcome would document the Software overestimated the PFL.

Objective 2: Ruler Variability

The frequency and magnitude of error observed when clinicians use a ruler to measure the PFL was demonstrated by comparing: A) Ruler measures to caliper measures; B) Ruler measures to Software measures; and C) Ruler measures obtained by two clinicians. All data collection and analysis had Human Subjects Review Board approval.

A. *Ruler versus Caliper*

In 2000, the author invited 11 clinicians at the University of Washington to participate in an exercise in which they were asked to measure her left PFL to the best of their ability with a 15 cm plastic ruler (Fig. 4). These clinicians were selected because measuring PFLs was a routine part of their clinical practice. The only instruction they received was to view the image in Fig. 4B documenting the endocanthion and exocanthion landmarks that define the PFL. They were asked to write the PFL measure on a piece of paper and insert it into an envelope. The identity of the clinicians was not recorded. The true length of the palpebral fissure (obtained with a caliper) was shared with the clinician after they placed their measure in the envelope. They were asked not to reveal what measure they obtained, to maintain the anonymity of the exercise.

Data Analysis: The caliper measure of the author's left PFL and ruler measures obtained by 11 clinicians were plotted to illustrate inter-rater variability (Fig. 4).

B. *Ruler versus Software*

Over the past 20 years in the WA FAS DPN clinics, 1,027 patients had their PFLs measured by one of 21 different medical doctors using a 15 cm ruler. All 1,027 patients also had a digital facial photograph taken that was measured by the author using the FAS Facial Photographic Analysis Software. The 1,027 patients were 43% female and were on average 8.5 (5.5 SD) years of age. They ranged in age from 2 months to 48 years of age, with 92% under the age of 15 years.

Data Analysis: To compare the ruler versus Software measures of each patient's PFLs, the mean of the right and left PFLs derived by the Software was subtracted from the mean of the right and left PFLs obtained by the clinician using a

ruler (ruler mean PFL minus Software mean PFL). A negative difference reflected the Software measure of the mean PFL was longer than the ruler measure. A positive difference reflected the Software measure of the mean PFL was shorter than the ruler measure. Since the smallest unit of measure on the ruler is 1 mm (Fig. 2) and the smallest unit of measure using the Software is 0.1 mm, the ruler measure was considered a match to the Software measure if the ruler measure was within -0.9 to +0.9 mm of the Software measure. The outcomes were plotted by documenting what proportion of subjects had PFL measures that were < 1, 1, 2, or 3 or more mm different between the ruler and Software measures. Differences were categorized into 1 mm bins because 1 mm is the smallest unit of measurement demarcated on the ruler. An error of 1 mm is equivalent to an error of roughly three quarters of a SD on a normal growth chart for PFL.[5] A 1 mm error could result in an incorrect diagnosis under the umbrella of FASD. For example, if a 13 year old girl had a PFL that was truly 27 mm, her PFL would fall 0.6 standard deviations below the mean for a girl her age using the Stromland normal PFL growth charts[5]. The FASD 4-Digit Code would classify this PFL as being in the normal range (PFL ABC-score = A). If the clinician incorrectly measured her PFL by -1 mm, her 26 mm PFL would appear to be 1.3 SDs below the mean. The FASD 4-Digit Code would classify this PFL as being in the moderately short range (PFL ABC-score = B). If the clinician incorrectly measured her PFL by 2 mm, her 25 mm PFL would appear to be 2.0 SDs below the mean. The FASD 4-Digit Code would classify this PFL as being in the significantly short range (PFL ABC-score = C). Thus, a 1 mm error can incorrectly classify the PFL in the PFAS range and a 2mm error can incorrectly classify the PFL into the FAS range.

It is important to note that in the absence of a gold-standard measure (e.g., a caliper measure of the PFL), if a difference is observed between the ruler and Software measures, one of three conclusions can be drawn: 1) the ruler measure is incorrect; 2) the Software measure is incorrect; or 3) both measures are incorrect. The outcome of Objective 1 will help determine which of these three outcomes is supported.

C. *Ruler versus Ruler*

241 patients that had their PFLs measured with a ruler by both the medical doctor and the author. The 241 patients were 44% female and were on average 8.9 (5.1 SD) years of age. They ranged in age from 1.3 to 40 years of age, with 93% under the age of 15 years.

Data Analysis: To compare the two ruler measures of a patient's PFLs, the medical doctor's measure of the patient's left PFL was subtracted from the author's measure of the patient's left PFL (author's measure of PFL minus doctor's measure of PFL). A negative difference reflected the doctor's measure of the left PFL was longer than the author's measure. A positive difference reflected the doctor's measure of the left PFL was shorter than the author's measure. Since the smallest unit of measure on the ruler was 1 mm, the two clinicians' measures of the PFL were considered a match if they were within plus or minus 0.9 mm of one another. The outcomes were plotted by documenting what proportion of subjects had PFL measures that were < 1, 1, 2, or 3 or more mm different between the two ruler measures.

RESULTS

Objective 1. Software Accuracy:

The Software produced right and left PFL's that either matched or were no more than 0.2 mm different from the right and left PFLs measured with the calipers. These outcomes did not vary by gender, age (infant, child, adult), OFC (39-54.5 cm), or PFL (11.8 -30.0 mm) (Table 1).

Objective 2A. Ruler Variability:

Ruler versus Caliper

The PFL measures recorded by the 11 clinicians ranged from 25 mm to 48 mm (Fig. 4). The true PFL measured with a caliper was 28.02 mm. Eight of the 11 physician measures were incorrect by 2 to 16 mm. .

Objective 2B. Ruler Variability:

Ruler versus Software

One thousand twenty-seven patients across the full age span (infant to adult) had their PFLs measured by both the medical doctor using a ruler and from a photograph using the Software (Fig.

6). These measures involved 21 different doctors over 21 years. The doctor's measure with the ruler was within 1 mm of the Software measure 44.7% of the time. The two measures differed by 2 or more mm 21.1% of the time. When the ruler and Software PFL measures were compared among the subset of 166 patients that were under the age of 4 years, the distribution of error was near identical to that of the entire age spectrum. Since Objective 1 demonstrated the Software accurately derives a PFL from a 2D facial photo when the Software is used properly (high quality photos with proper alignment) and Objective 2A demonstrated high variability in ruler measures, the discordance between the ruler and Software measures presented here were most likely the result of incorrect ruler measures.

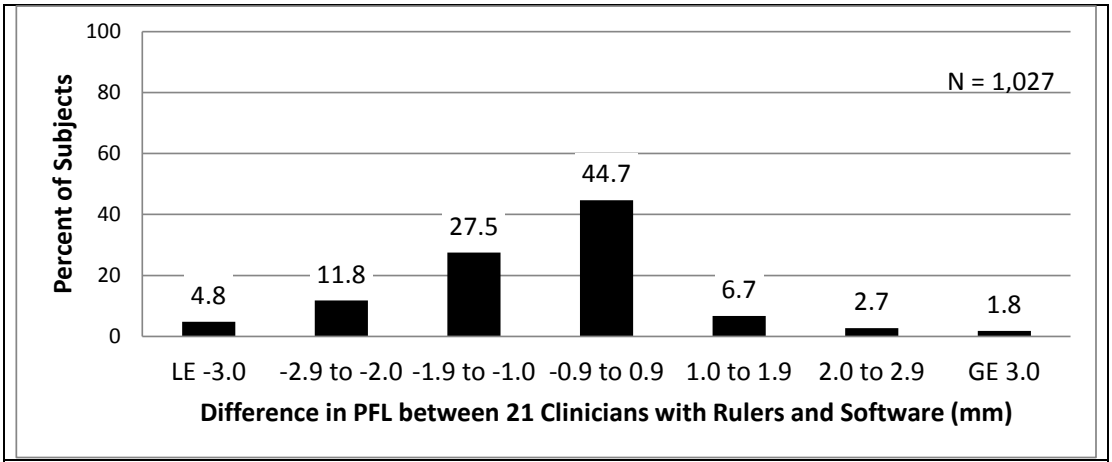

FIG. 6 ***Objective 2B*** The prevalence and magnitude of discordance is illustrated when the PFLs of 1,027 patients were measured from 2D facial photos using the FAS Facial Photographic Analysis Softare and measured by one of 21 medical doctors using a 15 cm ruler. The columns represent how often the ruler measure minus the Software measure was 1 or more mm diffferent. A negative difference reflects the ruler measure of the PFL was smaller than the Software measure of the PFL. A positive difference reflects the ruler measure was larger than the Software measure. Differences less than 1 mm were considered a match since 1 mm was the finest level of measurement marked on the ruler.

Of the 1,027 patients who had their PFL measured by a clinician using a ruler, 297 also had their PFL measured by the author. The 297 patients were 42% female and were on average 8.9 (5.0 SD) years of age. They ranged in age from 8 months to 40 years of age, with 94% under the age of 15 years. When the author's ruler measures were compared to the Software measures, 84.9 % of the ruler measures were less than 1 mm different from the Software measures (Fig. 7). Less than 2% were 2 or more mm different from the Software.

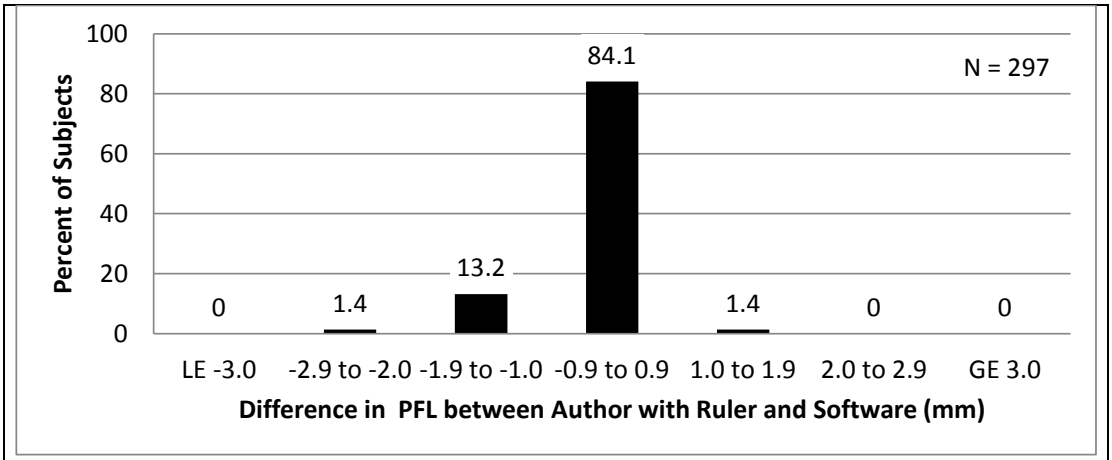

FIG. 7. ***Objective 2B:*** The prevalence and magnitude of discordance is illustrated when the PFLs of 297 patients were measured from 2D facial photos using the FAS Facial Photographic Analysis Softare and measured by the author using a 15 cm ruler. The columns represent how often the ruler measure minus the Software measure was 1 or more mm diffferent. A negative difference reflects the ruler measure of the PFL was smaller than the Software measure of the PFL. A positive difference reflects the ruler measure was larger than the Software measure. Differences less than 1 mm were considered a match since 1 mm was the finest level of measurement marked on the ruler.

As documented above, it is standard procedure in the University of Washington FAS DPN clinic to measure a patient's PFL directly with a ruler and from a photo using the Software. Due to the confirmed accuracy of the Software, we use the Software measure for the diagnosis. The ruler measure simply serves as an opportunity for the clinician to hone their skills with a ruler in the event they have to measure a patient without access to the Software. To demonstrate the value of this training, Fig. 8 documents the improvement in skill across three clinicians. The mean difference between the ruler and Software measures across all patients measured each year are presented from 2004 through 2011. These 320 patients were 42% female and were on average 8.1 (5.1 SD) years of age. They ranged in age from 2 months to 40 years of age, with 93% under the age of 15 years. When the Software was first introduced in the clinic in 2003, PFLs measured with a ruler were on average 2 mm discordant from the Software measures. Over time, the ruler measures moved into the green zone, documenting the ruler measures on average were more concordant (within 1 mm) of the Software measures. But it is important to point out that the 1 SD error bars (Fig. 8A) and the plot of individual patient measures (Fig. 8B) document the clinicians' individual measures still had an unacceptable level of variation from the Software measures, even if on average their measures were improving over time. Over half of the individual measures fell outside the green lines (were more than 1 mm discordant from the Software measure).

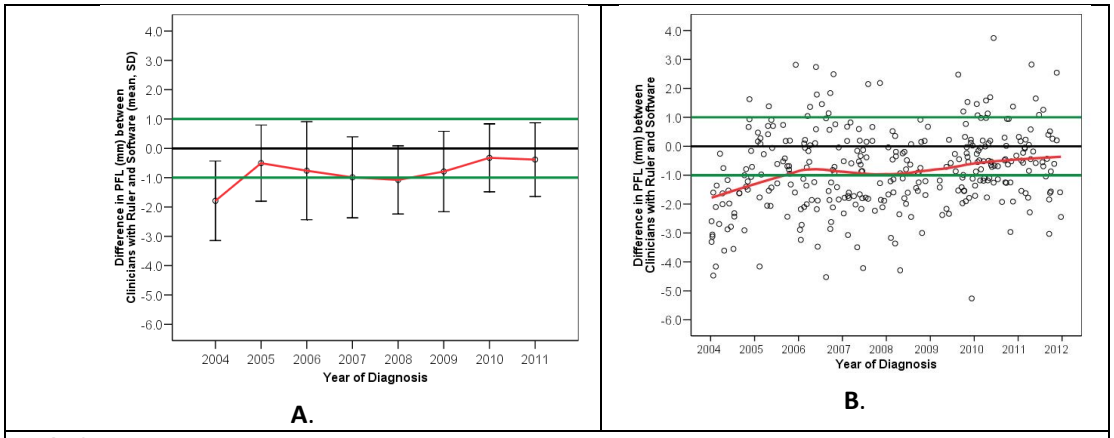

FIG. 8 ***Objective 2B:*** The difference in the ruler minus Software measure of the PFL is plotted annually across three clinicians and 320 patients. Ruler measures were collected at the beginning of the FASD diagnostic evaluation. Software measures were not available to compare to until the end of the evaluation. A. On average, the accuracy of PFL measures obtained with a ruler improved over time when the three clinicians had Software measures to compare to their ruler measures. The mean difference in the ruler minus Software measure of all PFLs collected each year are plotted with 1 SD error bars. The zone between the green lines reflects the perferred level of accuracy (less than 1 mm difference between the ruler and Software measures). The Software was introduced into the Clinic in 2003. Even though the mean difference tends to fall between the green lines (Fig. 8A), the magnitude of difference between the ruler and Software measures for each indivdiual patient (Fig 8B) continued to show far too much variability with over half the indivdual measures falling outside the green zone.

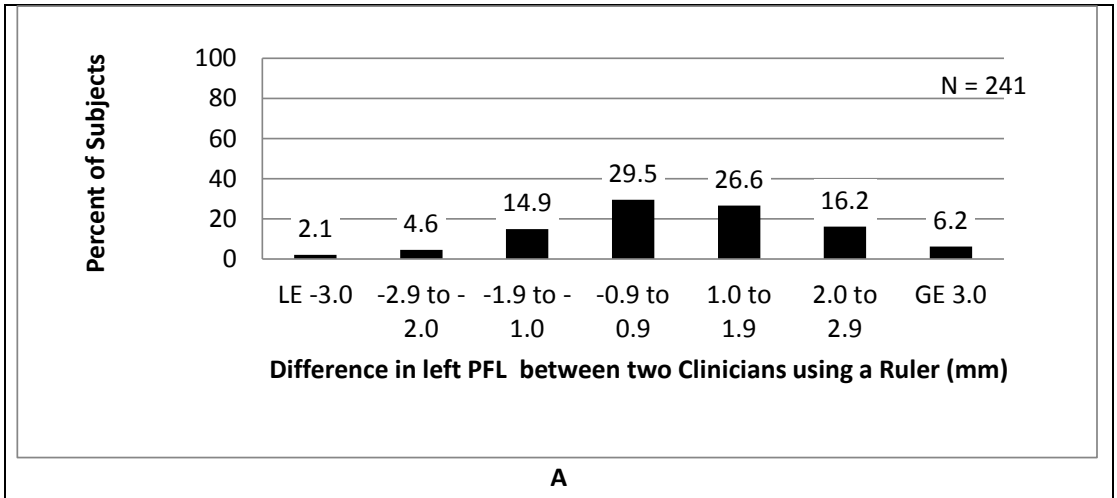

FIG. 9 ***Objective 2C:*** Ruler vs Ruler Measure. The prevalence and magnitude of discordance is illustrated when the left PFLs of 241 patients were measured by both the author and the medical doctor using a 15 cm ruler. The columns represent how often the two measures were 1 or more mm diffferent. A negative difference reflected the doctor's measure of the left PFL was longer than the author's measure. A positive difference reflected the doctor's measure of the left PFL was shorter than the author's measure. Since the smallest unit of measure on the ruler was 1 mm, the two clinicians' measures of the PFL were considered a match if they were within plus or minus 0.9 mm of one another.

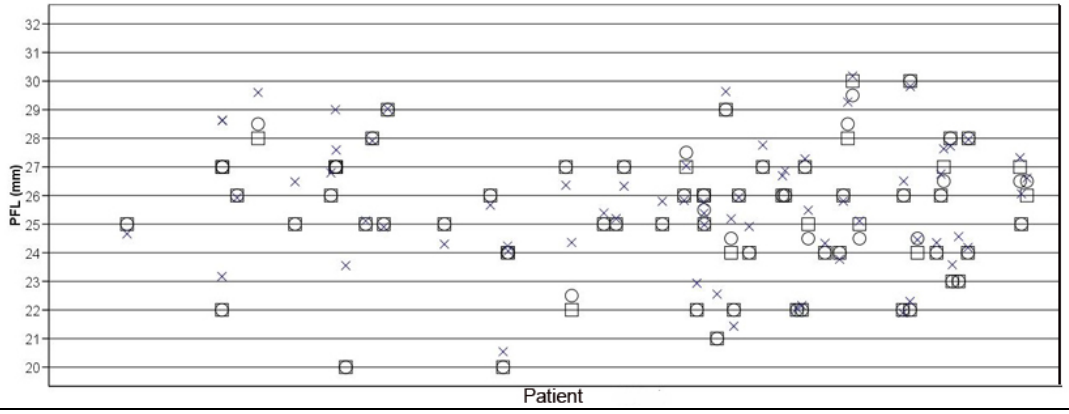

FIG. 10 ***Objective 2C***: Ruler vs Ruler vs Software Measures of the 71 (29.5%) patients in Fig. 9 with concordant ruler measures (measures within 0.9 mm of one another). It is important to note that when the two PFL measures obtained with a ruler were concordant (within 1 mm of one another), this does not confirm the PFL measures were correct. The two measures could be concordant and both incorrect. This figure documents that15 of the 71 patients with concordant PFL ruler measures have one or more ruler measures that are discordant (greater than 1 mm different) from the Software measure Key: Circle = Clinician 1. Square = Clinician 2. X = Software measure.

Objective 2C. Ruler Variability:

Ruler versus Ruler

When patients (n = 241) had their PFLs measured by two different individuals (the medical doctor and the author), the PFL measures were within 1 mm of one another 29.5% of the time (Fig. 9). One mm is the smallest unit of measure marked on the ruler. The PFL measures were 2 or more mm different 29.1 % of the time. Most importantly, the measures were discordant (1 or more mm different) 70.5% of the time. Despite the absence of a gold standard (caliper) measure of the patients' PFLs, one can still conclude that at least 70.5% of the patients had their PFL measured incorrectly by at least one of the two clinicians. It is also important to note that when the two PFL measures obtained with a ruler were concordant (within 1 mm of one another), this does not confirm the PFL measures were correct. The two measures could be concordant and both incorrect. The majority of these 241 patients also had their PFLs measured from a photo using the Software. Figure 10 documents how often the two ruler measurements matched the Software measurement among the 71 (29.5%) patients with concordant ruler measurements. If the Software measures are assumed accurate (as demonstrated in Objective 1), then 15 of the 71 patients with concordant PFL ruler measures have one or more ruler measures that are discordant (greater than 1 mm different) from the Software measure. This would suggest that 77% of the patients had their PFLs measured incorrectly (greater than 1 mm error) with a ruler by at least one of the two clinicians.

DISCUSSION

The data presented in this report confirm that the FAS Facial Photographic Analysis Software generates accurate measures of the PFL from a 2D digital facial photograph when compared to the gold standard. The gold standard was a sliding digital caliper with the caliper prongs placed directly in contact with the endocanthion and exocanthion landmarks that define the PFL. This measurement accuracy was confirmed prior to the

release of the Software. The release of the Software was contingent on its ability to generate accurate measures of the FAS facial features.

The data presented in this report also demonstrate the prevalence and magnitude of error when a patient's PFL is measured directly with a ruler. The prevalence and magnitude of this error was well known prior to the release of the Software.[4,8,9] One of the primary reasons the Software was developed was to overcome this error.

In 2004, a document was posted on the FAS DPN website demonstrating the Software's ability to accurately measure a PFL. The author's PFLs were measured with a ruler, with a caliper, and with the Software (Table 1). Photos of each measure were taken to document the outcomes. These data are included in this report (Fig. 4) to demonstrate the PFL is measured accurately whether obtained from a mannequin or human.

Two other investigative teams[10-12] have reported on the discordance of ruler, caliper, and Software measures of the PFL. Since neither study included a gold-standard measurement of the PFL, neither study could comment on the accuracy of any of the three methods of measurement. Inclusion of a gold standard of measurement in our study allowed us to confirm the technical accuracy of the FAS Facial Photographic Analysis Software. This confirmation provides some helpful context for comparing our outcomes to those reported in these two previous studies.

In the first study, the PFLs of 40 children (2 months to 15 years old) referred for a FASD evaluation were measured using both a ruler and the Software.[10,11] The number of clinicians involved was not reported. Avner et al[10,11] reported their Software measures of the PFLs were on average 2 mm shorter than their ruler measures across all 40 children; and 3 mm shorter among the subset of 21 children under 4 years of age. These contrasts are 3 to 4-fold greater than observed in our study. Our Software measures were on average 0.7 mm longer (not shorter) than the ruler measures across 1,027 patients measured by one of 21 clinicians, and 0.9 mm longer among the subset of 166 patients under 4 years of age. Since our study demonstrated the Software measures a PFL within 0.2 mm of a gold standard caliper measure in a properly standardized photograph, the 2.0 mm to 3.0 mm contrast between their ruler and Software measures cannot be explained by Software error. Contrasts that are 2.0 mm to 3.0 mm in magnitude are the result of User error. The investigators discuss the types of User error that may occur when measuring a PFL with a ruler (e.g., patient cooperation, examiner's skill), but there are also opportunities for User error when measuring a PFL with the Software (e.g. poor photo quality, eyes not fully open, inaccurate identification of landmarks by User, etc). These sources of error are discussed more fully below. The investigators went on to compare the number of children identified with PFLs 2 or more SDs below the mean using the ruler and Software methods of measurement. The ruler method identified 9 children; the Software method identified 14 children.

The investigators concluded "*The method of computer-assisted measurement tends to underestimate the true length and, hence, over diagnose short palpebral fissure, especially in children under four years old "*. The study methodology does not support this conclusion because the study did not have a measure of the "true" length of the palpebral fissure. The 'true' length of the palpebral fissure would require use of a gold standard method of measurement. The study did not incorporate a gold standard measure of the PFL. The investigators also computed sensitivity and specificity and reported "*Since the photographic method tends to overestimate the number of short PFLs (sensitivity=100%, specificity=64%), it is likely to over-diagnosis FAS. Therefore, telediagnosis would be most useful if it were followed by direct measurement, (since the photographic method alone produced false positives, but no false negatives*)." Once again the study methodology does not support this conclusion. Sensitivity and specificity require a gold standard measure of the PFL to represent the "true positive". The study had no gold standard measure of the PFL. Thus the study cannot compute the sensitivity or specificity for the ruler or the Software. Our current study demonstrates that it is highly unlikely that direct measurement of the PFL with a ruler would provide a more

accurate measure than the Software when the software is used properly.

In the second study a single clinician measured the PFLs of 50 children and 50 adults using all three tools (Software, ruler, and caliper).[12] Cranston et al[12] reported their Software measures were concordant with their ruler measures 42% of the time. This is consistent with our findings. We observed concordance between our Software measures and ruler measures 44.7% of the time across 1,027 patients measured by one of 21 clinicians. Cranston et al[12] also reported their Software measures were concordant with their caliper measures only 18% of the time. This is in stark contrast with our results. We observed 100% concordance between our Software and caliper measures of the PFL. The most likely reason their Software and caliper measures were discordant was because the Software was measuring the actual PFL and the caliper was measuring an approximation of the PFL. This is illustrated in their Figures 2 and 1B, respectively. Since their subjects were human, they could not obtain an accurate PFL with a caliper because it was too dangerous to place the prongs of the caliper directly on the individual's endocanthion and exocanthion landmarks that define the PFL. We used mannequins in our study to overcome this limitation.

Although the present study has demonstrated that the FAS Facial Photographic Analysis Software is programmed to accurately measure a PFL from a properly standardized 2D digital facial photograph, this does not mean that every measure of a PFL using the Software is accurate. The PFL measures obtained using the Software are only as accurate as the quality of the photo and the skills of the Software User. To minimize User error, the Software comes with detailed instructions and a practice case "John Doe" (Fig. 5A). The practice case serves two purposes. 1) It provides the User with an example of what a perfect set of standardized digital photographs (frontal, ¾, and lateral views) looks like. John Doe's photos display the following qualities: They are focused, well lit, high resolution, and properly aligned. John has no smile, his lips are gently closed, and his eyes are fully open. These qualities are not only important for accurate photo analysis of FAS facial features, they are also important when the facial features are being measured directly with a ruler and Lip-Philtrum Guide. 2) The Software also provides the User with an opportunity to practice measuring John Doe's photos to confirm they have the necessary skills to derive accurate measures. The Software comes with John Doe's photo set fully and accurately measured and permanently stored in the Software. When measuring facial features with the Software, whether for clinical or research purposes, it is imperative the User ensure and report the quality of the photos measured. It is also important they confirm they can measure John Doe's' photoset with high inter-rater reliability (i.e., their measures of John Doe's facial features match the gold-standard measures recorded in the Software). They should also confirm they have high test-retest reliability (i.e., they obtain the same PFL and lip circularity measures across multiple photos they have taken of a single individual).

The Software is particularly helpful in obtaining accurate facial measures from small moving targets like toddlers. The photo not only renders the moving target motionless, but a toddler is far more likely to let you approach them with a camera than a PFL ruler. While it may prove challenging at times to take a properly aligned photo of a toddler on the move, there are a number of tricks that will help you achieve this. Conduct the photo session in a small quiet room. Take multiple photos to ensure capture of the eyes and lips in proper repose. Keep in mind the eyes can be measured from one photo and the lips from another photo, if both could not be captured properly in a single photo. And if all else fails, simply set your camera to video mode, record 15-20 seconds of video, and capture the single frame or two where the facial features are in proper repose. Perhaps the greatest advantage of the photo over direct measure is the photo provides a permanent record which will prove invaluable for medical and research purposes.

CONCLUSIONS

In summary, the FAS Facial Photographic Analysis Software measures the PFL with the same accuracy as a sliding digital caliper, as it was programmed to do. Direct measurement of the PFL with a ruler is highly prone to error, even among clinicians who have measured hundreds of PFLs. Direct measurement of the PFL with a caliper is far too dangerous at any age, and should not be used.

The essential role of growth deficiency in the diagnosis of fetal alcohol spectrum disorder

Susan J. Astley [1*], Julia M. Bledsoe [1], Julian K. Davies [1]

1 University of Washington, Seattle, WA, USA

Abstract

Background: Laboratory studies confirm prenatal alcohol exposure (PAE) causes growth deficiency (GD). GD has traditionally been a core diagnostic feature of fetal alcohol spectrum disorders (FASD), but was removed from the Canadian and Australian FASD diagnostic guidelines in 2016. This study aimed to empirically assess the clinical role and value of GD in FASD diagnosis.

Methods: Data from 1814 patients with FASD from the University of Washington Fetal Alcohol Syndrome Diagnostic & Prevention dataset were analyzed to answer the following questions: 1) Is there evidence of a causal association between PAE and GD in our clinical population? 2) Is GD sufficiently prevalent among individuals with PAE to warrant its inclusion as a diagnostic criterion? 3) Does GD aid the diagnostic team in identifying and/or predicting which individuals will be most impaired by their PAE?

Results: GD significantly correlated with PAE. GD was as prevalent as the other core diagnostic features (facial and CNS abnormalities). GD occurred in all FASD diagnoses and increased in prevalence with increasing severity of diagnosis. The most prevalent form of GD was postnatal short stature. GD was as highly correlated with, and predictive of, severe brain dysfunction as the FAS facial phenotype. Individuals with GD had a two to three-fold increased risk for severe brain dysfunction. Sixty percent of patients with severe GD had severe brain dysfunction. GD accurately predicted which infants presented with severe brain dysfunction later in childhood

Conclusions: GD is an essential diagnostic criterion for FASD and will remain in the FASD 4-Digit Code.

Introduction

Fetal alcohol syndrome (FAS) is a birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The term FAS was first coined in 1973 [1,2], and is characterized by growth deficiency (GD), a specific cluster of minor facial anomalies, and central nervous system (CNS) structural and/or functional abnormalities. Not all individuals exposed to and damaged by prenatal alcohol exposure (PAE) have FAS. Rather, PAE causes growth, facial, and CNS abnormalities that each present along a continuum of abnormality from mild, moderate, to severe [3,4]. Taken together, these outcomes present along a continuum of diagnoses under the umbrella of fetal alcohol spectrum disorder (FASD): FAS, partial FAS (PFAS), static encephalopathy/alcohol-exposed

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

(SE/AE), and neurobehavioral disorder/alcohol-exposed (ND/AE).

GD has traditionally been a core diagnostic feature of FAS [5]. The original small group of patients from which the term was first derived was identified, in large part, because of their GD [6,7]. It is common for a new condition/syndrome to be recognized among the most severe cases. Thus, over time, it became clear that FAS was reflective of the most severe end of the fetal alcohol spectrum. Decades of laboratory and clinical-based studies unequivocally confirmed that PAE causes GD [8–12]. Nevertheless, not all individuals with PAE present with GD, and not all individuals with GD have PAE, so the question was raised as to whether GD should have been included as a core diagnostic feature of FAS.

In the 2016 revisions of the Canadian [13] and Australian [14] FASD diagnostic guidelines, GD was removed as a diagnostic criterion for FASD. The Canadian guidelines present the following justifications for removing GD:

1. Growth deficiency is neither sensitive nor sufficiently specific to indicate a diagnosis of FASD.
2. The predictive value of growth deficiency has been questioned.
3. FAS was 'discovered' in 1973 because a group of children referred to a clinic for growth deficiency were later found to have other features of what is now known as FAS.

The purpose of this study was to empirically assess the role and value of GD in FASD diagnosis. Laboratory studies confirm PAE causes GD. Is there evidence of a causal association between PAE and GD in our clinical population? Is GD sufficiently prevalent among individuals with PAE to warrant inclusion as a diagnostic criterion? The most debilitating aspect of FASD is CNS dysfunction. Does the presence of GD aid the clinical team in identifying and predicting which individuals will be most impaired by their PAE? The results of this study will be used to determine whether the FASD 4-Digit Diagnostic Code [3,4] described below maintains or removes GD as a core FASD diagnostic feature.

Methods

Data from 1814 patients evaluated consecutively from January 1993 through December 2012 at one of the University of Washington Fetal Alcohol Syndrome Diagnostic and Prevention (WA FASDPN) clinics were used in this study. The data source was the WA FASDPN research database. All patients evaluated at the WA FASDPN clinics are invited to have their FASD clinical data entered into the WA FASDPN research database, at the time of their diagnostic evaluation, for use in future research studies. Patient/caregiver consent is obtained in accordance with University of Washington Human Subjects Division oversight and approval. All patients were diagnosed in accordance with (or upgraded to) the 2004 FASD 4-Digit Diagnostic Code [3,4].

The FASD 4-Digit Code is described in full by Astley [3,4]. Briefly, the four digits reflect the magnitude of expression of the four key diagnostic features of FASD, in the following order: 1) growth deficiency, 2) FAS facial phenotype, 3) CNS structural/functional abnormalities, and 4) prenatal alcohol exposure (Figure 2A). The magnitude of expression of each feature is ranked independently on a four-point Likert scale, with 1 reflecting complete absence of the FASD feature, and 4 reflecting a strong 'classic' presence of the FASD feature. Each Likert rank is specifically case-defined. A total of 102 4-Digit Codes fall broadly under the umbrella of FASD. These codes cluster under four clinically meaningful FASD diagnostic subcategories: fetal alcohol syndrome (FAS), diagnostic categories A and B; partial FAS (PFAS): diagnostic category C; static encephalopathy/alcohol-exposed (SE/AE), diagnostic categories E and F; and neurobehavioral disorder/alcohol-exposed (ND/AE), diagnostic categories G and H. Each diagnosis has a version with and without GD (Table 1).

The 4-Digit Code takes a unique approach to ranking GD, placing emphasis on height deficiency over weight deficiency. Below are the instructions provided to clinicians for how to document growth deficiency using the FASD 4-Digit Code [3].

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

Table 1. FASD 4-Digit Code diagnoses with and without growth deficiency

With growth deficiency	Without growth deficiency
fetal alcohol syndrome (Categories A, B)	partial fetal alcohol syndrome (Category C)
static encephalopathy / alcohol-exposed (Category E)	static encephalopathy / alcohol-exposed (Category F)
neurobehavioral disorder / alcohol-exposed (Category G)	neurobehavioral disorder / alcohol-exposed (Category H)

What type of GD are we looking for?

We are looking for GD characteristic of a teratogenic insult, not of postnatal environmental factors such as nutritional deprivation or chronic or acute illness. We want to answer the question *'What is the patient's growth potential after controlling for parental height and postnatal environmental influences?'* GD of teratogenic origin is likely to present as a relatively consistent impairment over a period of time (i.e., the patient's growth follows the normal curve, but is below genetic expectation for family background). In contrast, GD caused by postnatal environmental influences is likely to present as periodic fluctuations in the curve. Separating the two growth patterns requires astute clinical judgment.

The method described below allows one to rank a patient's overall growth pattern on a single four-point Likert scale with 1 equal to 'normal' and 4 equal to 'significantly deficient'. Not all patients will have complete growth curves available; therefore, a guide is provided below to prioritize the ranking of the patient's growth over a lifetime.

How to measure and rank growth

A. The height percentile should be age-adjusted and gender-adjusted. Because there is a significant genetic component in attained stature, adjustment for mid-parent stature is also recommended when both parents' heights are known.

B. The weight percentile should be age-adjusted and gender-adjusted. Weight is not adjusted for height. Valid growth charts should be used. We recommend electronic computation of percentiles for increased accuracy. The FASDPN clinic uses the Hall [15] birth weight and length growth charts for gestational age; World Health Organization (WHO) [16] height and weight growth charts for children 0–2 years of age; the WHO [16] occipital–frontal circumference (OFC) charts for children 0–5 years of age; the Centers for Disease Control (CDC) 2000 [17] height and weight growth charts for patients 2 years of age and older, and the Nellhaus [18] head circumference growth charts for children 5–18 years of age.

C. For ranking purposes, the growth record is separated into two parts:

1. Prenatal growth (birth measures)

2. Postnatal growth (all measures collected after birth, i.e. infancy through adulthood)

Select the part of the growth record with the greatest deficiency in the height percentile.

If the prenatal height percentile is lower than all postnatal height percentiles, proceed to section D for instructions on how to rank prenatal growth.

If any of the postnatal height percentiles are lower than the prenatal height percentile, select the point or consecutive points in the growth record that reflect the lowest height percentiles that cannot be attributed to postnatal environmental influences such as nutritional deprivation or chronic illness. If the height deficiency is reflected in a series of points in the growth record, as opposed to a single point, rank the level of deficiency based on the percentile range where the majority of the points fall. Proceed to section D for instructions.

Table 2. Deriving the ABC-Score for growth

	Circle the ABC-Scores for:	
Percentile range	Height	Weight
≤ third	C	C
>third and ≤ 10th	B	B
>10th	A	A

D. Rank the level of deficiency of the height and weight percentiles, for the part of the growth record with greatest deficiency in the height percentile by

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

circling A, B, or C in the ABC-Score table at the bottom of page 1 of the FASD Diagnostic Form (Table 2).

The height and weight percentiles selected for ranking should be matched sets. For example, if the height at 10 years of age is selected for ranking, the corresponding weight percentile at 10 years of age should also be selected for ranking.

E. Next, refer to Table 3 to determine the 4-Digit Diagnostic rank of the Height–Weight ABC-Score recorded in Table 2. Transfer the resulting 4-Digit Diagnostic rank for growth to the 4-Digit Diagnostic Code Grid at the top of page 1 of the FASD Diagnostic Form.

Table 3. Converting the Growth ABC-Score to a 4-Digit Diagnostic Rank for growth

4-Digit diagnostic Rank	Growth deficiency Category	Height–weight ABC-Score combinations*	Percentile translation
4	Severe	CC	Height and weight ≤ third
3	Moderate	CB, BC, CA, AC	Height or weight ≤ third
2	Mild	BA, BB, AB	Neither height nor weight < third and both not > 10^{th}
1	None	AA	Height and weight > 10^{th}

*The ABC-Scores outlined in dark borders are defined by the information provided in the surrounding cells

Statistical analyses

Descriptive statistics (means, standard deviations (SD), valid percentages) were used to profile the study population. Chi-squared and Fisher Exact tests were used to compare groups and linear trends across groups for outcomes measured on nominal or ordinal scales. One-way analysis of variance (ANOVA) with Student–Newman–Keuls (SNK) multiple comparison posthoc tests were used to compare means and detect linear trends across three or more groups when outcomes were measured on a continuous scale. T-tests and paired T-tests were used to compare means between two groups for independent or paired subject groups. Logistic regression (forward stepwise with *P*-value for entry = 0.05 and *P*-value for removal = 0.10) was used to determine the odds of severe CNS dysfunction (CNS Rank 3) among patients with growth deficiency, FAS facial features, and/or microcephaly. Logistic regression was also used to assess the association between PAE and prenatal and postnatal growth deficiency after adjustment for prenatal tobacco exposure. This study had 80% power at a 95% level of confidence to detect a 50% increase in the odds of a classification of CNS Rank 3 (odds ratio (OR) = 1.50) for subjects with growth deficiency or FAS facial features relative to subjects without growth deficiency or FAS facial features.

Results

Study population

The study population included 1814 individuals with PAE diagnosed across the full spectrum of FASD (Table 4, Figure 1). Ages ranged from infant to adult (0.2 to 50.9 years of age) with 60% of subjects being of school-age (6–18 years old). The population was 42% female and 48% Caucasian.

Prevalence and profile of GD

Thirty-five percent of subjects presented with height and/or weight ≤ 10^{th} percentile, with postnatal short stature the most common form of GD.

The GD criterion for FAS is commonly defined by height and/or weight ≤ 10^{th} percentile at any time across the lifespan (Astley, 2011). Four key measures documenting growth are age-adjusted and gender-adjusted percentiles for birth length, birth weight, height at diagnosis, and weight at diagnosis.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

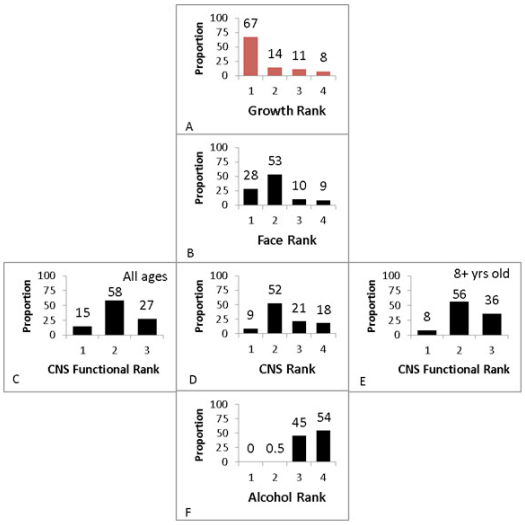

Figure 1. FASD 4-Digit Code Ranks for growth, face, central nervous system , and alcohol for 1814 subjects

Bars reflect the proportion of the population receiving Ranks 1–4 for each diagnostic feature. Face Ranks: 1 = no features; 2 = 1 or 2 features; 3 = 2.5 features; 4 = all 3 FAS facial features. Central nervous system (CNS) Ranks: 1 = normal function; 2 = moderate dysfunction; 3 = severe dysfunction; 4 = structural brain abnormalities. Alcohol Ranks: 1 = no prenatal exposure; 2 = unknown exposure; 3 = confirmed exposure to moderate levels; 4 = confirmed exposure to high levels. CNS functional Ranks: subjects with CNS Rank 4 are reclassified in accordance with their functional CNS Rank (1, 2 or 3). CNS functional Rank is presented across all ages (N = 1814). Fifty-two percent of the population was too young (< 8 years old) at the time of diagnosis to confirm or rule out CNS Rank 3 classification, thus the 27% CNS Rank 3 is an underestimate of the true prevalence of severe dysfunction. To portray a more accurate prevalence of severe CNS dysfunction (36%) observed in this alcohol-exposed population the CNS functional Ranks for the 870 subjects aged 8 years and older at the time of diagnosis is presented.

When each of these measures was assessed independently, 5.7–11.6% were ≤ third percentile, and 14.0–24.4% were ≤ 10th percentile (Table 5). GD criteria for FAS, however, require these four measures be assessed collectively (e.g., what proportion of subjects present with height and/or weight ≤ 10th percentile at any time across the lifespan?). When viewed collectively, the prevalence of GD increased.

Table 4. Study population (N = 1,814): demographic and clinical characteristics

ADVANCES IN PEDIATRIC RESEARCH

Eighteen percent of patients presented with growth ≤ third percentile, and 35% presented with growth ≤ 10th percentile. Among the 35% with GD, the most common form of GD was postnatal short stature (69.3%) (Table 5). GD manifested differently across the lifespan (Table 6).

Table 5. Profile of growth deficiency at birth and at the age of diagnosis

Growth measures	Total N	n	Valid %	n	Valid %
Gestational age < 37 weeks	1396	367	26.3	--	--

6.0–12.9	805	155	20.6	98	12.1
13.0–18.9	281	54	19.3	25	8.9
19.0–51.9	82	29	35.8	12	14.8
Among the 639 with height or weight ≦ 10th percentile at birth or at diagnosis		At birth		At diagnosis	
Proportion with height deficiency	639	164	38.2	443	69.3
Proportion with weight deficiency	639	213	41.4	285	44.6

While the majority of patients with height and/or weight deficiency presented with these deficiencies postnatally at the time of their diagnosis, 22% of subjects with height deficiency were only height-deficient at birth, and 39% of subjects with weight deficiency were only weight-deficient at birth.

The 4-Digit Code provides a more comprehensive view of the collective pattern and magnitude of GD across the population (Fig. 2). The height and weight ABC-Scores for this population document that height deficiency ≤ 10th percentile (ABC-Scores B and C) was more prevalent (29%) than weight deficiency (20%) (Fig. 2A1, 2A2). Nineteen percent of patients presented with growth ≤ third percentile (Growth Ranks 3 and 4: height and/or weight ≤ third percentile) and 33% presented with growth ≤ 10th percentile (Growth Ranks 2, 3 and 4: height and/or weight at or below the 10th percentile) (Fig. 2C). Height and weight percentiles were rarely concordant in an individual. Only one-third of the subjects presenting with growth deficiency had both height and weight moderately (ABC-Score = BB) or severely deficient (ABC-Score = CC) (Fig. 2B).

GD was as prevalent as the other core diagnostic features of FASD (i.e. FAS facial features and CNS abnormalities).

The prevalence of Rank 3 (11%) and Rank 4 (8%) GD (Fig. 1) was near-identical to the prevalence of Rank 3 (10%) and Rank 4 (9%) expressions of the FAS facial phenotype (Fig. 1). However, not everyone with Rank 3 or 4 facial phenotypes had Rank 3 or 4 GD. Only 37% (130/349) of those with Rank 3 or 4 GD (height and/or weight ≤ third percentile) had Rank 3 or 4 facial phenotypes, and only 38% (130/340) of those with Rank 3 or 4 facial phenotypes had Rank 3 or 4 GD. In contrast, 87% (305/349) with Rank 2, 3, or 4 GD (height or weight ≤ 10th percentile) had Rank 3 or 4 facial phenotypes. The prevalence of GD ≤ 10th percentile (Growth Ranks 2, 3 and 4) (33%) is equivalent to the prevalence of severe CNS structural/functional abnormalities (CNS Ranks 3 and 4) (39%) and the prevalence of severe CNS dysfunction (CNS Rank 3) (36%) among subjects who were 8 years of age and older (Fig. 1).

Table 6. Discordance between height and weight deficiency ≤ 10th percentile at birth and age of diagnosis

Parameter	Total*	Growth-deficient subgroup**	N (% of total) % of growth-deficient subgroup		
	N	N	Height deficiency only	Weight deficiency only	Height and weight deficiency
At birth	1162	243	69 (5.9) 28	79 (6.8) 33	95 (8.2) 39
At diagnosis	1814	509	224 (12.3) 44	66 (3.6) 13	219 (12.1) 43
			GD at birth only	GD at diagnosis only	GD at birth and diagnosis
Height	1170	352	79 (6.8) 22	188 (16.1) 53	85 (7.3) 24
Weight	1387	351	136 (9.8) 39	138 (9.9) 39	77 (5.6) 22

*Total N reflects the number of subjects with data for both parameters being addressed in that row (e.g., At birth, 1,162 subjects had both height and weight data available at birth)

**The growth-deficient subgroup reflects the number of subjects with growth deficiency ≤ 10th percentile for each parameter being addressed in that row (e.g., at birth, 243 subjects had height and/or weight ≤ 10th percentile)

Growth profiles changed with age: height percentiles decreased and weight percentiles increased.

Among the 1162 patients with height and weight measures recorded in the FASDPN database at birth and at diagnosis, their mean birth weight percentile (48.0, SD = 31) was significantly lower than their mean birth length percentile (52.9, SD = 33) (paired T = 6.0, $P = 0.000$) (Fig. 3). Later in life, at the time of diagnosis, their mean weight percentile (51.0, SD = 32) was significantly higher than their mean height percentile (40.3, SD = 30) (paired T = –14.3, $P = 0.000$). Their mean weight percentile increased slightly but significantly by 3 percentage points after birth (paired T = 2.9, $P = 0.004$). In contrast, their mean height percentile decreased substantially (by 12.5 percentage points) and significantly after birth (paired T = –11.7, P = 0.000).

Growth patterns were comparable between females and males, with females being approximately 3–5 percentile points smaller in size. Of the 164 subjects with birth lengths ≤ 10th percentile, 52% had height percentiles later in life that were ≤ 10th percentile. Of the 174 subjects with birth weight ≤ 10th percentile, 37% had weight percentiles later in life that were ≤ 10th percentile.

Although FAS is defined by GD at any time across the lifespan (birth through adulthood), the 4-Digit Code Growth Rank was based on birth measures only 18% (324/1814) of the time.

FASD diagnostic guidelines, including the 4-Digit Code, allow prenatal and/or postnatal evidence of GD to meet criterion for FAS. It is important to note that when ranking growth using the 4-Digit Code, the clinician first separates the growth curve into two parts: 1) prenatal growth, i.e. birth measures; and 2) postnatal growth, i.e. all measures subsequent to birth (infancy through adulthood). Growth is then ranked based on the part of the growth curve presenting with the lowest height percentile. The 4-Digit Code emphasizes height deficiency; this is because weight gain and loss is more easily influenced by other risk factors such as nutrition and illness. Using this more prescribed approach, we queried how often the Growth Rank was derived from birth measures, and how often the birth length percentile was lower than all height percentiles measured later in life (infancy through adulthood).

Within our cohort, 1163 (64%) patients had both their birth lengths and birth weights recorded. The 4-Digit Code allows only height and weight measures taken on the same day to be used to rank growth. Of the

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

1163 subjects, only 324 (28%) had their Growth Rank derived from birth measures. In other words, only 28% had a birth length percentile that was lower than all subsequent height percentiles measured later in life. Not all of these 324 subjects were GD at ≤ 10th percentile: Rank 4, N = 22 (7%); Rank 3, N = 39 (12%); Rank 2, N = 47 (15%); and Rank 1, N = 216 (67%). Across the entire cohort of 1814 subjects, Growth Rank was derived from birth measures in only 18% of patients (324/1814). This finding is key to addressing our next question: is GD correlated with PAE in this clinical population?

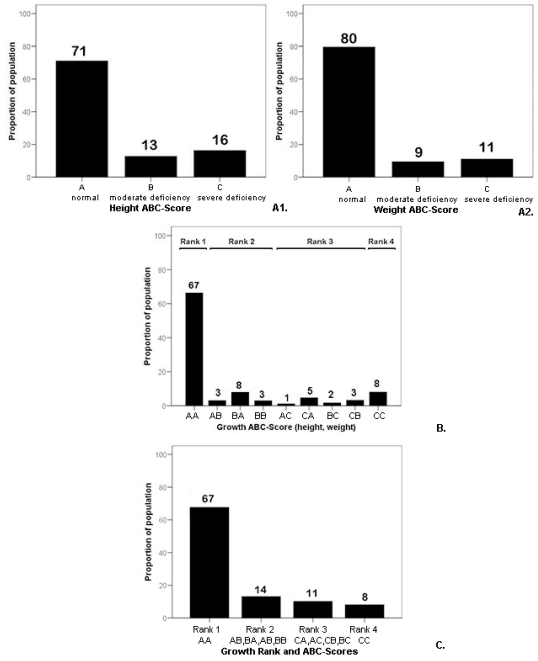

Figure 2. Prevalence and pattern of growth deficiency among 1814 subjects

A) Prevalence of 4-Digit Code height ABC-Score and weight ABC-Score (A = > 10th percentile, B = >third and ≤ 10th percentile; C = ≤ third percentile.). B) Prevalence of 4-Digit Code Growth ABC-Scores (the two letters reflect the height and weight ABC-Scores respectively). C) Prevalence of the 4-Digit Code Growth Ranks.

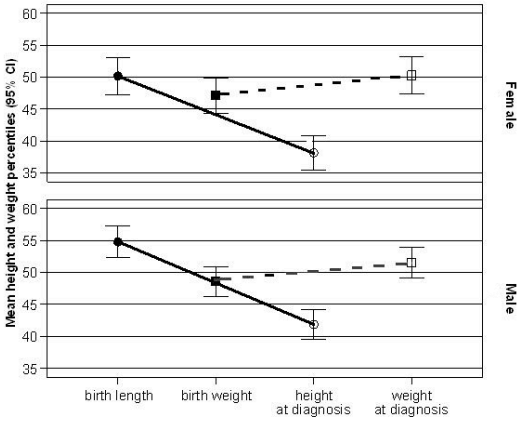

Figure 3. Growth profiles changed with age: height percentiles decreased and weight percentiles increased

Among 1162 patients with height and weight measures at birth and later in life at the time of diagnosis, paired analyses documented the mean weight percentile (dotted line) increased slightly, but significantly with age. The mean height percentile decreased substantially with age (solid line). At birth, mean weight was significantly lower than mean length. Later in life, at the time of diagnosis, mean height was significantly lower than mean weight. Growth patterns were comparable between females and males with females roughly 3–5 percentile points smaller in size. CI, confidence interval.

Correlation between PAE and GD

Growth deficiency, as uniquely ranked by the 4-Digit Code, was significantly correlated with PAE after controlling for other risk factors, including prenatal tobacco exposure.

The mean number of days per week of alcohol exposure during pregnancy increased linearly and significantly with increased GD Rank (Fig. 4A). The prevalence of prenatal exposure to tobacco was high (86–91%), but did not vary significantly with Growth Rank (Fig. 4B). Smoking status was available for 63% of the population. Growth Rank in this clinical population of 1,814 patients was derived from birth measures only 18% of the time, thus smoking status had very little impact on the correlation detected in Fig. 4A between alcohol exposure and the 4-Digit Code Growth Rank.

Since the analyses above document that the 4-Digit Code Growth Rank was based on postnatal growth measures 82% of the time, we looked at other

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

postnatal risk factors (physical/sexual abuse, foster care placement) that may impair childhood growth. The prevalence of these individual factors did not increase with increasing Growth deficiency Rank (Fig. 4B.). To the contrary, the prevalence of physical/sexual abuse and out-of-home placement was lowest among those with the most severe GD (Growth Rank 4).

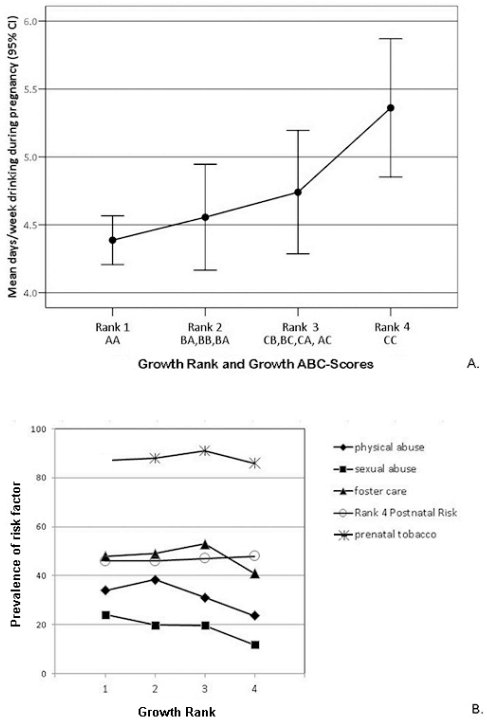

Figure 4. Growth deficiency was significantly correlated with PAE after control for other risk factors including tobacco

A) The mean number of days per week of drinking during pregnancy increased linearly with increased growth deficiency measured by Growth Rank (n = 968, one-way ANOVA: F = 4.5, P = 0.004, linear F = 12.4 P = 0.000). Error bars reflect 95% confidence intervals. The Growth ABC-Scores are defined in Tables 2 and 3. B) The prevalence of prenatal exposure to tobacco was high (86–91%), but did not vary significantly with Growth Rank. The prevalence of other postnatal risk factors that may impair growth (trauma, foster placement) did not increase with increasing Growth Rank.

Finally, the 4-Digit Code generates a composite measure of postnatal risk for each patient, called the Postnatal Risk Rank, that documents the number and severity of all adverse postnatal conditions the patient experienced on a 4-point scale (1= no risk, 2 = unknown risk, 3 = some risk, 4 = high risk).

The prevalence of patients experiencing the highest level of overall postnatal risk (Rank 4) did not vary across the four Growth Ranks (Fig. 4B).

PAE was significantly correlated with preterm birth (< 37 weeks of gestation) and postnatal short stature (height ≤ 10th percentile).

Univariate analyses document that mean percentiles for birth length, birth weight, and height at diagnosis were significantly lower among subjects with PAE across all three trimesters than among subjects with PAE only in the first trimester (T = 2.1, P = 0.04; T = 2.3, P = 0.02; T = 2.2, P = 0.03, respectively) (Fig. 5A). Mean gestational age was marginally, but significantly lower among subjects with three trimesters of alcohol exposure (37.9 weeks, SD = 3.2) compared to subjects with exposure in just the first trimester (37.3 weeks, SD = 3.5) (T = 2.2, P = 0.03) (Fig. 5A). Clinically, the prevalence of preterm delivery (< 37 weeks of gestation) increased with increasing trimesters of exposure (first trimester only, 20%; first and second trimesters only, 23%; all three trimesters, 28%) (Chi^2 linear trend = 6.7, P = 0.01). Logistic regression documented that subjects with alcohol exposure across all three trimesters were at a 1.6-fold increased risk (95% CI 1.1–2.5) of postnatal short stature relative to subjects with alcohol exposure only in the first trimester. Prenatal tobacco exposure was not significantly associated with any postnatal growth outcomes (Fig. 5B) and did not attenuate the risk of postnatal short stature associated with PAE in the logistic regression analysis.

Prenatal tobacco exposure was significantly correlated with low birth weight.

Mean birth length percentile was significantly lower (53.2, SD = 33.5) among those with prenatal tobacco exposure than among those without prenatal tobacco exposure (64.4, SD = 32.0; T = 2.9, P = 0.004) (Fig.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

5B). Mean birth weight percentile was also significantly lower (48.1, SD = 31.2) among those with prenatal tobacco exposure than among those without prenatal tobacco exposure (55.2, SD = 31.0; T = 2.2, *P* = 0.03).

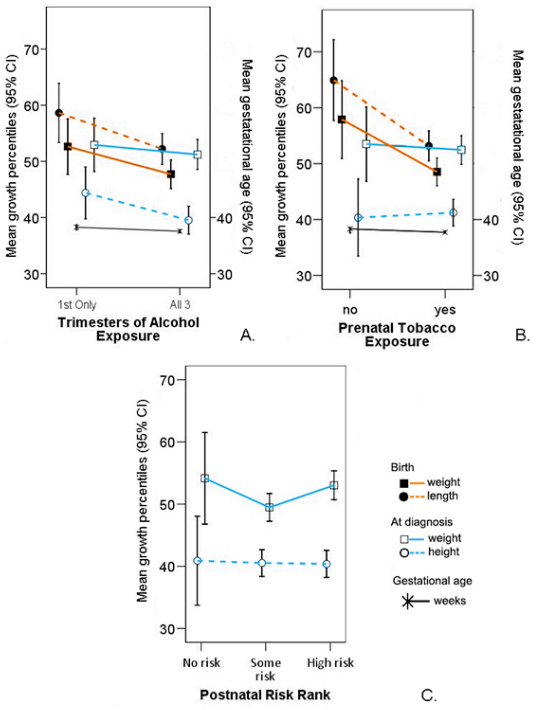

Figure 5. Prenatal alcohol exposure was significantly correlated with preterm birth and postnatal short stature

A) Mean percentiles for birth length, birth weight, and height at diagnosis were significantly lower among subjects with prenatal alcohol exposure all three trimesters compared to just the first trimester (T = 2.1, P = 0.04; T = 2.3, P = 0.02; T = 2.2, P = 0.03 respectively). B) Prenatal tobacco exposure was correlated with a significant reduction in prenatal, but not postnatal growth measures (birth length T = 2.9, P = 0.004; birth weight T = 2.2, P = 0.03). Growth Rank in this study sample of 1814 patients was derived from birth measures only 2.9% of the time, thus smoking status had very little impact on the correlation detected in Fig. 4A between alcohol exposure and the 4-Digit Code Growth Rank in our population. Mean gestational age in weeks was marginally, but significantly lower among those with three trimesters of alcohol exposure (37.9 weeks, SD = 3.2) compared to those with exposure in just the first trimester (37.3 weeks, SD = 3.5) (T = 2.2, P = 0.03). Mean gestational age was comparable between smokers and nonsmokers. C). Postnatal growth (mean height and weight percentiles at the time of diagnosis) did not vary significantly with increasing Postnatal Risk Rank, as defined by the 4-Digit Code.

Mean gestational age was comparable between those with (37.4 weeks, SD = 3.1) and without (37.6 weeks, SD = 3.9) prenatal tobacco exposure (Fig. 5B). Logistic regression documented that subjects with exposure to prenatal tobacco were at a 2.1-fold increased risk (95% CI 1.1–4.3) for birth weight ≤ 10th percentile relative to subjects with no tobacco exposure. Prenatal alcohol exposure did not attenuate this risk or further contribute to the risk for low birth weight.

Other postnatal risks (trauma, foster placement) were not associated with postnatal growth deficiency.

Postnatal growth (mean height and weight percentiles at the time of diagnosis) did not vary significantly with increasing Postnatal Risk Rank (1, no risk; 2, unknown risk; 3, some risk; 4, high risk) (Fig. 5C).

Growth deficiency was highly correlated with, and predictive of, CNS dysfunction

Growth deficiency was as highly correlated with severe CNS dysfunction as the FAS facial phenotype.

Among patients old enough to engage in comprehensive neuropsychological assessments (8 years of age and older), the prevalence of severe CNS dysfunction (CNS Rank 3) increased significantly and linearly with increasing GD as measured by the Growth Rank (Fig. 6A1). Mean Full Scale IQ was significantly lower among patients with moderate to severe GD (Ranks 3 and 4) compared to patients with normal or mild GD (Ranks 1 and 2) (Fig. 6A2). The correlations between growth deficiency and CNS dysfunction were near identical to the correlations between the FAS facial phenotype and CNS dysfunction (Fig. 6B1, 6B2).

GD occurs across the full spectrum of FASD diagnoses (FAS, PFAS, SE/AE and ND/AE). The more severe the diagnosis, the more prevalent and severe the GD.

All measures of growth (mean height and weight percentiles at birth and at the age of diagnosis) decreased linearly and significantly with increasing severity of FASD diagnosis (Fig. 7A). This was also

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

reflected in the Growth Rank. The prevalence of GD (Growth Ranks 2, 3 and 4) increased linearly with increasing severity of FASD diagnosis (Fig. 7B).

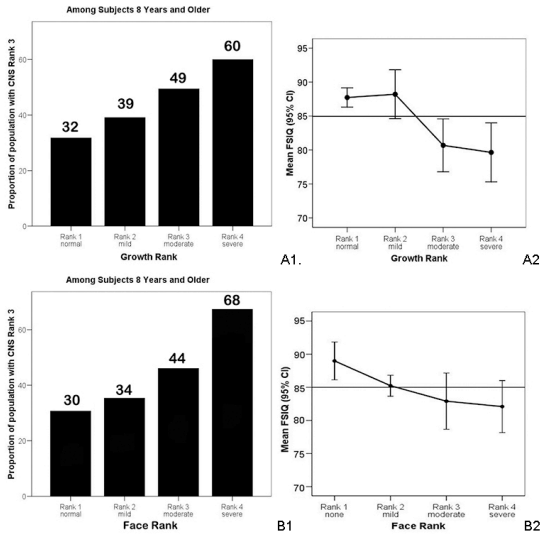

Figure 6. The correlation between growth deficiency and central nervous system (CNS) dysfunction was as strong as the correlation between the FAS facial phenotype and CNS dysfunction

A1). The prevalence of severe CNS dysfunction (CNS Rank 3) increased significantly with increasing Growth Rank among those aged 8 years and older at the time of diagnosis (i.e. those old enough to have CNS function assessed) (N = 871: Chi2 linear-by-linear association = 24.8, P = 0.000). A2) The mean FSIQ among subjects with Rank 3 or 4 growth deficiency was significantly lower than among subjects with Growth Ranks 1 or 2 (one-way ANOVA: F = 7.2, P = 0.000: SNK: Ranks 3, 4 < Ranks 1, 2). B1) The prevalence of severe CNS dysfunction (CNS Rank 3) increased significantly with increasing Growth Rank among those aged 8 years and older at the time of (N = 871: Chi2 linear-by-linear association = 24.8, P = 0.000). B2) The mean FSIQ among subjects with Rank 3 or 4 FAS facial phenotypes were significantly lower than among subjects with Rank 1 or 2 facial phenotypes (one-way ANOVA: F = 3.5, P = 0.02: SNK: Ranks 3,4 < Ranks 1,2).Chi2, Chi square test; CI, confidence interval; CNS, central nervous system; FSIQ, full scale intelligence quotient; SNK Student–Newman–Keuls test.

FAS has the lowest mean growth percentiles and the highest prevalence of GD (100%) because GD is required for a diagnosis of FAS, but the PFAS, SEAE, and NDAE diagnostic criteria do not require GD (height and/or weight ≤ 10th percentile). Nevertheless, even those with just moderate CNS dysfunction (ND/AE) presented with GD ≤ 10th percentile, albeit only half as often (24%) as those with PFAS (46%). Thus, the significant reduction in mean height and weight percentiles at birth and at the age of diagnosis with increasing severity of diagnosis (ND/AE, SE/AE and PFAS) further illustrates the correlation between growth and CNS impairment across the full spectrum of FASD.

Intercorrelation and concordance of GD, the FAS facial phenotype, and microcephaly

GD is highly correlated with the FAS facial phenotype and microcephaly, but not every patient with the FAS facial phenotype and/or microcephaly has GD.

The three core physical features of FASD are GD, the FAS facial phenotype, and microcephaly.

Although the presence of these features is highly intercorrelated, they are not 100% concordant within each patient. Patients do not present with all or none of these physical features (Table 7). For example, GD ≤ 10th percentile (Ranks 2–4) was present in 26% (n = 382) of 1470 subjects who did not present with the FAS facial phenotype (Rank 4) or microcephaly (occipital–frontal circumference [OFC] ≤ third percentile). Documentation of GD Rank 2, 3, or 4 in their FASD 4-Digit Code alerts clinicians that these 382 subjects are at a two-fold increased risk for severe CNS dysfunction, despite absence of the FAS facial phenotype and microcephaly. Almost half will present with severe CNS dysfunction later in childhood. Among the 172 patients who were old enough to fully assess CNS function (≥ 8 years old), 42% presented with severe CNS dysfunction (CNS Rank 3).

GD and the FAS facial phenotype

GD is highly correlated, but not highly concordant with the FAS facial phenotype.

Mean height and weight percentiles at birth and at the age of diagnosis decreased significantly with increasing severity of the FAS facial features Rank (Fig. 8A).

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

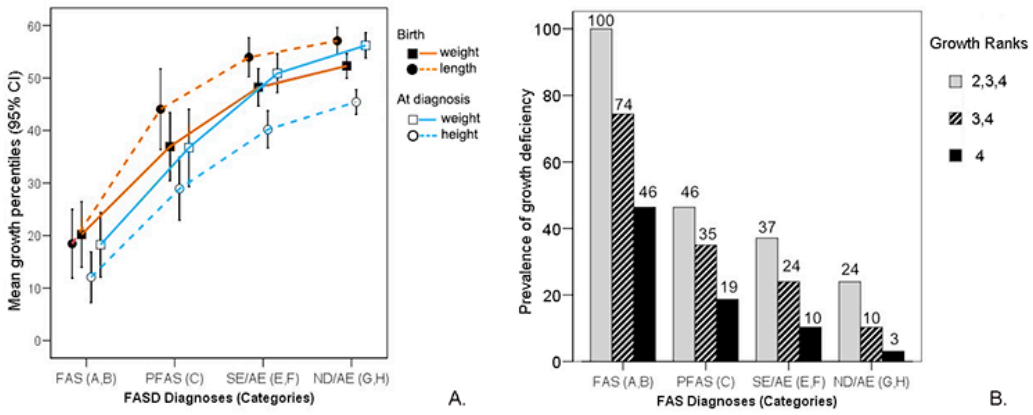

Figure 7. The more severe the FASD diagnosis, the more prevalent and severe the growth deficiency

A) Growth deficiency occurs across the full spectrum of FASD diagnoses (FAS, PFAS, SE/AE and ND/AE). All measures of growth (height and weight percentiles at birth and at the age at diagnosis) decreased significantly with increasing severity of FASD diagnosis (one-way ANOVA linear terms: F = 78.8, 72.0, 111.5, and 120.1 respectively; all P = 0.000). B) Clinically, the prevalence of patients with Growth deficiency Ranks 2, 3 and/or 4 increased significantly with increasing severity of FASD diagnosis (Chi2 linear-by-linear = 179, P = 0.000). The gray bars reflect individuals with height or weight < the 10th percentile. Striped bars reflect individuals with height or weight < third percentile. The black bars reflect individuals with height and weight < third percentile. CI, confidence interval; PFAS, partial FAS; SE/AE, static encephalopathy/alcohol-exposed; ND/AE, neurobehavioral disorder/alcohol-exposed.

Clinically, the proportion of patients with one, two, or all three of the FAS facial features increased significantly and linearly with increasing GD Rank (Fig. 8B).

Despite these significant correlations, most (83%) patients with GD (Growth Ranks 2, 3 and 4; N = 603) did not present with the Rank 4 FAS facial phenotype (N = 502) (Table 7). Since GD is a major predictor of severe CNS dysfunction in this population, excluding GD as a FASD diagnostic criteria would prevent clinicians from identifying those infants/toddlers under the age of 8 years who are at a two-fold increased risk for severe CNS dysfunction; dysfunction that will not be detectable until later in childhood. In our population, 44% (93/213) of children aged 8 years and older who presented with GD (Ranks 2–4), but not the Rank 4 FAS facial phenotype, had severe CNS dysfunction (CNS Rank 3).

GD and microcephaly

GD is highly correlated, but not highly concordant, with microcephaly.

The OFC percentile decreased significantly with decreasing birth length, birth weight, height at diagnosis, and weight at diagnosis percentiles (Pearson correlation coefficients: 0.33, 0.37, 0.42, and 0.52, respectively; all *P*-values = 0.000). Mean OFC decreased significantly and linearly with increased Growth Rank (one-way ANOVA, F = 311, *P* = .000) (Fig. 9A). Individuals with severe GD (Rank 4) had a mean OFC percentile of 11.6 (SD = 15) compared to 51.7 (SD = 27) among individuals with normal growth (Rank 1). Clinically, the prevalence of microcephaly (OFC ≦ third percentile) increased significantly and linearly with increased Growth Rank (Chi^2 linear-by-linear association = 309, *P* = 0.000) (Fig. 9B).

		4: severe	12	30 (71)	42
		Total	103	59 (36)	162
Grand total			1570	244 (13)	1814

*Correlations between Growth Ranks, Face Ranks, and presence of microcephaly: growth and face, $Chi^2 = 185.8$, $P = 0.0$; growth and microcephaly: $Chi^2 = 327.3$, $P = 0.0$; face and microcephaly: $Chi^2 = 132.0$, $P = 0.000$

Despite these significant correlations, most (71%) patients with GD (N = 603) did not have microcephaly (N = 426) (Table 7). Thirteen percent of the entire study population (244/1814) had microcephaly (OFC $\leq$ 3rd percentile). The distribution of Growth Ranks among these 244 subjects was: Rank 4 (34%), Rank 3 (23%), Rank 2 (16%), and Rank 1 (27%).

In contrast, 33% of the study population (603/1814) had GD (Growth Ranks 2, 3, or 4), and only 29% of those with GD (177/603) had microcephaly. Again, since GD is a major predictor of severe CNS dysfunction in this population, exclusion of GD as a FASD diagnostic criterion would prevent clinicians from identifying the infants/toddlers under 8 years of age that are at two-fold increased risk for severe CNS dysfunction; dysfunction that will not be detectable until later in childhood. In our population, 45% (86/192) of children aged 8 years or older who presented with GD (Ranks 2-4), but no microcephaly, had severe CNS dysfunction (Rank 3). Furthermore, 42% (72/171) of children aged 8 years or older who presented with GD (Ranks 2-4), but no microcephaly or Rank 4 FAS facial phenotype, had severe CNS dysfunction (Rank 3). Microcephaly and the FAS facial phenotype may be highly correlated with GD, but they cannot be used in lieu of growth measures to identify all infant/toddlers at risk for severe CNS dysfunction.

Can GD be used to predict which infants and toddlers will present with severe CNS dysfunction later in childhood when they are old enough to assess brain function?

Individuals with Growth Ranks 3 or 4 were twice as likely to present with severe CNS dysfunction than individuals with no GD.

Logistic regression analyses provided evidence that individuals with Growth Ranks 3 and 4 were at significantly greater risk for severe CNS dysfunction (CNS Rank 3) than individuals with normal growth (Rank 1) (Table 8). This risk was even higher for individuals presenting with FAS facial phenotypes at Ranks 3 or 4. Among 735 patients aged 9 years or older, and compared to patients with normal growth (Rank 1), those with Growth Rank 4 had a 1.96-fold greater risk of having CNS Rank 3, and patients with Growth Rank 3 had a 1.8-fold increased risk of having CNS Rank 3.

ADVANCES IN PEDIATRIC RESEARCH

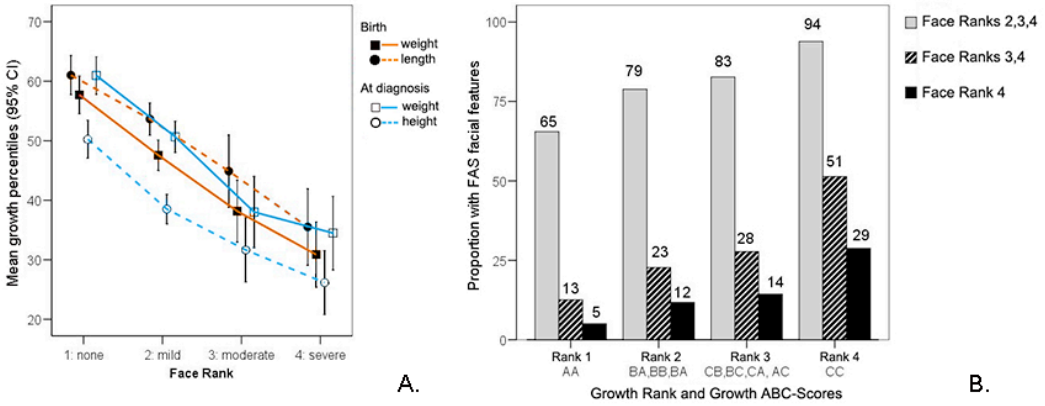

Figure 8. The more severe the growth deficiency, the more severe the FAS facial phenotype

A) Mean height and weight percentiles at birth, and at the age of diagnosis, decrease significantly with increasing severity of the FAS facial phenotype, (one-way ANOVA: birth length, F = 21.4; P = 0.000; birth weight, F = 30.3, P = 0.000; height at diagnosis, F = 36.8, P = 0.000; weight at diagnosis, F = 35.6; P = 0.000). B) Clinically, the proportion of patients with one, two or all three of the FAS facial features increased with increasing Growth deficiency Rank. (Chi2 linear-by-linear = 171, P = 0.000). . Gray bars reflect individuals with 1 to all 3 of the FAS facial features. Striped bars reflect individuals with 2.5 to all 3 facial features. Black bars reflect individuals with all 3 of the FAS facial features. CI, confidence interval.

Compared to patients with normal facial features (Rank 1), those with the full FAS facial phenotype (Rank 4) had a 3.8-fold increased risk of having CNS Rank 3, and patients with Face Rank 3 had a 1.9-fold increased risk of having CNS Rank 3.

Infants/toddlers with GD were twice as likely to have severe CNS dysfunction upon re-evaluation later in childhood.

Although most patients evaluated in the FASDPN clinic are seen only once, 46 subjects received a second diagnostic evaluation because they were too young (≦ 8 years of age) at their first evaluation to engage in the comprehensive neurocognitive assessment required to confirm or rule out severe CNS dysfunction (CNS Rank 3) (Table 9).

Data from these subjects allowed longitudinal assessment of how well GD (and the FAS facial features) predicted which toddlers/infants would present with severe CNS dysfunction (CNS Rank 3) upon re-evaluation later in childhood when they were old enough to engage in more comprehensive neurocognitive assessments. The 46 children were, on average, 4.3 years old (SD = 2.1) at their first evaluation, and 10.3 years old (SD = 3.4) at their second evaluation. Their gender, racial, and FASD diagnostic profiles matched that of the entire study population. GD and FAS facial features were highly predictive of who would present with severe CNS dysfunction (CNS Rank 3) later in childhood (Table 9).

These outcomes are consistent with the logistic regression outcomes described above. Seventy percent of infants/toddlers with Growth Ranks 2, 3, or 4 (9/13) received a CNS Rank 3 upon re-evaluation later in childhood. Only 46% (15/33) with Growth Rank 1 received a CNS Rank 3 upon re-evaluation. Risk of severe CNS dysfunction appeared to increase linearly with increasing severity of GD. Sixty-five percent of those with Face Ranks 2, 3 or 4 (22/34) received a CNS Rank 3 upon re-evaluation. Only 17% (2/12) with Face Rank 1 received a CNS Rank 3 upon re-evaluation (Fisher exact $P < 0.05$). Those with microcephaly were also at increased risk for severe CNS dysfunction.

Eighty percent of those with microcephaly received a CNS Rank 3 upon re-evaluation.

OPEN ACCESS Freely available online

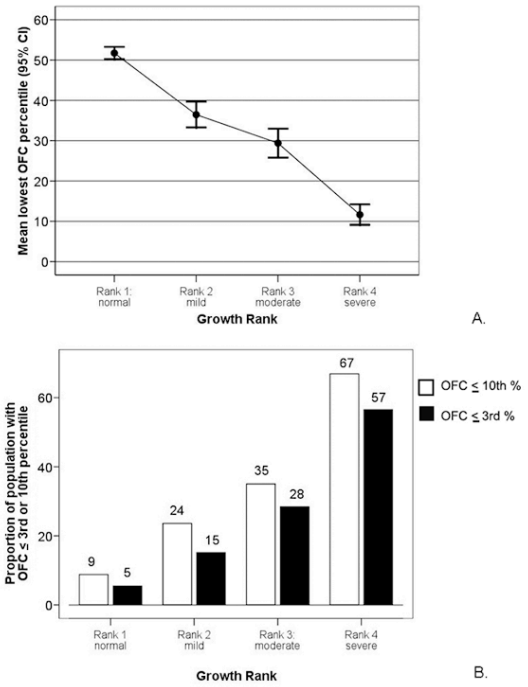

Figure 9. The more severe the growth deficiency, the smaller the head circumference

A) The mean OFC percentile decreased significantly and linearly with increasing Growth deficiency Rank. B) Clinically, the proportion of subjects with an OFC ≤ third percentile (black bars) or ≤ 10th percentile (white bars) increased significantly with increasing Growth deficiency Rank). CI, confidence interval; OFC, occipital–frontal circumference.

Only 49% of those with normal head circumferences received a CNS Rank 3 upon re-evaluation.

Does the risk of severe CNS dysfunction (Rank 3) increase when a patient presents with one, two, or all three of the sentinel physical features of FASD (GD, FAS facial features, and microcephaly)?

With the addition of each sentinel physical feature (GD; GD + FAS facial features; GD + FAS facial features + microcephaly) the prevalence of severe CNS dysfunction increased significantly from 41% to 56% to 67%.

Table 8. Individuals with growth deficiency or facial features were over 2-fold more likely to have severe CNS dysfunction†

	Frequency		Unadjusted		Adjusted for Face or Growth	
	N	CNS Rank 3* n (%)	OR	95% CI	OR	95% CI

4	59	39 (66%)	4.88	2.60–9.13	3.82	1.98–7.33

†Odds Ratio (OR) and 95% confidence intervals for the association between the 4-Digit Code Face and Growth Ranks and severe CNS dysfunction (CNS Rank 3) among 735 patients 9 years of age or older (old enough to accurately assess CNS function).

*CNS Rank 3 is defined by 3 or more domains of brain function, 2 or more SDs below the mean.

**Explanation: The odds of CNS rank 3 for a patient with Rank 4 growth are 1.96 times the odds of CNS Rank 3 for a patient with Rank 1 growth, all other things being equal. 95% confidence intervals that do not include 1.00 are statistically significant at $p < 0.05$.

The prevalence of severe CNS dysfunction (CNS Rank 3) increased significantly among subjects who presented with one or more of the sentinel physical features of FAS (GD, FAS facial features, and/or microcephaly) (Table 10). Prevalence of CNS Rank 3 increased with increasing magnitude of GD and increased number of sentinel physical features. The data shown in Table 8 are from children aged 8 years and older – these children were deemed old enough to engage in a sufficient level of functional assessment to confirm or rule out a CNS Rank 3 classification.

†Among 46 subjects with two evaluations when they were on average 4 and 10 years of age, respectively, those with growth deficiency, FAS facial features, or microcephaly at the first diagnostic evaluation were more likely to present with severe CNS dysfunction (CNS Rank 3) at their second diagnostic evaluation.

*Chi^2 linear-by-linear association 3.7; $P < 0.05$. ** Fisher exact for Rank 1 vs Ranks 2,3,4 $P < 0.05$. *** Fisher's Exact Test $P = 0.20$

OFC, occipital–frontal circumference

A CNS Rank 3 requires 3 or more domains of function (e.g., intellect, executive function, language, memory, etc) to be two or more standard deviations below the mean on standardized tests administered by professional clinicians. Severe CNS dysfunction occurred in 30% of patients with none of the sentinel physical features. With the addition of each sentinel physical feature (GD $\leq 10^{th}$ percentile [Ranks 2, 3 and 4], FAS facial features [Ranks 3 and 4], and microcephaly $\leq$ third percentile), the prevalence of severe CNS dysfunction increased significantly from 41% to 56% to 67%, respectively.

Table 10. Prevalence of severe CNS dysfunction among 854 subjects† that presented with sentinel physical features

Sentinel physical feature(s) present	Proportion with CNS Rank 3: severe dysfunction			
	Growth Ranks 2,3,4 Height and/or weight $\leq 10^{th}$ %		Growth Ranks 3,4 Height and/or weight $\leq 3\%$	
	%	n	%	n
None	30	153/514	31	182/594
Growth deficiency only	41*	63/153	47*	34/73
Growth and face	56*	20/36	68*	13/19
Growth, face, and microcephaly	67*	18/27	68*	17/25

† Subjects are 8 years of age and older presenting with one or more sentinel physical features of FASD

* Chi^2, $P < 0.05$ when compared to prevalence of CNS Rank 3 when no features present

Microcephaly is occipital–frontal circumference (OFC) ≤ third percentile. Face includes Face Ranks 3 and 4. Growth reflects the definitions in the two column headings

Discussion

Since the discovery of FAS in 1973 [1,2,6,7], GD has been a core diagnostic feature of FASD [3–5,19]. Based on the findings of this study (see Appendix), and near identical findings published by Carter et al. [20], we recommend that GD should remain a core diagnostic feature of FASD.

GD is caused by PAE

Laboratory studies have unequivocally confirmed that PAE causes prenatal and postnatal GD [8,10,11]. However, attributing the extent of GD that is caused by PAE in a clinical population is challenging because of the multitude of other prenatal and postnatal adverse exposures and events that also contribute to GD, such as prenatal tobacco exposure, trauma, and neglect [19,21]. Nevertheless, in our population, postnatal short stature was the most prevalent form of GD in our clinical population, and

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

was significantly correlated with PAE after controlling for these other risk factors.

Our findings are remarkably consistent with the literature, both past and present. For example, as far back as 1998, Habbick et al. [22] concluded, "*despite retarded bone age readings, children with FAS do not show significant catch-up growth in height, although they do show relative gain in weight. Short stature can be used as a diagnostic criterion in individuals with FAS beyond childhood, whereas thinness is a less reliable feature.*" More recently, in a review of growth among children prenatally exposed to drugs, Nordstrom-Klee et al. [12] report that while growth deficits caused solely by prenatal cigarette exposure are unlikely to persist beyond infancy, the effects of prenatal exposure to alcohol on growth continue well into childhood. In one study, Greene et al. [23] found PAE to negatively affect average preschool height, but not weight. This difference persisted after controlling for the use of other substances and background factors. Carter et al. [20] recently reported that, among children with heavy PAE, "*children born small for gestational age (SGA) with postnatal growth restriction (height ≦ 10th percentile) were most heavily exposed. Exposure was intermediate for those born SGA with catch-up growth and lowest for those without prenatal or postnatal growth restriction. Effects on neurocognition were strongest in children with both prenatal and long-term growth restriction, more moderate in those with fetal growth restriction and postnatal catch-up, and weakest in those without growth restriction*".

The strong correlation between GD and the FAS facial features in our study provide further support that PAE is contributing to the GD observed in our clinical population. It is well understood that GD is not specific to (caused only by) PAE, but the FAS facial phenotype is. The fact that GD correlates with both the FAS Facial Rank and PAE leaves little doubt that PAE is contributing to GD in our clinical population.

GD is prevalent

Second, GD is not a rare outcome among individuals with PAE. In fact, it occurred in 33% of our clinical population and was as prevalent as the other core diagnostic features of FASD (the FAS facial features and severe CNS dysfunction). GD also occurred across the full spectrum of FASD, not just among those with full FAS. Over the decades, clinicians, including us, have questioned whether GD should ever have been included as a diagnostic criterion, since the small group of children from whom the term FAS was coined in 1973 came from a failure-to-thrive clinic [2,6,7]. Clearly, they all had GD; but were they a representative sample of all individuals with FAS? The results of our study affirm that they were. Individuals with PAE who present with GD and the FAS facial phenotype present with the most severe CNS dysfunction. In our clinical population, 92% of patients with GD and the FAS facial phenotype also presented with severe CNS abnormalities and met the criteria for FAS. As the prevalence and severity of GD decreases, so does the prevalence and severity of the FAS facial features and CNS dysfunction. The result is a spectrum of FASD diagnoses that correlate linearly with the spectrum of GD (FAS: 100% GD; PFAS: 46% GD; SE/AE: 37% GD; ND/AE: 24% GD).

GD is highly correlated with, and predictive of, CNS dysfunction

Finally, and perhaps of greatest clinical importance, GD is highly correlated with and predictive of CNS dysfunction. Many studies have documented the correlation between GD – especially short stature – and cognitive/behavioral dysfunction [24,25]. In our clinical population with PAE, we too found highly significant linear correlations between GD (especially postnatal short stature) and CNS dysfunction – this finding is especially important when evaluating infants and toddlers with PAE. Most children with cognitive or other developmental challenges caused by PAE do not fully exhibit these challenges until they reach school-age. For example, half of the children in our clinical population diagnosed with full FAS had normal Bayley developmental scores as infants; thus, it would be a mistake to interpret their early normal development as evidence that PAE caused no harm. Although infants and toddlers are too young to engage in a comprehensive assessment of brain function, their growth and facial features are

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

easily measured. This study has confirmed that GD is as powerful a predictor of severe CNS dysfunction as the FAS facial features. Infants and toddlers with PAE, normal early development, and Rank 3 or 4 GD were two to three-fold more likely to present with severe CNS dysfunction later in childhood than those without GD. Those with Rank 3 or 4 FAS facial phenotypes were two to five-fold more likely to present with severe CNS dysfunction. Those with both GD and the FAS facial features were almost assured of presenting with severe CNS dysfunction later in childhood. GD is an indispensable tool for the early identification of infants/toddlers at the highest risk for severe CNS dysfunction. Infants and toddlers with PAE who present with GD and/or the FAS facial phenotype should be referred to, and should qualify for, early intervention to mitigate this risk.

Conclusions

The outcomes of this study empirically confirm and illustrate the role of GD in the diagnosis of, and early intervention for, FASD. We will continue to include GD as a core diagnostic feature of FASD in the 4-Digit Code for the following reasons:

1. Laboratory studies confirm PAE causes GD. The 4-Digit Code Growth Rank documents GD attributable to PAE.
2. GD is not only prevalent across the full spectrum of FASD; it is as prevalent as the other core diagnostic features (e.g., the FAS facial features and CNS abnormalities).
3. GD is not only highly correlated with severe CNS dysfunction, but is highly predictive of severe CNS dysfunction. In fact, GD is so highly predictive of severe CNS dysfunction, it should be used to identify those infants/toddlers with PAE who are at high risk for severe CNS dysfunction, and qualify them for early intervention services – despite apparently normal early development.

Appendix. Summary of key findings

1. GD is as prevalent as the other core diagnostic features of FASD (the FAS facial features and CNS abnormalities).
    a. 19% had GD $\leqq$ third percentile (Growth Ranks 3 and 4)
        - 19% had the FAS facial features (Face Ranks 3, 4)
        - 18% had CNS structural/neurological abnormalities (CNS Rank 4)
    b. 33% had GD $\leqq 10^{th}$ percentile (Growth Ranks 2, 3 and 4)
        - 36% had severe CNS dysfunction (CNS Rank 3)
2. GD $\leqq 10^{th}$ percentile occurs across the full spectrum of FASD diagnoses and increases significantly in prevalence with increasing severity of diagnosis (ND/AE 24%; SE/AE 37%; PFAS 46%; FAS 100%).
3. The profile of GD changes with age, with the most prevalent form being postnatal short stature.
    a. Weight is more deficient (by 5 percentile points) than length at birth.
    b. Height is more deficient (by 11 percentile points) than weight later in life (infancy to adulthood).
    c. The mean weight percentile increases slightly and significantly (by 3 percentage points) with age.
    d. The mean height percentile decreases substantially and significantly (by 13 percentage points) with age.
    e. These patterns are comparable between males and females.
4. The 4-Digit Code uses a unique method for documenting GD across a patient's lifespan. Growth is ranked based on the section of the patient's growth curve, prenatal (birth) or postnatal (infancy-adulthood) that has the lowest height percentile. Using this approach on the 1162 patients with growth measures at birth and diagnosis:
    a. 72% of Growth Ranks were based on postnatal growth.
    b. The height percentile was lowest at birth in only 28% of subjects.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

5. Although GD is caused by many risk factors including prenatal tobacco exposure, the 4-Digit Code Growth Rank uniquely captures the GD associated with PAE because:
    a. Prenatal tobacco exposure impairs prenatal growth, not postnatal growth. This is reported in the literature [12] and observed in our dataset.
    b. PAE impairs postnatal growth, not prenatal growth, with its greatest impact on postnatal short stature. This is reported in the literature [9] and observed in our dataset.
    c. Since the 4-Digit Code ranks growth based on the age when the height percentile was lowest, this resulted in 82% of the growth ranks for 1814 subjects being derived from postnatal measures of growth. Since tobacco does not influence postnatal growth, this explains why the 4-Digit Growth Rank is significantly correlated with PAE and not with prenatal tobacco exposure in our dataset.
    d. Postnatal risks (neglect, abuse, multiple home placements) did not impair postnatal height percentiles, but were associated with a slight increase in weight percentiles.
6. GD is as highly correlated with severe CNS dysfunction as the FAS facial phenotype.
    a. The prevalence of severe CNS dysfunction (CNS Rank 3) increased significantly and linearly with increasing Growth Rank (Growth Rank 1 (32%); Rank 2 (39%); Rank 3 3 (49%); Rank 4 (60%)).
    b. The prevalence of severe CNS dysfunction (CNS Rank 3) increased significantly and linearly with increasing Face Rank(Face Rank 1, 30%; Rank 2, 34%; Rank 3, 44%; Rank 4, 68%).
7. Growth Rank is as predictive of severe CNS dysfunction as the 4-Digit Code FAS Face Rank.
    a. Individuals with Growth Ranks 3 and 4 (height and/or weight $\leqq$ third percentile) had a two to three-fold increased risk for severe CNS dysfunction. This finding was statistically significant.
    b. Individuals with Face Ranks 3 and 4 (2.5 to all 3 of the FAS facial features) had a two to five-fold increased risk for severe CNS dysfunction. This finding was statistically significant.
    c. GD was especially powerful in predicting which infants/toddlers with PAE and normal early development presented with severe CNS dysfunction later in childhood.
8. GD is highly correlated, but not highly concordant, with the FAS facial phenotype and microcephaly.
    a. Mean height and weight percentiles at birth, and at the age of diagnosis, decreased significantly with increasing severity of the FAS facial phenotype.
    b. The prevalence and magnitude of microcephaly increased significantly with increasing magnitude of GD.
    c. Despite these significant correlations, most patients with GD (83% and 71%, respectively) do not have the Rank 4 FAS facial phenotype or microcephaly. Thus, it is necessary to document GD to identify most individuals with PAE at risk for severe CNS dysfunction.

Letter to the Editor Regarding Coles, Gailey, Mulle, Kable, Lynch, and Jones (2016): A Comparison Among 5 Methods for the Clinical Diagnosis of Fetal Alcohol Spectrum Disorders

Susan Astley

To the Editor:

IN THIS LETTER to the Editor, I discuss a study conducted by Coles and colleagues (2016) that took on the important task of comparing the outcomes of 5 fetal alcohol spectrum disorder (FASD) diagnostic systems when retroactively applied to the records of 1,581 patients. Valid comparisons require valid administration of each diagnostic system. The purpose of this Letter to the Editor is to share with readers the methods used, but not reported, that influenced the outcomes of this study. These additional details will allow readers to more accurately interpret this study.

Coles and colleagues (2016) applied 5 FASD diagnostic systems: Emory, FASD 4-Digit Code, CDC, Canadian, and Hoyme (Astley, 2004, 2013; Bertrand et al., 2004; Blackston et al., 2005; Chudley et al., 2005; Coles et al., 1997; Hoyme et al., 2005) to the records of 1,581 patients. These patients received an evaluation at the Emory clinic for alcohol- and drug-exposed children between 1995 and 2011. Fifty-two percent of the population had a confirmed prenatal alcohol exposure and 46% of the population was African American. Data from records collected at the patient's evaluation were used to retrospectively render FASD diagnoses in accordance with the criteria for each diagnostic system. The purpose of their study was to compare the prevalence of fetal alcohol syndrome (FAS), partial FAS (pFAS), and alcohol-related neurodevelopmental disorder (ARND) across the 5 different diagnostic systems. The authors reported the percent of alcohol-related diagnoses by diagnostic system as follows:

- 4-Digit Code: FAS 0.25%, pFAS 12.97%
- Canada: FAS 1.83%, pFAS 10.31%
- CDC: FAS 4.74%, pFAS N/A
- Hoyme: FAS 12.21%p, FAS 22.83%
- Emory-20: FAS 13.73%p, FAS 16.13%

To derive these outcomes, the authors reported they administered the 4-Digit Code "fully consistent with instruction for clinical coding for this system (Astley, 2004) (Coles et al., 2016, p. 1004)." They went on to report "these 4-digit codes were then translated into diagnostic categories as recommended by this system (Astley, 2004)" (Coles et al., 2016, p. 1004). "In all cases when norms were required (e.g., palpebral fissure length, PFL), we used those recommended by the diagnostic systems themselves (Coles et al., 2016, p. 1001)." The authors offered to provide more detailed information on request.

Two outcomes caught my attention: (i) the strikingly low prevalence of FAS (0.25%) and (ii) the comparatively high prevalence of pFAS (12.97%) reported for the 4-Digit Code. These outcomes were in stark contrast to the diagnostic outcomes we observe in the University of Washington Fetal Alcohol Syndrome Diagnostic and Prevention Network (Astley, 2013). In our population of 2,496 patients with prenatal alcohol exposure receiving a FASD diagnostic evaluation using the 4-Digit Code between 1993 and 2016, the prevalence of FAS is 3.5% and the prevalence of pFAS is 5.5%. Our population is 7.4% African American. Their population was 46% African American. But the prevalence of FAS and pFAS is comparable across all races in our clinic population. The prevalence of prenatal alcohol exposure in their population was 52%; ours is 100%. If you recomputed the prevalence of FAS and pFAS among just those with prenatal alcohol exposure (FAS 0.48% and pFAS 24.94%), the prevalence estimates are even more discrepant from what we observe in our clinical population. In an effort to understand why their 4-Digit Code prevalence estimates were so discrepant from ours, I conversed with the authors and they were kind enough to provide me the following additional information regarding how they administered the 4-Digit Code. Below is how they redefined which 4-Digit Code Diagnostic Categories A-V were used to define each diagnosis.

- FAS: Categories A, B
- pFAS: Categories C, E, G

From the Department of Epidemiology (SA), University of Washington, Seattle, Washington.

DOI: 10.1111/acer.13268

- ARND: Categories F, H
- Other Diagnosis: Categories D, I to V

It is important to note that the 4-Digit Code case-defines pFAS as Diagnostic Category C only (Astley, 2004). Category C includes 20 different 4-Digit Code combinations that meet the 4-Digit Code's growth, facial, central nervous system (CNS), and alcohol exposure criteria for pFAS. In contrast, Coles and colleagues (2016) redefined the 4-Digit Code's diagnosis of pFAS to include diagnostic Categories C, E, and G. Diagnostic Category E is Sentinel Physical Findings/Static Encephalopathy/Alcohol-Exposed. Diagnostic Category G is Sentinel Physical Findings/Neurobehavioral Disorder/Alcohol-Exposed. Thus, in contrast to their published methods, the authors did not *translate the 4-Digit Codes into diagnostic categories as recommended by the system* (Astley, 2004). They redefined the 4-Digit Code's pFAS diagnosis. This increased the number of 4-Digit Codes that case-defined pFAS from 20 to 60, resulting in a substantially elevated prevalence of pFAS. In addition, although the authors reported they used the physical features and neurobehavioral deficit (defined as per each system), the physical features and neurobehavioral deficit for pFAS (as defined per the 4-Digit Code) were not used. For example, individuals in Diagnostic Category G have moderate CNS dysfunction. But, pFAS (as defined per the 4-Digit Code) requires severe CNS dysfunction. pFAS also requires the FAS facial phenotype be a Rank 3 or Rank 4. But, none of the individuals in Diagnostic Category E met this criterion.

The authors also reported that "In all cases when norms were required (e.g. PFL), we used those recommended by the diagnostic systems themselves" (Coles et al., 2016, p. 1001). This was not true for the 4-Digit Code. The 4-Digit Code requires African American PFL charts be used on African Americans (e.g., Iosub et al., 1985), because African Americans have PFLs that are significantly larger (2 to 3 mm larger) than Caucasians. This is illustrated in a study by Astley (2011). The authors used the Stromland Scandinavian (Caucasian) PFL charts (Stromland et al., 1999) on the 788 African Americans in their study population. In accordance with the 4-Digit Code, an individual must present with PFLs 2 or more standard deviations (SD) below the mean to meet 1 of the 3 required facial features for FAS. As African Americans have significantly larger PFLs than Caucasians, it would be near impossible for an African American to have PFLs 2 SDs below the mean on the Stromland Caucasian PFL chart. Their PFLs would have to be 3 to 4 SDs below the mean on an African American PFL chart to register as 2 SDs below the mean on the Stromland Caucasian PFL chart. As 46% of the authors' study population was African American (n = 788), use of the Stromland Caucasian PFL chart would have a significant impact on the prevalence estimates of FAS and pFAS. The prevalence of FAS would be substantially under estimated and prevalence of pFAS would be substantially over estimated. Upon request, the authors revealed the following FAS and pFAS diagnostic prevalence estimates for the 788 African American subjects who made up 46% of their study population:

- 4-Digit Code as revised by Coles and colleagues (2016): FAS n = 0 (0.0%), pFAS n = 119 (16.0%)
- Canadian: FAS n = 16 (2.2%), pFAS n = 85 (11.4%)
- CDC: FAS n = 39 (5.2%), pFAS N/A
- Hoyme: FAS n = 100 (13.5%), pFAS n = 175 (23.6%)
- Emory: FAS n = 117 (15.7%), pFAS n = 141 (19.0%)

As anticipated, not a single African American received a diagnosis of FAS using the 4-Digit Code. Also as anticipated, the prevalence of pFAS was unusually high (16%). The 4-Digit Code criterion for pFAS allows the PFL to be relaxed to 1 SD below the mean. The 4-Digit Code criteria for FAS requires the PFL to be 2 or more SDs below the mean. Use of the wrong PFL chart on the African Americans prevented them from meeting the −2 SD PFL criterion for FAS, but allowed many to meet the −1 SD PFL criterion for pFAS.

When the 4-Digit Code is administered in accordance with the published instructions, as it has been for patients evaluated in the UW FASDPN clinic over the past 24 years, the prevalence of FAS and pFAS among Caucasian and African American individuals with prenatal alcohol exposure is as follows: Caucasian (4% FAS, 6% pFAS) and African American (6% FAS, 10% pFAS). The prevalence of pFAS is higher than FAS, but <2-fold higher. In stark contrast, the revisions imposed on the 4-Digit Code by Coles and colleagues (2016) resulted in a prevalence of pFAS that was 52-fold higher than FAS (12.97% vs. 0.25%, respectively). The prevalence of pFAS relative to FAS for the other diagnostic systems ranged from <2-fold higher to 5-fold higher.

The Journal published an Erratum (2016) to alert Readers that the authors used a PFL growth chart for the 4-Digit Code that was not consistent with their published methods: "In all cases when norms were required (e.g. PFL), we used those recommended by the diagnostic systems themselves."

In the Erratum (2016), the authors expressed concern about the applicability of the Iosub PFL chart for African Americans. The chart is based on a relatively small sample (n = 170) and binned into age ranges (<1 year, 1 to 2, 3 to 5, and 6 to 15 years of age). Despite these constraints, the Iosub PFL chart is a more accurate reflection of African American PFLs than the Stromland Scandinavian (Caucasian) PFL chart. The 4-Digit Code uses the Iosub PFL chart because, to date, it is the only chart available for African Americans that addresses the full age span and it reports PFLs that are commensurate with other published African American PFL charts for adults, as detailed below. It is confirmed in both the published literature and in our 24-year clinical experience (Astley, 2011) that the PFL for African Americans is significantly larger (by 1.5 to 2.4 mm) than the Caucasian PFL. Starting at birth, Fuchs and colleagues (1980) reported the PFL was 1.5 mm longer among African American term

neonates (20.0 mm, 2.0 SD) compared to Caucasian neonates (18.5 mm, 1.3 SD). Among adults, Barretto and Mathog (1999) reported the PFL was 2.6 mm longer among African Americans (32.0 mm, 2.3 SD) compared to Caucasians (29.4 mm, 2.3 SD). Farkas and colleagues (2005) reported the PFL was 1.6 mm longer among African American adults (32.6 mm, 2.0 SD) compared to Caucasians (31.0 mm, 1.3 SD). Stromland and colleagues (1999) report the PFL for 18-year-old Scandinavians is 29.1 mm (1.6 SD), commensurate with the Caucasian PFL reported by Barretto and Mathog (1999) and Farkas and colleagues (2005). Iosub and colleagues (1985) report the PFL for African Americans 6 to 15 years of age is 33.0 mm (3.0 SD), commensurate with the African American PFL reported by Barretto and Mathog (1999) and Farkas and colleagues (2005). The magnitude of difference between African American and Caucasian PFLs necessitates the use of PFL charts normed to their respective races. African American PFL normal growth charts exist (Barretto and Mathog, 1999; Farkas et al., 2005; Fuchs et al., 1980; Iosub et al., 1985), but as we reported back in 2011 (Astley, 2011), would benefit from an update.

In conclusion, the prevalence of FAS, pFAS, and ARND reported for the 4-Digit Code do not reflect the 4-Digit Code or any published FASD diagnostic system. The 4-Digit Code case-definition for pFAS was substantially revised and the administration of the 4-Digit Code was not *fully consistent with instruction for clinical coding for this system,* as reported by the authors. As a result, the prevalence estimates for FAS, pFAS, and ARND reported for the 4-Digit Code cannot be validly compared to one another and cannot be validly compared to the diagnostic prevalence estimates reported for the other diagnostic systems.

CONFLICT OF INTEREST

The author declares she has no conflict of interest.

Comparison of the FASD 4-Digit Code and Hoyme et al. 2016 FASD diagnostic guidelines

Susan J. Astley [1*], Julia M. Bledsoe [1], Julian K. Davies [1], John C. Thorne [1]

1 University of Washington, Seattle, WA, USA

Abstract

Background: As clinicians strive to achieve consensus worldwide on how best to diagnose fetal alcohol spectrum disorders (FASD), the most recent FASD diagnostic systems exhibit convergence and divergence. Applying these systems to a single clinical population illustrates contrasts between them, but validation studies are ultimately required to identify the best system. Currently, only the 4-Digit Code has published comprehensive validation studies.

Methods: The 4-Digit Code and Hoyme 2016 FASD systems were applied to the records of 1,392 patients evaluated for FASD at the University of Washington to: 1) Compare the diagnostic criteria and tools used by each system, 2) Compare the prevalence and concordance of diagnostic outcomes and assess measures of validity.

Results: Only 38% of patients received concordant diagnoses. The Hoyme criteria rendered half as many diagnoses under the umbrella of FASD (n=558) as the 4-Digit Code (n=1,092) and diagnosed a much higher proportion (53%) as fetal alcohol syndrome/partial fetal alcohol syndrome (FAS/PFAS) than the 4-Digit Code (7%). Key Hoyme factors contributing to discordance included relaxation of facial criteria (40% had the Hoyme FAS face, including patients with confirmed absence of alcohol exposure); setting alcohol exposure thresholds prevented 1/3 with confirmed exposure from receiving FAS/FASD diagnoses; and setting minimum age limits for Alcohol-Related Neurodevelopmental Disorder prevented 79% of alcohol-exposed infants with neurodevelopmental impairment a FASD diagnosis. The Hoyme Lip/Philtrum Guides differ substantively from the 4-Digit Lip-Philtrum Guides and thus are not valid for use with the 4-Digit Code.

Conclusions: All FASD diagnostic systems need to publish comprehensive validation studies to identify which is the most accurate, reproducible, and medically valid**.**

ADVANCES IN PEDIATRIC RESEARCH

Introduction

As the field of fetal alcohol spectrum disorders (FASD) strives to achieve consensus worldwide on how best to diagnose FASD, the most recent versions of published guidelines (4-Digit Code, 2004 [1]) Canadian, 2015 [2], Hoyme et al., 2016 [3], and Australian, 2016 [4]) show both convergence and divergence. The new Canadian and Australian systems share many features in common, but diverge substantially from the 4-Digit Code and Hoyme et al. systems by dropping the growth deficiency criteria [5] and adopting a nomenclature (FASD with the face, and FASD without the face) that no longer reflects the spectrum of outcome. The 4-Digit Code [1] and Hoyme et al. [3] criteria continue to generate a spectrum of diagnoses under the umbrella of FASD (fetal alcohol syndrome (FAS), partial FAS (PFAS), Alcohol Related Neurodevelopmental Disorder (ARND), Static Encephalopathy/Alcohol Exposed (SE/AE), Neurobehavioral Disorder/Alcohol Exposed (ND/AE), and Alcohol Related Birth Defects (ARBD)) and maintain the 3 original core diagnostic criteria (growth deficiency, facial anomalies, and CNS abnormalities). The 4-Digit Code and Hoyme et al. systems differ in their diagnostic nomenclature, diagnostic tools, and the specific criteria used to generate each diagnosis. Comparing the diagnostic outcomes generated by the different systems when applied to a single clinical population serves to illustrate the major contrasts and similarities between the systems, but empirical validation studies are ultimately needed to identify the best system.

The objectives of this study were to: (1) compare the tools and criteria used by the 4-Digit Code and Hoyme et al. 2016 FASD diagnostic systems; and (2) administer each system to the records of 1,392 patients to compare the prevalence of FASD diagnoses produced by each system, assess diagnostic concordance between the two systems, and compare measures of validity applied to each system.

The outcomes of Objective 1 helped guide the study design (methods and study population) for Objective 2. Thus, the methods and results for Objective 1 are presented first, followed by the methods and results for Objective 2.

Objective 1. Comparison of the diagnostic tools and Criteria

Methods

Tools

Lip-philtrum guides: Both diagnostic systems provide 5-point, pictorial lip-philtrum guides for ranking the magnitude of philtrum smoothness and upper lip thinness. The 4-Digit Code provides two guides: Lip-Philtrum Guide 1 for Caucasians and all races with thinner upper lips like Caucasian, and Lip-Philtrum Guide 2 for African Americans and all races with thicker upper lips like African Americans (Figures 1 and 2). Hoyme et al. have also introduced two lip/philtrum guides: the North American Lip/Philtrum Guide [3] produced from a U.S. white population and the South African Mixed Race Lip/Philtrum Guide [6] produced from a Cape Coloured (mixed race) population in the Western Cape Province (Figures 1 and 2).

Philtrum: The Rank 1-5 philtrums depicted on the 4-Digit Code Caucasian and Hoyme et al. North American guides were visually compared to determine if the magnitude of philtrum depth or smoothness depicted by each Rank was comparable between the two guides (e.g. was the Rank 4 philtrum smoothness depicted on the 4-Digit Guide the same as the Rank 4 philtrum smoothness depicted on the Hoyme et al. Guide?). This visual comparison was repeated for the 4-Digit African American and Hoyme et al. South African guides.

Upper lip: The Rank 1-5 lips depicted on the 4-Digit Code Caucasian and Hoyme et al. North American guides were compared using the objective, quantitative measure of lip thinness called lip circularity (perimeter2/area) generated by the FAS Facial Photographic Analysis Software [7]. Circularity is computed by outlining the vermilion border of the upper lip with the mouse (Figure 2C); the thinner the lip, the bigger the circularity.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

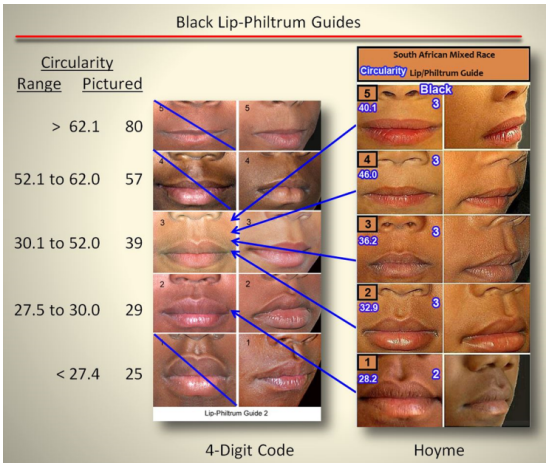

Figure 1. The Hoyme South-African Mixed-Race Lip/Philtrum Guide differs from the "African-American" 4-Digit Code Lip-Philtrum Guide 2

Upper lip: The objective measure of upper lip thinness (circularity = perimeter^2/area) is printed to the left of the 4-Digit Code Guide and in white font with a blue border on the Hoyme Guide. For example, the 4-Digit Code Rank 4 lip has a circularity of 57 and is defined by the range of circularities 52.1 to 62.0. The Hoyme Rank 4 lip has a circularity of 46.0, thus is equivalent to the 4-Digit Code Rank 3 lip. Circularity confirmed the Hoyme et al. Ranks 1, 2, 3, 4 and 5 lips were equivalent to the 4-Digit Ranks 2, 3, 3, 3, and 3 respectively. There are no lip images on the Hoyme et al. Guide that correspond to (fall within the circularity ranges that define) the 4-Digit Ranks 1, 4, or 5. Lips on the Hoyme et al. Guide do not increase in thinness in linear fashion as they do on the 4-Digit Code Guide 2. The Hoyme et al. Rank 5 lip is thicker (circularity 40.1) than the Hoyme et al. Rank 4 lip (circularity 46.0). Most importantly, the Hoyme et al. Rank 4 lip (the clinical cut-off for FAS) is thicker than the 4-Digit Code Rank 4 lip. The Hoyme et al. Rank 4 lip (circularity 46.0) falls within the circularity range depicted by the 4-Digit Rank 3 lip (30.1 to 52.0). The Hoyme et al. Rank 5 lip (circularity 40.1) is substantially thicker than the 4-Digit Rank 5 lip (circularity 80).
Philtrum: The Rank 1 through 5 philtrums depicted on both guides appeared broadly equivalent by visual inspection. Based on our findings and the findings of Hoyme et al. [6], the South African Mixed Race Lip/Philtrum Guide is not appropriate for use on an African American population. (South African Mixed Race Lip/Philtrum Guide used with permission from Wiley & Sons, Inc).

Lip Ranks 1-5 on the 4-Digit Code Lip-Philtrum Guides are case-defined by the range of lip circularities posted on the backside of each Lip-Philtrum Guide (Figure 2B). Lip circularity was computed for each lip on the Hoyme et al. North American Lip/Philtrum Guide. The lip circularities on the 4-Digit Code Caucasian and Hoyme et al. North American guides were compared to determine if the magnitude of lip thinness depicted by each Rank was comparable (e.g., was the Rank 4 lip thinness depicted on the 4-Digit Caucasian Guide the same as the Rank 4 lip thinness depicted on the Hoyme et al. North American Guide?). This comparison of lip circularities was repeated for the 4-Digit Code African American and Hoyme et al. South African guides

Facial analysis software: The 4-Digit Code advises measuring the facial features from 2D digital photos using the FAS Facial Photographic Analysis Software [7]. The authors of the Hoyme et al. system "feel direct examinations of facial features are more practical in an office setting." Since empirical studies have already confirmed the superior accuracy of the photo versus direct method of facial measurement [8, 9], a formal assessment of photo versus direct measurement of facial features was not repeated in this study.

Diagnostic nomenclature and criteria

Figures were created to illustrate the key contrasts between the diagnoses generated by each system, the nomenclature assigned to each diagnosis, and the diagnostic criteria.

Results

Tools: Contrasts in lip-philtrum guides

The Hoyme et al 2015 South African Mixed Race Lip/Philtrum Guide [6] does not match the "African American" 4-Digit Code Lip-Philtrum Guide 2 (Figure 1).

Philtrum: The Rank 1 through 5 philtrums depicted on both guides appeared broadly equivalent by visual inspection.

Upper lip: Circularity confirms the Hoyme et al. Rank 4 lip (the clinical cut-off for FAS) is thicker than the 4-Digit Code Rank 4 lip (e.g., it is equivalent to the 4-Digit Code Rank 3 lip).

ADVANCES IN PEDIATRIC RESEARCH

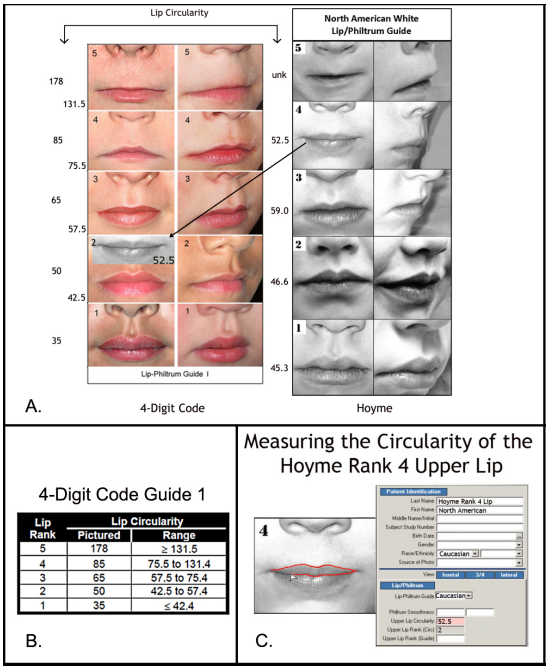

Figure 2. The Hoyme North-American White Lip/Philtrum Guide differs from the 4-Digit Code "Caucasian" Lip-Philtrum Guide 1

The Rank 1 through 5 philtrums depicted on both Guides appear broadly equivalent, but the upper lips are substantially different. A) Lip circularity (perimeter^2/area) is printed to the left of each guide. B) The range of circularities that define each 4-Digit Code Lip Rank are presented in the Lip Circularity table printed on the backside of the 4-Digit Code Lip-Philtrum Guide. C) The FAS Facial Photographic Analysis Software [7] computes circularity when the User outlines the vermilion border of the upper lip (click on video link for demonstration https://youtu.be/6SbiXF220PM). Lip circularity confirms that the Hoyme et al. Rank 1, 2, 3, 4 and 5 upper lips are equivalent to the 4-Digit Code Ranks 2, 2, 3, 2 and 5 respectively. There is no lip image on the Hoyme et al. Guide that reflects the 4-Digit Rank 1 or Rank 4 lips. The lips on the 4-Digit Guide become progressively thinner (circularity becomes progressively larger) with increasing Rank. This is not true for the Hoyme et al. Guide. The circularity of the Hoyme et al. Rank 4 lip (the clinical cut-off for FAS) is 52.5, confirming it falls within the circularity range of the 4-Digit Code Rank 2 lip. The black and white overlay (A) of the Hoyme et al. Rank 4 lip on the 4-Digit Code Guide 1 demonstrates both visually and numerically that the Hoyme et al. Rank 4 lip is substantially thicker than the 4-Digit Code Rank 4 lip. This analysis confirms the Hoyme et al. North American White Lip/Philtrum Guide is not a valid tool for use with the FASD 4-Digit Diagnostic Code.(North American White Lip/Philtrum Guide used with permission from the American Academy of Pediatrics).

Unlike the 4-Digit Code Lip-Philtrum Guide, the lips pictured on the Hoyme et al. Guide do not progressively become thinner as Rank increases and no lip on the Hoyme et al. Guide is equivalent to the 4-Digit Code Rank 1, 4 or 5 lips. Based on our findings here and the findings of Hoyme et al. [6], the South African Mixed Race Lip/Philtrum Guide is not appropriate for use on an African American population and thus was not used to address Study Objective 2. The study population for Objective 2 was adjusted accordingly (as described below) to accommodate this finding.

The Hoyme et al. 2016 [3] North American White Lip/Philtrum Guide does not match the "Caucasian" 4-Digit Code Lip-Philtrum Guide 1 (Figure 2).

Philtrum: The Rank 1 through 5 philtrums depicted on both guides appeared broadly equivalent by visual inspection.

Upper lip: Circularity (perimeter^2/area) confirms the Hoyme et al. Rank 4 lip (the clinical cut-off for FAS) is substantially thicker than the 4-Digit Code Rank 4 lip (e.g., it is equivalent to the 4-Digit Code Rank 2 lip). The 4-Digit Code defines the Rank 2 lip as within the normal range, slightly thicker than the population mean depicted by Lip Rank 3. Unlike the 4-Digit Code Lip-Philtrum Guide 1, the lips pictured on the Hoyme et al. Guide do not progressively become thinner as Rank increases and no lip on the Hoyme et al. Guide is equivalent to the 4-Digit Code Rank 1 or Rank 4 lips.

Despite the contrasts between the two lip/philtrum guides, both are intended for use on North American Caucasian populations and thus were used to address Objective 2 below.

Contrasts in diagnoses and nomenclature

The key contrasts between the 4-Digit Code and Hoyme et al diagnoses and nomenclature are highlighted in Figures 3 and 4, respectively.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

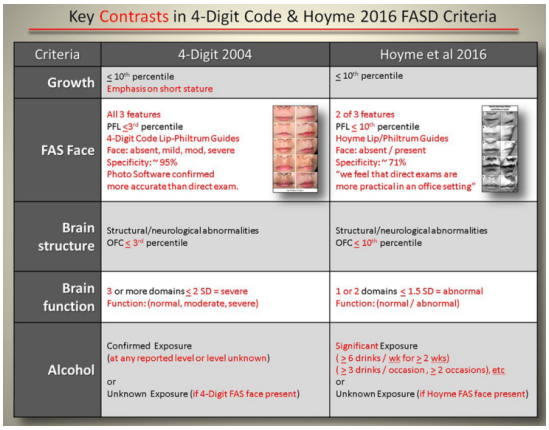

Figure 3. Key contrasts between the 4-Digit Code and Hoyme et al. 2016 FASD diagnostic criteria

Key contrasts between the two diagnostic systems are presented in red font. Full criteria are presented in the 4-Digit Code [1] and Hoyme et al. [3] published guidelines.

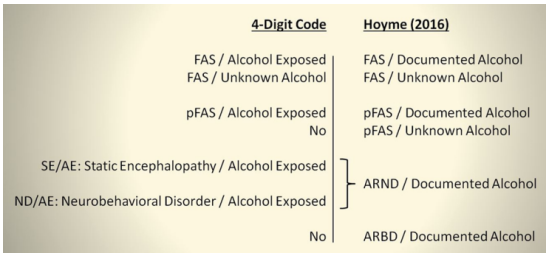

Figure 4. Key contrasts between the 4-Digit Code and Hoyme FASD diagnostic nomenclature

The 4-Digit Code [1] defines five FASD diagnostic categories, the Hoyme et al. [3} defines six. Although both diagnostic systems have three diagnostic categories that share the same name, the criteria used to define each are markedly different between the two systems. The 4-Digit Code does not include diagnostic categories labeled pFAS/Unknown Alcohol or ARBD. The diagnosis SE/AE is defined by severe structural and/or functional CNS abnormalities, but lacks the physical characteristics that would qualify for FAS or pFAS. ND/AE is defined by moderate functional CNS abnormalities. The CNS functional abnormalities of ARND are broadly equivalent to the moderate and severe CNS functional abnormalities defined by ND/AE and SE/AE combined. The 4-Digit Code Diagnostic Categories that case-define each diagnosis [1] are as follows: FAS/Alcohol Exposed (Category A); FAS/Unknown Alcohol (B); PFAS/Alcohol Exposed (C); SE/AE (E,F); and ND/AE (G,H).

ARND: Alcohol Related Neurodevelopmental Disorder; ARBD: Alcohol Related Birth Defects; FAS: fetal alcohol syndrome; FASD: fetal alcohol spectrum disorders; ND/AE: neurobehavioral disorder/alcohol exposed; pFAS: partial fetal alcohol syndrome; SE/AE: static encephalopathy/alcohol exposed.

Contrasts in diagnostic criteria

Growth deficiency: The Hoyme et al criteria use the same cut-off (prenatal or postnatal height and/or weight ≤ 10th percentile) to define growth deficiency as the 4-Digit Code, but the Hoyme et al. criteria classify growth deficiency on a dichotomous scale (present/absent), whereas the 4-Digit Code ranks growth deficiency on a 4-point ordinal scale with emphasis on short stature; a method that is confirmed to be highly predictive of CNS dysfunction [5].

Facial phenotype: When compared to the 4-Digit Code Rank 4 FAS facial phenotype, the Hoyme et al. FAS facial phenotype is substantially relaxed. This is best illustrated using the 4-Digit Code Facial ABC-Score printed on the backside of the 4-Digit Code "Caucasian" Lip-Philtrum Guide 1 (Figure 5). The 4-Digit Code FAS facial phenotype is defined by a single ABC-Score (Facial ABC-Score CCC, Face Rank 4) (Figure 5A). The three letters "CCC" reflect the magnitude of expression of the short palpebral fissure length (PFL), smooth philtrum, and thin upper lip in that order. C reflects severe expression in the FAS range, B reflects moderate expression, and A reflects normal expression. The Hoyme et al. FAS facial criteria are relaxed relative to the 4-Digit Code in three ways:

1. Only 2 of 3 cardinal features are required.

2. The PFL is relaxed to the 10th percentile.

3. As shown in our analysis above, the Rank 4 lip on the Hoyme et al. North American Lip/Philtrum Guide has a circularity equivalent to the Rank 2 lip on the 4-Digit Lip-Philtrum Guide 1.

This results in almost every 4-Digit Code Facial ABC-Score meeting the relaxed Hoyme et al. facial criteria (Figure 5B) including 13 of the 15 ABC-Scores that depict the 4-Digit Code Rank 2 (mild) facial phenotype and 3 of the 8 ABC-Scores that depict the complete absence of all three FAS facial features (Rank 1). Clinically, the 4-Digit Code classifies Rank 1 and 2 facial phenotypes as being within the normal range. The practical clinical impact of this relaxation is illustrated in Figure 6 in which an adolescent with high function (e.g., FSIQ 123) and confirmed absence of prenatal alcohol

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

exposure met the Hoyme et al. criteria for the full FAS facial phenotype.

In addition to the contrasts in facial criteria, the scales of measurement used to clinically classify the facial phenotype also differ. The 4-Digit Code documents the full continuum of expression of the FAS facial phenotype (Face Ranks 1 through 4), a continuum confirmed to be highly predictive of CNS dysfunction [5, 10]. In contrast, the Hoyme et al system documents the facial phenotype as simply present or absent.

CNS dysfunction: The Hoyme et al. criteria that define neurobehavioral impairment (broadly defined as at least one neurobehavioral domain >1.5 standard deviations (SD) below the mean) appeared broadly equivalent to the 4-Digit Code criteria for moderate to severe CNS dysfunction (CNS Ranks 2 and 3). CNS Rank 3 (severe dysfunction, labeled Static Encephalopathy) is defined by 3 or more domains of function, 2 or more SDs below the mean. CNS Rank 2 (moderate dysfunction, labeled Neurobehavioral Disorder) is defined by at least one domain of function between 1 and 2 SDs below the mean, and not more than 3 domains of function 2 or more SDs below the mean. CNS Rank 1 reflects normal function across all domains [1]. Validation studies confirm CNS Ranks 1, 2 and 3 are significantly and linearly correlated with the severity of underlying CNS structural abnormalities, the magnitude of expression of the FAS facial phenotype, and the level of prenatal alcohol exposure [11].

CNS structural abnormalities: The Hoyme et al. criteria for deficient brain growth, abnormal morphogenesis, or abnormal neurophysiology were largely equivalent to the 4-Digit Code criteria for CNS structural and neurological abnormalities (CNS Rank 4) with the exception of the cut-off used to define microcephaly (Hoyme et al. criteria: ≤ 10th percentile; 4-Digit Code: ≤ 3rd percentile).

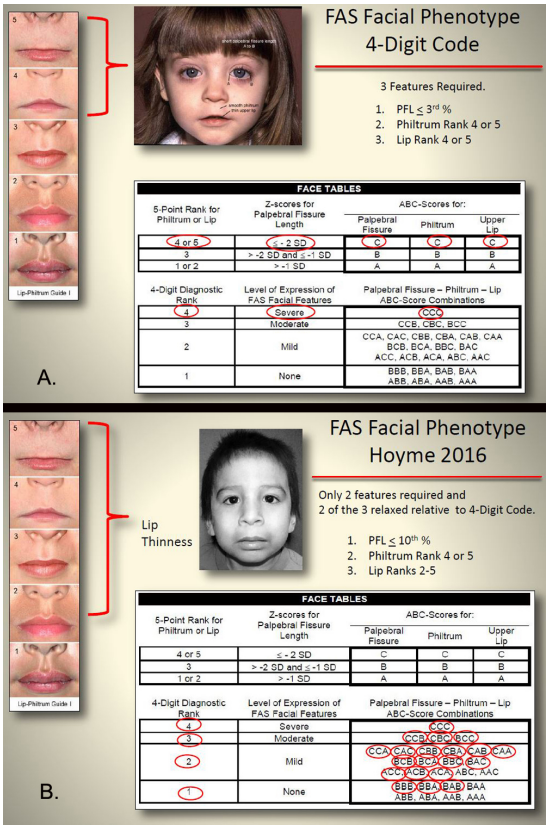

Figure 5. The Hoyme FAS face is substantially relaxed relative to the 4-Digit Code FAS face.

A) The 4-Digit Code uses the Facial ABC-Score to document all combinations of expression of the 3 FAS facial features. These ABC-Scores are clustered to define the 4-Digit Code Face Ranks 1-4. The 4-Digit Code FAS facial phenotype is defined by a single ABC-Score (Facial ABC-Score CCC, Face Rank 4). **B)** In contrast, the relaxation of the Hoyme et al. FAS facial criteria (e.g., only 2 of 3 features required, PFL relaxed to 10th percentile, and Rank 4 lip relaxed to 4-Digit Rank 2 lip) results in most every 4-Digit Code Facial ABC-Score meeting the relaxed criteria, including ABC-Scores that define Face Ranks 1 and 2. Clinically, the 4-Digit Code classifies Rank 1 and 2 facial phenotypes as being within the normal range. (FAS facial phenotype from Hoyme et al, 2016 used with permission from the American Academy of Pediatrics).

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

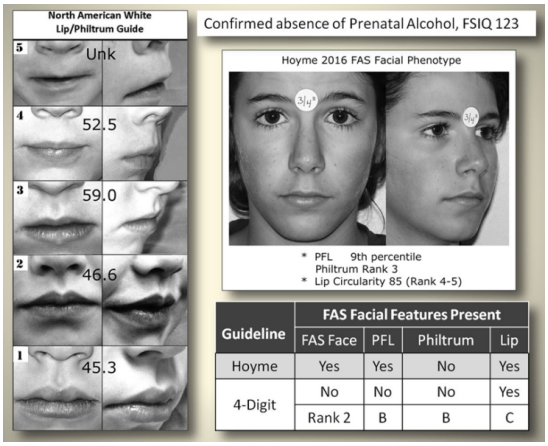

Figure 6. The Hoyme FAS facial criteria are so relaxed even individuals with confirmed absence of prenatal alcohol exposure meet the criteria.

When the Hoyme et al. [3] FAS facial criteria were applied to an adolescent with high function (FSIQ 123) and confirmed absence of prenatal alcohol exposure, the adolescent met the Hoyme et al. criteria for the full FAS facial phenotype. When measured directly and with the FAS Facial Photographic Analysis Software, she presented with 2 of the 3 features: palpebral fissure length (PFL) ≤10th percentile using the Stromland Caucasian PFL charts and a thin upper lip ≥ Rank 4 on the Hoyme North American Lip/Philtrum Guide. Both visual inspection and lip circularity (85) confirm her lip was as thin or thinner than the Hoyme Rank 4 lip (circularity 52.5). In contrast, the 4-Digit Code FAS facial criteria classified her within the normal range (Face ABC-Score BBC, Face Rank 2), presenting with just 1 of the 3 features in the FAS range (a thin upper lip, 4-Digit Code Lip Rank 4).

Alcohol exposure: The Hoyme et al., criteria for documented prenatal alcohol exposure are more stringent overall than the 4-Digit Code and include thresholds (≥6 drinks/week for ≥2 weeks during pregnancy or ≥3 drinks per occasion on ≥2 occasions during pregnancy). The 4-Digit Code requires a confirmed exposure, but does not set thresholds because recall and reporting of quantity, frequency, and timing of exposure have been confirmed highly unreliable in a clinical setting and exposure below a designated threshold has not been confirmed safe for all fetuses [11]. The Hoyme et al. system allows FAS and PFAS to be diagnosed when exposure is unknown. The 4-Digit Code allows FAS to be diagnosed when exposure is unknown because FAS requires the presence of the Rank 4 FAS facial phenotype and the Rank 4 face is confirmed to be highly specific to (caused only by) prenatal alcohol exposure [11].

Objective 2: Comparison of diagnostic outcomes

Methods

Study population

The records of 1,392 patients were drawn from 1,522 consecutive patients that received an FASD diagnostic evaluation at the University of Washington Fetal Alcohol Syndrome Diagnostic & Prevention Network (FASDPN). The diagnostic evaluations were performed by an interdisciplinary team between 1993 and 2012 using the FASD 4-Digit Code [1]. The interdisciplinary team included a medical doctor, psychologist, occupational therapist, speech language pathologist, social worker, family advocate, and public health professional [11, 12]. All patients with one or both birth parents African American (130 of the 1,522) were excluded from the study because it was unclear which PFL normal growth chart to use for African Americans when applying the Hoyme et al. system [13] and our findings in Objective 1 and those reported by Hoyme et al. [6] confirm the South African Mixed Race Lip/Philtrum Guide is inappropriate for use on an African American population.

Historically, all records resulting from each patient's FASD diagnostic evaluation have been entered into a research database since 1992 with University of Washington Human Subjects approval and patient consent. Over 95% of patients provide consent for their clinical data to be used for research purposes. Patients' records include the following standardized 4-Digit Code data forms: the New Patient Information Form, the FASD Diagnostic Form, digital facial photos, and the FAS Facial Photographic Analysis Report [1, 7]. These data are entered into a research database shortly after the patient's FASD diagnostic evaluation reflecting the tools and growth norms available at that time. Over the decades the 4-Digit Code has evolved (First edition 1997, Third edition 2004) [1, 14-16], new

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

tools have been developed like the FAS Facial Photographic Analysis Software (Version 1.0 in 2004, Version 2.1 in 2016) [7], and new more accurate growth norms have been adopted (CDC growth charts [17] and Stromland Scandinavian PFL charts [18].

For the purposes of research, all patients' clinical 4-Digit Codes are updated to "research" 4-Digit Codes to reflect the most current tools and norms available at the time of the research study. For this study, all 4-Digit Codes were updated to reflect the most current third edition of the 4-Digit Code [1].

Application of the diagnostic tools and norms

The following tools and norms were used to update the 4-Digit Code FASD diagnoses and generate the Hoyme et al. [3] FASD diagnoses. The Reader is encouraged to familiarize themselves with the diagnostic criteria specific to each diagnostic system [1, 3] as space does not permit replication of the criteria here.

Growth: The Hoyme et al. criteria use the same cut-off (prenatal or postnatal height and/or weight ≤ 10th percentile) to define growth deficiency as the 4-Digit Code, thus all patients with 4-Digit Code Growth Ranks 2,3 or 4 were classified as meeting the Hoyme et al. growth deficiency criteria.

Height and weight normal growth charts: Height and weight percentiles were generated from the Hall [19] birth weight and length growth charts by gestational age; the World Health Organization (WHO) [20] height and weight growth charts for children 0–2 years of age, and the Centers for Disease Control (CDC) 2000 [17] height and weight growth charts for patients 2 years of age and older. The height percentile was adjusted for mid-parental height [21] when both parents' heights were reported.

Facial features: At the time of each patient's FASD diagnostic evaluation, three standardized, digital facial photographs (Figure 7) were taken and measured using the FAS Facial Photographic Analysis Software [7]. As a result, each patient's research record included the following facial measures: PFLs in millimeters, philtrum smoothness (Rank 1 to 5 on the 4-Digit Code Lip-Philtrum Guide 1) and upper lip circularity (perimeter^2/area) and corresponding Lip Rank (Rank 1 to 5 on the 4-Digit Code Lip-Philtrum Guide 1).

PFL: For the purposes of this research study, all PFL z-scores were updated to reflect the Stromland Scandinavian PFL growth charts. The Stromland charts are confirmed valid for use on a North American population [8] and address the full age span (birth through adult) represented in our study population. In addition, the Stromland PFL growth charts were generated from digital images, thus meeting the recommendation by Hoyme et al. [3] that PFLs measured from photos should be compared to PFL normal growth charts generated from photos.

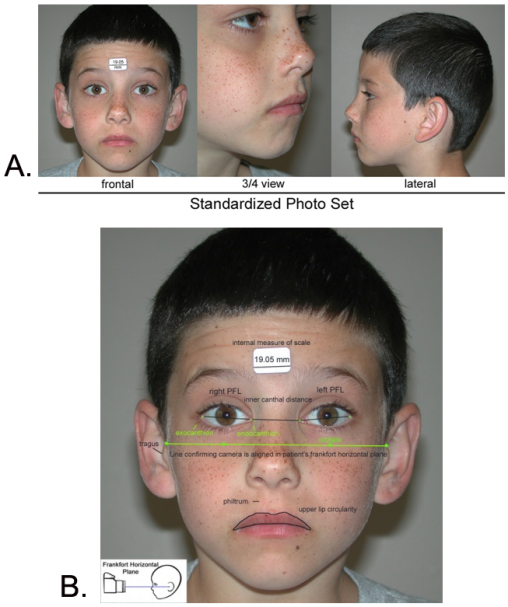

Figure 7. The FAS Facial Photographic Analysis Software was used to measure the 3 FAS facial features.

A) The palpebral fissure length (PFL), philtrum smoothness, and upper lip thinness are measured from three standardized, digital photographs. B) Standardization includes proper rotation, exposure, focus, and facial expression. An internal measure of scale (a 3/4 inch (19.05 mm) paper sticker) is placed on the forehead to measure the PFLs in millimeters.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

Philtrum smoothness and upper lip thinness: The 4-Digit Code "Caucasian" Lip-Philtrum Guide 1 and the Hoyme et al. North American Lip/Philtrum Guide were used to rank philtrum smoothness and lip thinness. Since the images depicting the Rank 1 through 5 philtrums on the 4-Digit Code and Hoyme et al. guides appeared broadly equivalent (per Objective 1), the philtrum rank assigned at the time of diagnosis using the 4-Digit Code guide was the same philtrum rank assigned to the patient using the Hoyme et al. guide (Figure 2) (e.g., if the patient had a Rank 4 philtrum using the 4-Digit Code guide, they received a Rank 4 philtrum using the Hoyme et al. guide). In contrast, the analyses in Objective 1 confirmed the Rank 1 through 5 images depicting upper lip thinness did not match between the 4-Digit Guide 1 and the Hoyme et al. North American Guide (Figure 2). The 4-Digit Code uses the full range of Lip Ranks 1-5 to classify the FAS facial phenotype on a 4-point Likert scale from normal (Face Rank 1) to severe FAS (Face Rank 4). In contrast, the Hoyme et al. FAS/PFAS facial criteria measure lip thinness on a dichotomous scale (thin: ≥Rank 4, not thin: <Rank 4) to classify the FAS/PFAS facial phenotype on a dichotomous scale (present, absent). To accurately and objectively identify which patients met the Hoyme et al. diagnostic criteria for a thin upper lip (≥Rank 4), the Rank 4 upper lip on the Hoyme et al. North American Lip/Philtrum Guide was outlined using the facial software. The video clip in Figure 2C demonstrates this procedure. The circularity of the Hoyme et al. Rank 4 lip was 52.5; equivalent to the 4-Digit Rank 2 lip (defined by the circularity range 42.5 to 57.4). Thus all patients with an upper lip circularity of 52.5 or greater met the Hoyme et al. criteria for a thin upper lip (Rank 4 or 5 on the Hoyme et al. North American Lip/Philtrum Guide).

CNS dysfunction: Based on our findings in Objective 1, all patients with 4-Digit Code CNS Ranks of 2 or 3 (moderate to severe CNS dysfunction) were classified as meeting the Hoyme et al. criteria for neurobehavioral impairment.

CNS structural abnormalities: Based on our findings in Objective 1, all patients with a 4-Digit Code CNS Rank 4 (structural/neurological abnormalities) were classified as meeting the Hoyme et al. criteria for deficient brain growth, abnormal morphogenesis, or abnormal neurophysiology. In addition, all patients with an occipital frontal circumference (OFC) ≤10th percentile were classified as meeting the Hoyme et al. CNS criteria. The WHO [20] OFC charts for children 0-5 years of age and the Nellhaus [22] OFC growth charts for children 5-18 years of age were used.

Alcohol related birth defects (ARBD): The Hoyme et al. diagnosis labeled ARBD is not recognized in the 4-Digit Code or any FASD diagnostic system introduced subsequent to the 1996 Institute of Medicine FASD diagnostic guidelines [12, 23]. For this reason, this diagnostic classification was not included in this study.

Statistical analyses

Descriptive statistics (valid percentages) were used to profile the study population. Chi-square tests were used to compare groups and linear trends across groups for outcomes measured on nominal or ordinal scales. One-way analysis of variance (ANOVA) was used to compare means and detect linear trends across three or more groups when outcomes were measured on a continuous scale. T-tests were used to compare means between two independent groups.

Results

Objective 2: Compare the diagnostic outcomes between the two systems.

Study population

The socio-demographic profile of the study population (n=1,392) is presented in Table 1. The population spanned the entire age range from newborn to adult with 57% Caucasian and 44% female.

Objective 2a: Compare the prevalence of FASD diagnostic outcomes generated by each system

The 4-Digit Code classified 78% (1,092/1,392) of the patients broadly under the umbrella of FASD (FAS, PFAS, SE/AE, and ND/AE) (Figure 8A). The prevalence of FAS and PFAS was 2% (n=28) and

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

4% (n=53), respectively. In contrast, the Hoyme et al. system classified only 40% (558/1,392) of the patients under the umbrella of FASD. The prevalence of FAS (6%; n=89) and PFAS (15%, n=208) generated by the Hoyme et al. system was 3- to 4-fold greater than the prevalence of FAS and PFAS generated by the 4-Digit Code.

Table 1. Sociodemographic and exposure profile of the study population (n = 1,392)

Characteristic	N	Valid %
Gender		
Female	608	44%
Male	784	56%
Race/ethnicity		
Caucasian	788	57%
Native American	126	9%
Hispanic	37	3%
African American	0	0%
Other	434	31%
Age at FASD diagnostic evaluation (years)		
0-2	141	10%
3-5	314	23%
6-7	234	17%
8-12	411	30%
13-18	236	17%
19+	56	4%
Prenatal Alcohol Exposure		
Confirmed (4-Digit Code Ranks 3 and 4)	1,117	85%
Unknown (4-Digit Code Rank 2)	215	15%

Thirty-five percent (379/1,092) of the patients who received a diagnosis of FASD using the 4-Digit Code did not receive a diagnosis of FASD using the Hoyme et al. system (Figure 8B). They all had confirmed prenatal alcohol exposures (e.g., birth mother reported drinking throughout the pregnancy), but their record of exposure did not meet the more stringent criteria (e.g., intoxication confirmed by BAC; positive biomarker test like analysis of FAEE; positive outcome on a validated screening tool like the T-ACE or AUDIT; or number of drinks per week or occasion reported) or the level of exposure (e.g., ≥ 6 drinks/week or ≥ 2 weeks or ≥2 drinks/occasion on ≥ 2 occasions) required by the Hoyme et al. system. In some cases, as illustrated in Figure 9, a patient diagnosed with severe FAS (4-Digit Code 4443) did not receive a diagnosis under the umbrella of FASD using the Hoyme et al. system because the exposure level reported directly by the birth mother (1 drink/week throughout pregnancy) was not high enough to meet the Hoyme et al. alcohol-exposure criteria (≥6 drinks/week for ≥2 weeks during pregnancy).

Among the subset of 141 alcohol-exposed patients under 3 years of age, the 4-Digit Code classified 70% (98/141) under the umbrella of FASD (Figure 8C). The prevalence of SE/AE and ND/AE was 21% (n=29) and 41% (n=58) respectively. In contrast, the Hoyme et al. system classified only 15% (21/141) under the umbrella of FASD. No infant/toddler received a diagnosis of ARND because the Hoyme et al. system does not permit a diagnosis of ARND in patients less than 3 years of age.

Objective 2b: Assess diagnostic concordance between the two systems

Diagnostic concordance was observed in 38% (n=528) of the 1,392 patients (Figure 10). The two diagnostic systems ruled-out FASD in 239 patients and both rendered the same diagnosis under the umbrella of FASD for 289 patients. Diagnostic discordance was observed in 62% (n=864) of the 1,392 patients. The discordance ranged from subtle differences (e.g., the patient received a diagnosis of FAS by one system and PFAS by the other system) to marked contrasts (e.g., the patient received a diagnosis of FAS by one system and no diagnosis under the umbrella of FASD by the other system).

To illustrate some of the more striking contrasts, of the 21 patients that received a diagnosis of FAS/Alcohol Exposed using the 4-Digit Code, 10 had FASD ruled-out altogether using the Hoyme et al. system (see the 4-Digit Code FAS/AE column in Figure 10). All 10 patients were less than 5 years of age. They presented with CNS structural abnormalities (e.g., microcephaly: OFC ≤ 3rd percentile), but early development was broadly within the normal range. All ten were too young to engage in the necessary level of testing to accurately rule-out moderate or severe CNS dysfunction. The Hoyme et al. system require both CNS structural abnormalities (e.g., OFC ≤ 10th percentile) and evidence of CNS dysfunction for a diagnosis of FAS.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

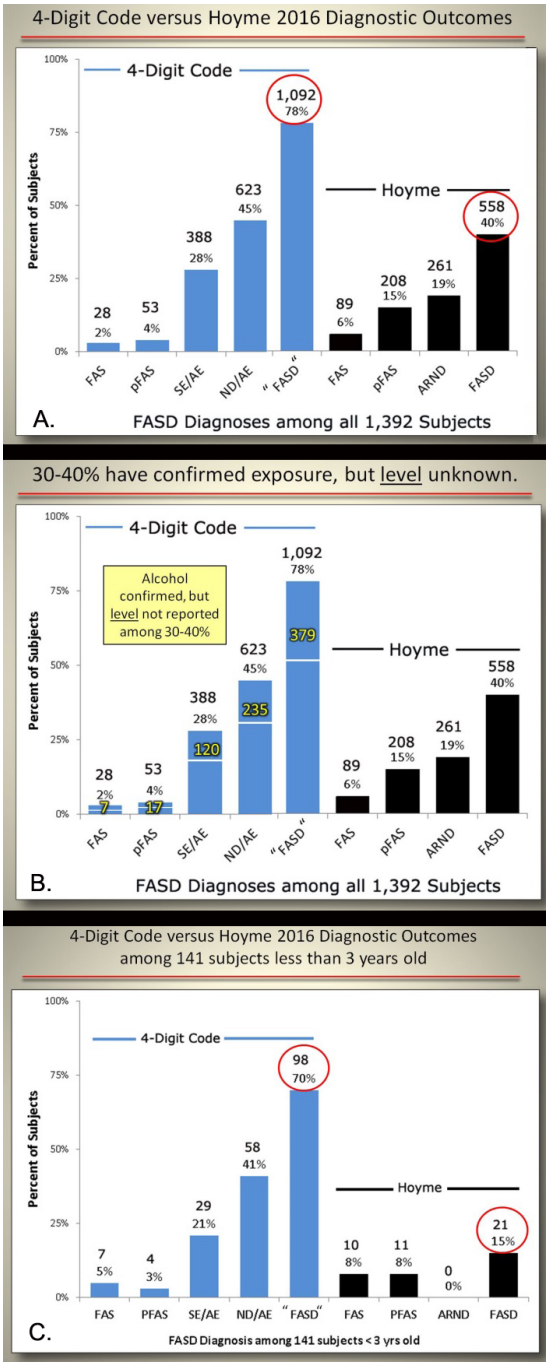

Figure 8. Contrasts in diagnostic outcomes when the 4-Digit Code and Hoyme FASD diagnostic systems were applied.

A) Contrast in outcomes among all 1,392 patients. B) The impact of the more stringent Hoyme et al. [3] alcohol exposure criteria on the outcomes. The numbers in yellow document the number of patients with confirmed prenatal alcohol exposure that did not meet the more stringent Hoyme et al. criteria. For example, if the more stringent Hoyme et al. alcohol criteria were applied, 379 of the 1,092 would not have received a FASD diagnosis using the 4-Digit Code. C) Contrast in outcomes among the subset of 141 patients who were less than 3 years of age at the time of diagnosis. No infant/toddler received a diagnosis of ARND because the Hoyme et al. system does not permit a diagnosis of ARND in patients less than 3 years of age.
FAS: fetal alcohol syndrome; pFAS: partial fetal alcohol syndrome; SE/AE: static encephalopathy/alcohol exposed; ND/AE: neurobehavioral disorder/alcohol exposed; FASD: fetal alcohol spectrum disorders; ARND: alcohol related birth defects.

An Actual Case of Full FAS (4443) in a 21 year old		
Growth	Rank 4	Height 1%, Weight 1%
Face	FAS Rank 4 (CCC)	PFL 1%, Philtrum Rank 4, Lip Rank 4
CNS structure	CNS Rank 4	Microcephaly 2 %
CNS dysfunction	CNS Rank 3, Severe	FSIQ 76, Adaptation 65, Math Calc 60, Core Lang 67, Memory 59
Alcohol	Rank 3 Birth mother report	1 drink/wk for > 2 wk during pregnancy (all 3 trimesters) 1 drink per occasion on > 2 occasions during pregnancy

Figure 9. FAS does occur when the reported alcohol exposure is below the Hoyme et al. threshold.

The outcomes displayed reflect an actual case of full FAS with confirmed prenatal alcohol exposure (4-Digit Code 4443) in a 21-year-old diagnosed at the University of Washington. This example demonstrates that FAS does occur when *reported* alcohol is less than the threshold (≥6 drinks/week for ≥2 weeks during pregnancy and/or ≥3 drinks per occasion on ≥2 occasions during pregnancy) required by the Hoyme et al. [3] FASD diagnostic system. The outcomes reported for CNS dysfunction are standard scores (mean 100, SD 15) for measures of cognition, adaptation, math calculation, core language skills, and memory.
CNS: central nervous system; PFL: palpebral fissure length.

Among the 208 patients that were classified "Not FASD" by the 4-Digit Code, 39 received a FAS (n=16) or PFAS (n=23) diagnosis using the Hoyme et al. system (Figure 10). The 4-Digit Code does not render a diagnosis under the umbrella of FASD if: 1) alcohol exposure is unknown and 2) the Rank 4 FAS face is absent. If an individual does not have a confirmed prenatal alcohol exposure, the 4-Digit Code Rank 4 FAS face can serve as confirmation of exposure because the phenotype is confirmed to be so highly specific to (caused only by) prenatal

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

alcohol exposure (>95% specificity) [11]. The Hoyme et al. system allowed these 39 patients with unknown alcohol exposures to receive a diagnosis of FAS or PFAS because they presented with the Hoyme et al. FAS face. But the Hoyme et al. FAS facial criteria are so relaxed (specificity 71% to 75% [24, 25]) that the facial phenotype does not provide the necessary level of specificity to alcohol to use the facial phenotype to confirm exposure. Among the 39 patients with unknown prenatal alcohol exposure and a Hoyme et al. diagnosis of FAS or PFAS, 18 had relaxed PFLs (4^{th}–10^{th} percentile), 17 had relaxed philtrums (4-Digit Philtrum Ranks 2 and 3), 22 had relaxed lips (4-Digit Lip Ranks 1-3); 4 had no FAS facial features (4-Digit Face Rank 1); and 19 had only 1 FAS facial feature (4-Digit Face Rank 2).

Among the 834 patients that were classified "Not FASD" using the Hoyme et al. system, 31 received a FAS/PFAS diagnosis (Figure 10, red bars in the Hoyme et al. Not FASD row) using the 4-Digit Code. All 31 presented with the Hoyme et al. FAS face, but none met the Hoyme et al. FAS or PFAS diagnostic criteria. The Hoyme et al. FAS criteria require the presence of both CNS structural abnormalities (e.g., OFC ≤10th percentile) and neurobehavioral impairment. Eighteen presented with a small head circumference (OFC ≤10th percentile), but did not present with neurobehavioral impairment. All 18 were under 6 years of age. Of the 18 infants/toddlers, 5 were microcephalic (OFC ≤3rd percentile), but did not present with developmental delay ≥1.5 SD below the mean. All five were under 3 years of age and received the most severe FAS 4-Digit Code: 4444. Eight of the 31 presented with severe CNS dysfunction, but were normocephalic. Of the 29 with confirmed prenatal alcohol exposures, 5 had confirmed prenatal alcohol exposures, but the levels were reportedly too low to meet the Hoyme et al. alcohol exposure criteria.

The prevalence of each of the four core features that define FASD (growth deficiency, FAS facial phenotype, CNS abnormalities, and alcohol exposure) differed between the two diagnostic systems (Figure 11). Both systems identified 32% of patients with growth deficiency (height and/or weight ≤10^{th} percentile).

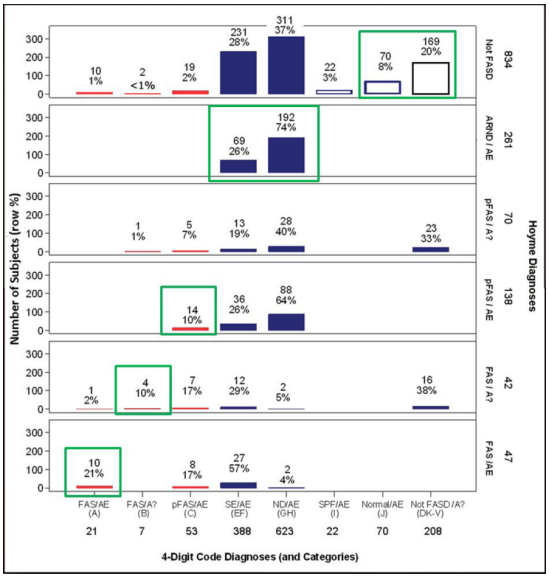

Figure 10. Cross-tabulation of the 4-Digit Code and Hoyme et al. FASD diagnostic outcomes.

Diagnostic concordance (green boxes) between the two systems was observed in 38% (528/1,392) of the patients. Diagnostic discordance (all diagnoses not outlined in green) was observed in 62% (864/1,392) of the patients. Red bars reflect FAS and PFAS diagnoses using the 4-Digit Code. As a demonstration for how to interpret this figure; 21 patients received a 4-Digit Code Diagnosis of FAS/AE. Of the 21 patients, 10 received a FAS/AE diagnosis, 1 received a FAS/A?, and 10 did not receive a diagnosis under the umbrella using the Hoyme et al. [3] diagnostic system. 4-Digit Code Categories A-V are case-defined in the Diagnostic Guide for FASD [1].

AE: alcohol exposed; A?: alcohol exposure unknown; ND: neurodevelopmental disorder; Not FASD/A?: Individuals who present with or without growth, facial, and/or CNS abnormalitities, but are not under the umbrella of FASD because their prenatal alcohol exposure is unknown and they do not meet the criteria for FAS/A?. SE: static encephalopathy; SPF: Sentinel Physical Findings, individuals who present with growth deficiency and/or 1 to 3 FAS facial features, but have normal CNS structure and function; Normal: no evidence of growth, facial, or CNS structural/functional abnormalites.

The Hoyme et al. system identified a higher proportion of patients (23%) with CNS structural/neurological abnormalities than the 4-Digit Code (17%). The higher prevalence with the Hoyme et al. system reflected the relaxation of the OFC criterion to the 10^{th} percentile. Both systems identified 1,219 (88%) with CNS dysfunction.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

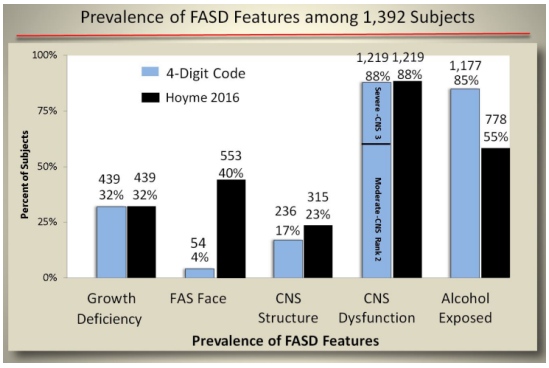

Figure 11. The prevalence of FASD features differed between the 4-Digit Code and Hoyme FASD diagnostic systems.

The prevalence of growth deficiency, the FAS facial phenotype, CNS abnormalities, and alcohol exposure differed when the two diagnostic systems were applied to the 1,392 patients. The most striking contrast is the 10-fold higher prevalence of the FAS facial phenotype with the Hoyme et al. criteria. Of the 1,219 with CNS dysfunction, the 4-Digit Code identified 828 (68%) with Rank 2 moderate CNS dysfunction and 391 (32%) with Rank 3 severe CNS dysfunction. The blue bars reflect the 4-Digit Code: (growth deficiency=Growth Ranks 2–4; FAS face=Face Rank 4; CNS structure=CNS Rank 4; Alcohol Exposed=Alcohol Ranks 3 and 4). CNS: central nervous system.

Of the 1,219 with CNS dysfunction, the 4-Digit Code identified 828 (68%) with Rank 2 moderate CNS dysfunction and 391 (32%) with Rank 3 severe CNS dysfunction. The prevalence of the FAS facial phenotype was 10-fold higher using the Hoyme et al. criteria (n=553; 40%) compared to the 4-Digit Code (n=54; 4%). Only 55% of the 1,392 patients met the more stringent Hoyme et al. alcohol exposure criteria. In contrast, 85% met the 4-Digit Code alcohol exposure criteria (Alcohol Rank 3 or 4).

The prevalence of the individual FAS facial features also differed between the two diagnostic systems (Figure 12). More patients were classified with short PFLs using the Hoyme et al. system (77% $\leq 10^{th}$ percentile) than the 4-Digit Code (59% $\leq 3^{rd}$ percentile). Three times more patients were classified with thin upper lips using the Hoyme et al. Lip/Philtrum Guide (64% with Lip Rank ≥ 4; lip circularity ≥ 52.5) compared to using the 4-Digit Code Lip-Philtrum Guide (23% with Lip Rank ≥ 4; lip circularity ≥ 75.5). The philtrums depicted on the two lip-philtrum guides appeared to be roughly equivalent resulting in both diagnostic systems identifying 20% of patients with Rank 4 or 5 smooth philtrums. The relaxation of the PFL and lip criteria in addition to requiring only 2 of the 3 facial features resulted in the Hoyme et al. criteria identifying 10 times more patients with the full Hoyme et al. FAS face (n=553, 40%) than the 4-Digit Code FAS face (Rank 4; n=54, 4%). The relaxation of the Hoyme et al. FAS facial criteria resulted in 71% (395/553) of the Hoyme et al. FAS faces to fall within the clinically normal range (Face Ranks 1 and 2) as defined by the 4-Digit Code (Figure 12B).

Cross tabulation of the CNS structural abnormalities and alcohol exposure classification document further contrasts between the two systems (Figure 13). Relaxation of the head circumference criteria in the Hoyme et al. system resulted in 315 patients with OFC $\leq 10^{th}$ percentile compared to 236 $\leq 3^{rd}$ percentile using the 4-Digit Code. The more stringent Hoyme et al. criteria for alcohol exposure resulted in substantially fewer patients being classified as alcohol exposed (n=778, 55%) compared to the 4-Digit Code (n=1,177, 85%). Most notably, 399 patients with confirmed alcohol exposures (Rank 3 and 4) did not meet the more stringent Hoyme et al. alcohol criteria because the requisite details of exposure were unknown (e.g., quantity, frequency, timing, BAC, etc.). When the details of the Hoyme et al. alcohol criteria are displayed, it becomes more clear which of these criteria are most likely not to be met or available to clinicians (Figure 14).

Objective 2c: Assess measures of validation

Correlation between the FAS facial phenotype and prenatal alcohol exposure:

If the FAS facial phenotype is specific to (caused only by) prenatal alcohol exposure, the FAS facial phenotype should be more prevalent among those with higher exposure and should not occur in individuals with confirmed absence of prenatal alcohol exposure. One would also expect that the majority of (if not all) individuals presenting with the FAS facial phenotype would meet criteria for a diagnosis under the umbrella of FASD.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

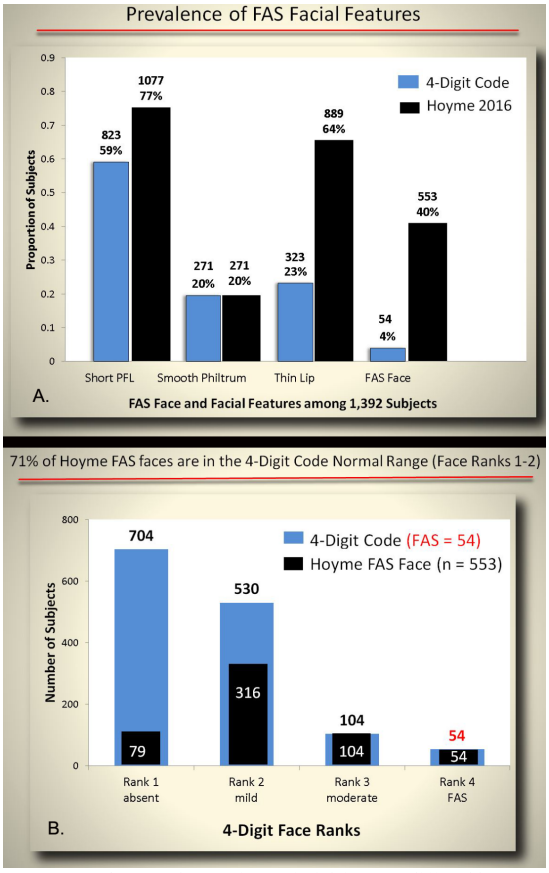

Figure 12. The prevalence of FAS facial features differed between the 4-Digit Code and Hoyme diagnostic systems.

A) When the facial criteria from each diagnostic system were applied to the 1,392 patients, the most striking contrast was the prevalence of the thin upper lip. Use of the Hoyme et al. North American Lip/Philtrum Guide resulted in 3 times more patients being classified as having a thin upper lip. The criteria used to define each bar: Short PFL (4-Digit Code $\leq 3^{rd}$ percentile; $\leq 10^{th}$ percentile Hoyme et al.); Smooth Philtrum and thin upper lip (Rank 4 or 5 on the 4-Digit Code or Hoyme et al. [3] lip philtrum guides); FAS Face (4-Digit Code Face Rank 4; Hoyme al. FAS/PFAS face). B) 71% of the Hoyme et al. FAS facial phenotypes fell in the 4-Digit Code normal range (Face Ranks 1 and 2).

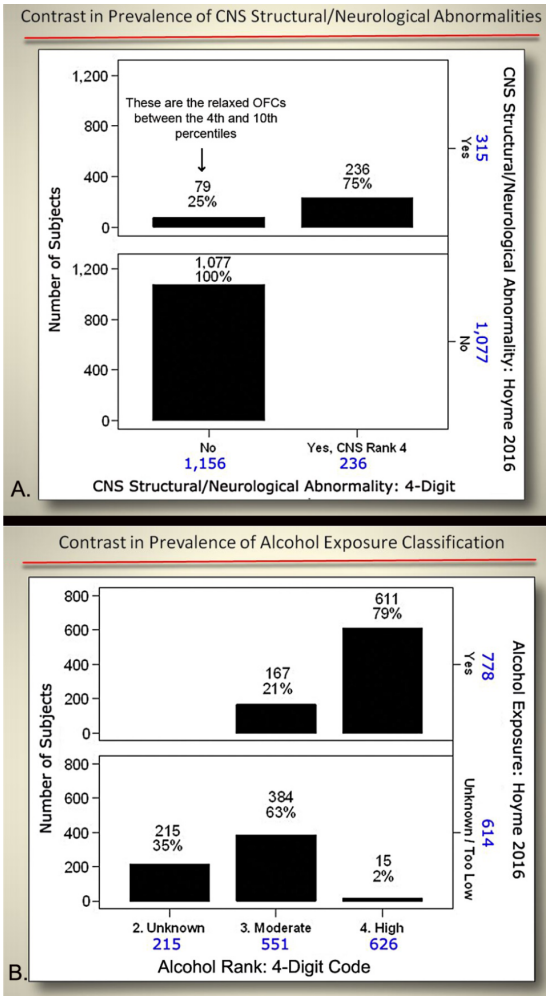

Figure 13. Cross-tabulation of CNS structural abnormalities and alcohol exposure classification between the 4-Digit Code and Hoyme systems.

To aid in interpretation; A) 315 patients met the Hoyme criteria for CNS structural/neurological abnormalities. Seventy-nine of the 315 did not meet the 4-Digit Code criteria for CNS Rank 4 because the head circumference was between the 4^{th} and 10^{th} percentiles. The 4-Digit Code requires a head circumference $\leq 3^{rd}$ percentile. B) 552 patients were classified as having moderate prenatal alcohol exposure using the 4-Digit Code (Alcohol Rank 3). Of the 551, only 167 met the Hoyme criteria of alcohol exposure. The remaining 384 had confirmed exposures, but details on quantity, frequency, timing, blood alcohol levels, etc. were not available to meet the more stringent Hoyme criteria. OFC: occipital frontal circumference.

ADVANCES IN PEDIATRIC RESEARCH

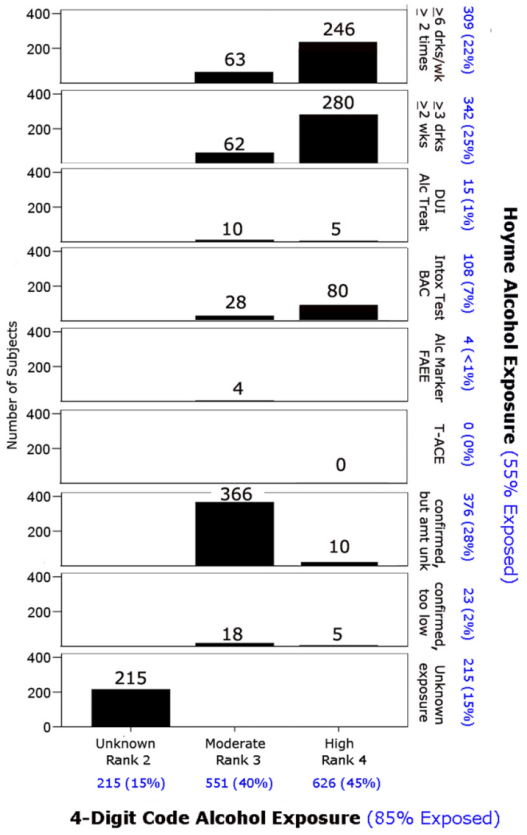

Figure 14. Cross-tabulation of the alcohol exposure classifications by the two 4-Digit Code and Hoyme diagnostic systems.

The Hoyme et al. alcohol exposure categories listed along the right border are fully defined in Table 2 published in the Hoyme et al. diagnostic guidelines [3]. Patients in this study were classified into only one of these categories starting with the top category (e.g., if a patient was exposed to ≥6 drinks/week ≥2 times and had a DUI, they were classified only in the ≥6 drinks/week ≥2 times category). Overall, 55% of the patients met the Hoyme alcohol criteria, whereas 85% met the 4-Digit Code alcohol criteria.

The 4-Digit Code Rank 4 FAS facial phenotype was significantly more prevalent among patients with higher prenatal alcohol exposure (Figure 15C, D). In contrast, the prevalence of the Hoyme et al. FAS facial phenotype was not more prevalent among patients with higher alcohol exposures. (Figure 15A, B).

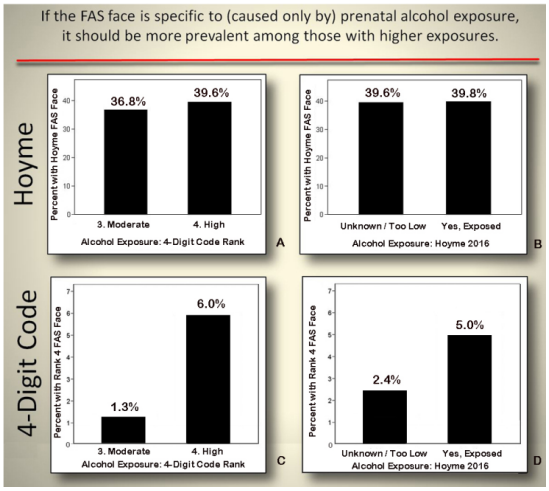

Figure 15. Only the 4-Digit Code FAS face was significantly more prevalent among patients with higher alcohol exposure.

A) The Hoyme et al. FAS face was equally prevalent and highly prevalent in the moderate (4-Digit Code Alcohol Rank 3) and high (4-Digit Code Alcohol Rank 4) alcohol exposure groups (Chi^2 0.9, p=0.33). B) The Hoyme et al. FAS face was also equally prevalent and highly prevalent between those that did and did not meet the Hoyme et al. alcohol exposure criteria (Chi^2 0.01, p=0.92). In contrast, the 4-Digit Code FAS facial phenotype was highly correlated with measures of prenatal alcohol exposure. C) The 4-Digit Code Rank 4 FAS face was 5 times more prevalent in the high exposure group (4-Digit Code Alcohol Rank 4) than the moderate exposure (Digit Code Alcohol Rank 3) group Chi^2 17.5, p=.000). D) The association between the 4-Digit Code Rank 4 FAS facial phenotype and alcohol was substantially weakened when the Hoyme et al. criteria for alcohol exposure were applied (Chi^2 6.1, p=0.02). The 4-Digit FAS face was only 2-fold more prevalent in the Hoyme et al. exposed group relative to the Hoyme et al. unknown/too low exposure group.

The mean number of days/week of drinking during pregnancy increased significantly with increasing magnitude of expression of the 4-Digit Code FAS facial phenotype (Figure 16A). The mean number of days/week of drinking during pregnancy was only marginally higher among those with the Hoyme et al. FAS facial phenotype, but this was driven largely by the inclusion of 65 patients who also met the more stringent 4-Digit Code FAS facial criteria (Figure 16B).

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

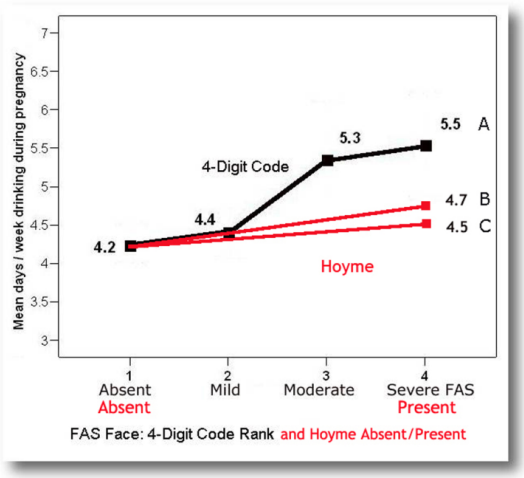

Figure 16. The 4-Digit FAS face was significantly associated with days/week of prenatal alcohol exposure.

A) A strong, significant, linear association was observed between the mean number of days/week of drinking during pregnancy and increasing magnitude of expression of the 4-Digit Code FAS facial phenotype (Face Rank 1 to 4) (One-way ANOVA Linear term: F=12.7, p=.000; n=615). Patients with the full Rank 4 FAS facial phenotype were exposed, on average, 1.3 more days per week than the patients with no FAS facial features (Face Rank 1). B) A much weaker, but significant, association was observed between alcohol exposure and the Hoyme et al. [3] FAS facial phenotype. Patients with the Hoyme et al. FAS face were exposed, on average, 0.5 more days per week than the patients without the Hoyme et al. FAS face (4.7 days/week vs 4.2 days/week respectively; T=-2.9, p=0.04). Sixty-five of the 242 patients with the Hoyme et al. FAS facial phenotype had moderate to severe FAS facial phenotypes in accordance with the 4-Digit Code (Face Ranks 3 and 4). C) When these 65 patients were removed from the analysis to assess the correlation between the relaxed Hoyme et al. facial criteria and prenatal alcohol exposure, patients with the relaxed Hoyme et al. FAS face were exposed, on average, only 0.3 more days per week than the patients without the Hoyme et al. FAS face; a difference that was no longer statistically significant (4.5 days/week vs 4.2 days/week; T=-1.4, p=0.16).

When these 65 patients were removed, there was no longer a significant contrast in alcohol exposure between those with and without the relaxed Hoyme FAS facial phenotype (Figure 16C).

When the Hoyme et al. and 4-Digit Code FAS facial criteria were applied to an adolescent with high function (FSIQ 123) and confirmed absence of prenatal alcohol exposure (4-Digit Code 1211), the adolescent met the Hoyme et al. criteria for the full FAS facial phenotype (Figure 6). In contrast, her facial phenotype was classified within the normal range by the 4-Digit Code (Face ABC-Score BBC, Face Rank 2).

Of the 553 patients with the Hoyme et al. FAS face, almost half (46%) did not receive a diagnosis under the umbrella of FASD using the Hoyme et al. system. In contrast, all 54 patients with the 4-Digit Code Rank 4 FAS face met criteria for a diagnosis under the umbrella of FASD using the 4-Digit Code.

Discussion

The FASD 4-Digit Code and Hoyme et al. 2016 FASD diagnostic systems produced markedly different outcomes. Only 38% of the 1,392 patients received concordant diagnoses from the two systems. Overall, the Hoyme et al. criteria rendered half as many diagnoses under the umbrella of FASD (n=558) as the 4-Digit Code (n=1,092) and placed a much higher proportion (53%; 297/558) in the FAS/PFAS categories than the 4-Digit Code (7%; 81/1,092).

Four factors accounted for the greatest contrasts in diagnostic outcomes between the two systems.

1. The more stringent Hoyme et al. alcohol exposure criteria prevented many with confirmed exposures from receiving a diagnosis of FASD. These more stringent criteria prevented almost one third (339; 29%) of the 1,177 patients with confirmed exposure from being able to receive a diagnosis under the umbrella of FASD (Figure 14). As we illustrated in Figure 9, individuals with *reported* prenatal alcohol exposures below the Hoyme et al. threshold can and do present with full FAS when using the 4-Digit Code. Either this patient was particularly vulnerable to the teratogenic impact of alcohol, or the *reported* exposure was not accurate. In a clinical setting, one is never in a position to know how accurate the exposure was recalled and reported. Setting a threshold implies the details of all reported exposures are accurate and no fetus can be harmed by exposures below the threshold. Neither statement is true and the latter sends a dangerous public health

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

message that lower levels are safe. Recognizing this, the 4-Digit Code requires a confirmed exposure, but does not set a threshold.

It is interesting to note that Petryk et al., [26] reported similar findings when they retrospectively assessed the impact of applying the Canadian [2] minimal prenatal alcohol exposure thresholds to 119 patients with confirmed prenatal alcohol exposure (4-Digit Code Alcohol Ranks 3 or 4) and severe structural and/or functional CNS abnormalities (4-Digit Code CNS Ranks 3 and/or 4). The more stringent Canadian [2] exposure criteria would have prevented 71% of these individuals from receiving a diagnosis under the umbrella of FASD because the reported exposure would not have met the required threshold.

2. The Hoyme et al. criteria require both CNS structural and functional abnormalities be present to receive a diagnosis of FAS. Almost half of the patients who met the 4-Digit Code criteria for FAS did not meet the Hoyme et al. criteria for FAS because the patients were microcephalic, but too young (<5 years old) to engage in the types of testing needed to identify moderate or severe CNS dysfunction. The 4-Digit Code has confirmed that over 90% of alcohol-exposed infants and toddlers who present with one or more of the sentinel physical features of FAS as defined by the 4-Digit Code (microcephaly $\leq 3^{rd}$ percentile, a Rank 4 FAS facial phenotype, or Rank 4 growth deficiency) will present with severe CNS Rank 3 dysfunction later in childhood [5]. FAS is a birth defect syndrome, thus, by definition, it is present at birth. Failure to identify and diagnose FAS in newborns and infants will prevent these highest-risk children from receiving the benefits of early intervention. The 4-Digit Code allows evidence of CNS structural or functional abnormality to meet the CNS criteria. This allows FAS to be diagnosed in the newborn/infant who presents with the physical features (growth deficiency, the FAS facial features, and microcephaly), knowing these sentinel features are highly predictive of underlying CNS dysfunction that will manifest later in childhood.

3. The Hoyme et al. criteria prevent children under 3 years of age from receiving a diagnosis of ARND. As a result, 84% of the 87 alcohol-exposed infants/toddlers under 3 years of age that presented with moderate to severe CNS dysfunction and received a 4-Digit diagnosis of ND/AE or SE/AE (Figure 8C) did not receive a diagnosis anywhere under the umbrella of FASD using the Hoyme et al. system. Since ARND, by definition, is Neurodevelopmental Disorder caused by prenatal alcohol exposure, individuals with ARND are born with ARND. Failure to diagnose ARND in alcohol-exposed infants less than 3 years of age may prevent them from receiving the benefits of early intervention. The 4-Digit Code does not place age restrictions on any of the diagnoses under the umbrella of FASD.

4. The relaxation of the Hoyme et al. FAS facial phenotype criteria greatly increased the prevalence of FAS and PFAS diagnoses and threatened the validity of these FAS and PFAS diagnoses.

- The Hoyme et al. system classified 10 times more patients with the FAS facial phenotype (n=553) than the 4-Digit Code (n=54).
- The Hoyme et al. system produced 16 times more FAS/PFAS diagnoses with unknown alcohol exposure (n=112) than the 4-Digit Code (n=7). This is particularly concerning because 68 (61%) of these patients had 4-Digit Code Rank 1 or Rank 2 facial phenotypes that are, by our definition, clinically "normal". The Rank 1 and 2 phenotypes have no specificity to prenatal alcohol exposure [27]. The only reason FASD diagnostic systems allow a diagnosis of FAS to be made when prenatal alcohol exposure is unknown is because the facial phenotype is so highly specific to (caused only by) prenatal alcohol exposure, the face serves to confirm the exposure. If the facial phenotype defined by the diagnostic system is not confirmed to be highly specific to alcohol, then: 1) the diagnosis cannot be validly labeled FAS or PFAS because a causal link cannot be confirmed between the patient's alcohol exposure and their adverse outcomes, and 2) the facial phenotype cannot be validly used to confirm prenatal alcohol exposure when the history of exposure is unknown.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

- The 4-Digit Code allows a diagnosis of FAS to be made when prenatal alcohol exposure is unknown because the 4-Digit Code Rank 4 FAS facial phenotype is confirmed to be >95% specific to prenatal alcohol exposure [11, 28]. The 4-Digit Code does not allow a diagnosis of PFAS to be made when alcohol exposure is unknown, because the facial criteria for PFAS is relaxed to a Face Rank 3, resulting in a subtle reduction in specificity. To err on the conservative side, the 4-Digit Code requires a confirmed exposure for PFAS.
- In the current study the relaxed Hoyme et al. FAS facial phenotype demonstrated no association with prenatal alcohol exposure. In contrast, the 4-Digit Code FAS facial phenotype demonstrated a strong, significant, linear association with prenatal alcohol exposure.

- The Hoyme et al. system produced 4 times more FAS/PFAS diagnoses (297) overall than the 4-Digit Code (n=81).
- 70% of the 297 Hoyme et al. FAS/PFAS cases had "normal" 4-Digit Code Face Ranks 1 or 2.
- 46% of the 553 patients with the Hoyme et al. FAS face did not receive a diagnosis under the umbrella of FASD using the Hoyme et al. system. In contrast, all 54 patients with the 4-Digit Code Rank 4 FAS face met criteria for a diagnosis under the umbrella of FASD using the 4-Digit Code.

In addition to the contrasts in diagnostic criteria, the methods and tools used to measure the facial features are also markedly different. The authors of the Hoyme et al. system "*feel direct examinations of facial features are more practical in an office setting.*" The 4-Digit Code advises measuring the facial features from 2D digital photos using the FAS Facial Photographic Analysis Software [7]. Empirical studies have confirmed the superior accuracy of the photo versus direct method of facial measurement [8, 9]. Significant contrasts also exist between the 4-Digit Code Lip-Philtrum Guide 1 and the Hoyme et al. North American Lip/Philtrum Guide. As illustrated in Figure 2, although the Hoyme et al. North American Lip/Philtrum Guide looks similar in appearance to the 4 Digit Code Lip-Philtrum Guide 1, these are not interchangeable tools. The lips ranked 1 through 5 on the Hoyme et al. Guide do not match the lips ranked 1 through 5 on the 4-Digit Code Guide. The lips on the 4-Digit Code Guide become progressively thinner as Rank increases from 1 to 5. The lips on the Hoyme et al. guide do not become progressively thinner as Rank increases (e.g., the Hoyme et al. Rank 4 lip is thicker than the Hoyme et al. Rank 3 lip). The images used to depict lip thinness for each Rank do not match between the two guides. When the Hoyme et al. lips are mapped onto the 4-Digit Guide based on the objective measure of thinness (circularity), the Hoyme et al. Rank 1, 2, 3, 4, and 5 lips are equivalent to the 4-Digit Code Lip Ranks 2, 2, 3, 2, and 5, respectively. Both systems define the thin upper lip of FAS as Rank 4 or thinner. But the Hoyme et al. Rank 4 lip is substantially thicker than the 4-Digit Rank 4 lip (it is equivalent to the 4-Digit Rank 2 lip). The introduction of the Hoyme et al. North American Lip/Philtrum Guide serves to further relax the Hoyme et al. FAS facial phenotype. Only 2 of the 3 cardinal features are required and 2 of the 3 features are relaxed relative to the 4-Digit Code. The PFL is relaxed from the 3rd percentile to the 10th percentile and lip thinness is relaxed from Rank 4 to Rank 2 on the 4-Digit Code Lip-Philtrum Guide 1. An individual presenting with PFLs at the 10th percentile, a Rank 1 deeply grooved philtrum, and a 4-Digit Code Rank 2 moderately thick upper lip would meet the Hoyme et al. criteria for the full FAS facial phenotype. The presence of a single, very minor anomaly (PFL at the 10th percentile) does not constitute a dysmorphic facial phenotype. In fact, it would be difficult to justify classifying any of these three features as minor anomalies outside the normal range. Yet, this facial phenotype is used by the Hoyme et al. system to confirm prenatal alcohol exposure when prenatal alcohol exposure is unknown. Of the 71 patients with unknown prenatal alcohol exposure and the Hoyme et al. FAS facial phenotype, 70% had a 4-Digit Code Rank 1 or Rank 2 facial phenotype. By definition, 4-Digit Face Ranks 1 and 2 reflect normal phenotypes with no specificity to prenatal alcohol exposure. This was clearly illustrated in our FASD MRI study [27]. Sixteen high-functioning

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

adolescents with confirmed absence of prenatal alcohol exposure were enrolled as controls in that study. Ten presented with Rank 1 facial phenotypes and 6 presented with Rank 2 facial phenotypes (one of which is illustrated in Figure 6). Based on the findings of the current study, the Hoyme et al. North American Lip/Philtrum Guide is not a valid tool for use with the 4-Digit Code. It is unfortunate and unclear why the Hoyme et al. system introduced a Lip-Philtrum Guide that emulates the 4-Digit Code Lip-Philtrum Guide (five images ranked 1 through 5 with Rank 4 identified as the clinical cut-off for the full FAS facial phenotype) when the Hoyme et al. FASD system only captures lip thinness and philtrum smoothness on a dichotomous (present/absent) scale. Only a single image (the Rank 4 image) is needed to classify the lip and philtrum as ≥Rank 4 on the Hoyme et al. North American Lip/Philtrum Guide. It is not clear why the tool includes Ranks 1, 2, 3 and 5 since none of these ranks or images are necessary to render Hoyme et al. FASD diagnoses.

Before leaving the topic of the FAS facial features, the presence/absence of a Cupid's bow warrants discussion. The Cupid's bow is the contour of the line formed by the vermilion border of the upper lip, resembling an archer's bow in the frontal view when a philtrum is present (Figure 17 A, B). Although the Hoyme et al.[3] diagnostic system clearly refers to the cardinal features of FAS as short palpebral fissures, smooth philtrum, and thin vermilion border of the upper lip and makes no reference to the Cupid's bow, Del Campo and Jones [29] suggest the Cupid's bow may be a more precise way to document a thin upper lip. Del Campo and Jones [29] describe a thin upper lip as follows, referencing the Hoyme et al. South African Mixed Race and North American White Lip/Philtrum Guides: "*A thin or narrow vermillion border of the upper lip has been considered another hallmark of the FAS since its initial definition. However many clinicians and investigators considered lack of the Cupid's bow shape of the upper lip as more precise in order to evaluate this feature as shown for scores 4 and 5 of the lip/philtrum guide*." The authors go on to report in the figure legend portraying the Lip/Philtrum Guides, "*For the vermillion border of the upper lip, the Cupid's bow shape is either lost (*Rank *5) or very underdeveloped (*Rank *4)*." While some in the field have referred to a thin upper lip as a thin vermilion border, it is not the border that is thin, it is the vermilion (or red) part of the upper lip that is thin. This red portion of the upper lip is more accurately referred to as the upper lip vermilion.

It is interesting to note that the although lip thinness on the Hoyme et al. North American Lip/Philtrum Guide does not increase linearly with increasing Rank as one would expect, the contour of the Cupid's bow does diminish linearly with increasing Lip Rank (Figure 2).

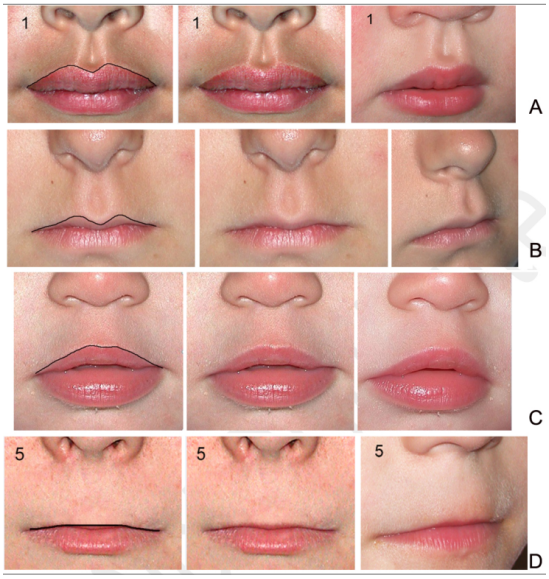

Figure 17. The absence of the Cupid's bow is not a more precise method for documenting a thin upper lip

The Cupid's bow (black line) is the contour of the line formed by the vermilion border of the upper lip, resembling an archer's bow in the frontal view. These images demonstrate that 1) the lower end of the philtrum groove and ridges form the Cupid's bow [30], and 2) the absence of the Cupid's bow is not a more precise method for documenting a thin upper lip [29]. The presence of a Cupid's bow is dependent on the depth of the philtrum, not the thinness of the upper lip. A deep philtrum will form a Cupid's bow even when the upper lip is thin. A and B) Examples of a deep philtrum creating a Cupid's bow in the contour of a thick and thin upper lip. C and D) Examples of a smooth philtrum failing to create a Cupid's bow in the contour of a thick and thin upper lip.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

Del Campo and Jones [29] appear to suggest that the lost or very underdeveloped Cupid's bow shape of the upper lip may be a more precise way to evaluate the thin upper lip feature.

We chose not to use the Hoyme et al. Lip/Philtrum Guide in this manner for the following reasons. First, the Hoyme et al. system makes no reference to the Cupid's bow as a cardinal feature of FAS. Second, the lack of a Cupid's bow reflects a smooth philtrum, not a thin upper lip. The Cupid's bow is formed by the philtrum intersecting with the vermilion border of the upper lip, thus the Cupid's bow is just another way of documenting the presence or absence of the philtrum (Figure 17). As defined by Hennekam et al. [30] in the Elements of Morphology, "*The philtrum is a vertical groove in the midline portion of the upper lip bordered by two lateral ridges or pillars It lies between the base of the nose (subnasale) and the vermilion border (labiale superius), which is also designated as the nasolabial distance. The lower end of the groove and the ridges form the central portion of the Cupid's bow of the vermilion."* And third, our dataset confirms that the absent or underdeveloped Cupid's bow depicted as Ranks 4 and 5 on the Hoyme et al. Lip/Philtrum Guide are not exclusively associated with Rank 4 or 5 thin upper lips. Individuals with thin upper lips present with distinct Cupid's bows when they have deep philtrums (Figure 17B) and individuals with thick upper lips have no Cupid's bow when they have smooth philtrums (Figure 17C). As stated in the Elements of Morphology [31], "*A thin upper lip vermilion may be associated with a smooth philtrum and an absence of the Cupid's bow, but these should be assessed separately."* In the absence of published validation studies supporting this proposed change in one of the cardinal facial features of FAS, clinical teams should adhere to the thin upper lip vermilion feature that is thoroughly validated [11, 28].

One anticipated critique of our use of lip circularity in this analysis is that Hoyme et al. may intend for their lip-philtrum guide to be used for in-person visual comparison, not for photographic analysis using an objective measurement of lip thinness. We considered using retrospective visual comparison with clinic photographs using the Hoyme lip-philtrum guide, but determined that since the lips on the Hoyme guide do not become progressively thinner as Rank increases, and there is some confusion as to whether lip thinness or flat Cupid's bow is being assessed with this guide, it would be too difficult to achieve adequate inter-rater reliability without relying upon the more objective measure of lip circularity.

The quintessential role of the FAS facial phenotype. Why are the criteria used to define the FAS facial phenotype so important to the medical validity of all diagnoses under the umbrella of FASD, not just the diagnosis of FAS? When one makes a diagnosis of FAS, one is stating explicitly that the individual has a syndrome caused by prenatal alcohol exposure [11]. One is also stating explicitly that the biological mother drank alcohol during pregnancy and, as a result, harmed her child. These are bold conclusions to draw and are not without medical, ethical, and even legal consequences. When the FAS face is not specific to FAS and prenatal alcohol exposure, the validity of the entire FASD diagnostic system collapses. Here is why.

- The term (FAS) is rendered invalid. If the face is NOT specific to (caused only by) alcohol, one can no longer label the condition fetal alcohol syndrome. One can no longer confirm alcohol is causally linked to any of the outcomes (growth, brain, or face) in an individual patient.
- The diagnosis (FAS with unknown alcohol exposure) is also rendered invalid. The FAS face can no longer serve as the confirmation of alcohol exposure when the exposure history is unknown.
- FAS is no longer distinct from ARND. ARND is essentially "FAS without the face." But if there is no FAS face, there is no distinction between FAS and ARND. Thus, one can no longer justify classifying FAS and ARND separately.
- The term "ARND" remains problematic. Since ARND has no feature specific to prenatal alcohol, one is in no position to declare the Neurodevelopmental Disorder is "Alcohol-Related" (ARND) in an individual patient.

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

There are ethical consequences to the FASD diagnostic nomenclature. With a term like ARND, one feels compelled to require a significant exposure to alcohol to increase the odds that the individual's impairments may be caused, at least in part, by their alcohol exposure. This is a dangerous road to go down.

- Setting a threshold of significant exposure for ARND does not confirm the patient's alcohol exposure is related to their neurodevelopmental disorder.
- Alcohol is never the only risk factor contributing to the neurodevelopmental disorder. In this study population, 92% were exposed to other prenatal risks including poor prenatal care, pregnancy complications, and exposure to illicit drugs and tobacco. One percent presented with other syndromes (Down, Williams, Sticklers, etc.). Ninety-six percent experienced postnatal risks including trauma, neglect, multiple home placements, and physical/sexual abuse. Seventy-seven percent were in foster/adoptive care at the time of their FASD diagnosis. These other risk factors are so important in the differential diagnostic process, the 4-Digit Code Ranks the severity of these prenatal and postnatal factors on 4-point scales (just like it does for growth, face, CNS, and alcohol exposure) and reports them in full in the patient's medical record.
- One is sending a dangerous message that lower levels of alcohol exposure are safe. As we illustrated in Figure 9, individuals with reported prenatal alcohol exposures below the Hoyme et al. threshold do present with full FAS. Either this patient was particularly vulnerable to the teratogenic insult of alcohol, or the reported exposure was not accurate. In a clinical setting, one is never in a position to know how accurate the exposure is recalled and reported. Setting a threshold implies the details of all reported exposures are accurate and no fetus can be harmed by exposures below the threshold.
- And one is blaming a woman for harming her child, when they have limited ability to make/defend such a claim.

The 4-Digit Code introduced the terms ND/AE and SE/AE back in 1997 [14]. These terms state the verifiable facts; the individual presents with a disorder and the individual was exposed to prenatal alcohol exposure. The terminology does not explicitly state their disorder is related to their alcohol exposure. In fact, the 4-Digit Code formally Ranks all other prenatal and postnatal risks factors to make clear that alcohol is never the only risk factor contributing to an individual's neurobehavioral disorder of static encephalopathy. In 2013, the DSM5 [32] took a similar nosological approach when it introduced the new term "Neurobehavioral disorder associated with prenatal alcohol exposure" (ND/PAE) as a condition for further study.

- When is it a FASD? Fetal Alcohol Spectrum Disorders are, by definition, adverse outcomes caused by prenatal alcohol exposure. In the absence of an outcome that is specific to (caused only by) prenatal alcohol exposure (like the Rank 4 FAS facial phenotype), one cannot confirm or rule-out the role prenatal alcohol exposure played in an individual's CNS dysfunction. So…

- Do all individuals with SE/AE, ND/AE (or ARND) have FASD? Not necessarily. Only the subset of individuals whose CNS dysfunction was caused (in whole or in part) by their alcohol exposure has FASD.

- Which subset is that? We currently have no way of knowing. This is why the 4-Digit Code refers to SE/AE and ND/AE as 'broadly" under the umbrella of FASD. Those with SE and ND caused by their alcohol exposure have FASD. Those with SE and ND that was not caused by their alcohol exposure do not have FASD.

- But if they are exposed to high alcohol levels, can't we just assume alcohol caused their disability? No. Not everyone exposed to high levels of alcohol presents with adverse outcomes. Among 2,576 alcohol-exposed patients evaluated in the University of Washington FASDPN Clinic to date, 26 with high exposures presented with full FAS (4-Digit Codes 4444) while 41 with high exposures presented with normal growth, face, and brain development (4-Digit Codes 1114). We also see discordant outcomes among fraternal twins. Among

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

20 twin pairs with identical high exposures, 5 had normal CNS function while their twin had moderate to severe CNS dysfunction.

When an individual presents with high alcohol exposure and severe CNS dysfunction, but no FAS facial phenotype, as depicted in the diagnosis SE/AE (4-Digit Code 2134):

- If their CNS dysfunction is caused (at least in part) by their alcohol exposure, then their SE/AE is an FASD.
- If their CNS dysfunction was caused by other risk factors, not their alcohol exposure, then their SE/AE is NOT an FASD.
- The only way we can link alcohol to an individual's CNS dysfunction is if they present with a highly specific Rank 4 FAS face (FAS 2434).

- If we cannot confirm alcohol caused their disabilities, does this impact our ability to provide them appropriate intervention? No. Intervention recommendations and a patient's access to services and supports should be based on their disabilities, not on what caused their disabilities. Twenty years of patient surveys [33] confirmed patients with a diagnosis of ND/AE and SE/AE were as likely to access and benefit from interventions as patients with FAS/PFAS. We did not have to label their disorder FAS or PFAS to qualify them for intervention and support services in Washington State.

- Does this impact our ability to prevent FASDs? No. To prevent FASD one must prevent prenatal alcohol exposure. To confirm efforts to prevent prenatal alcohol exposure are working, one needs to document prenatal alcohol exposure in a patient's medical record (regardless of outcome) and track the prevalence of prenatal alcohol exposure by birth cohort annually [34]. If one is reducing the prevalence of prenatal alcohol exposure, one is reducing the prevalence of FASD.

Sensitivity versus specificity

Hoyme et al. (3) reported *"Sensitivity and specificity are 2 sides of a diagnostic coin. Theoretically, the guidelines presented here* (the Hoyme et al. 2016 guidelines [3]) *demonstrating increased sensitivity could lead to over-diagnosis; thus, our advocacy for a structured expert multidisciplinary approach. On the other hand, strict diagnostic cutoffs associated with increased specificity could lead to under-diagnosis of affected children. Children with FASD are subject to a host of societal, educational, health, and judicial problems, all of which are affected by the time of diagnosis. Because early diagnosis and initiation of intervention should be of paramount importance, the authors assert that improved, sensitive, and inclusive diagnostic criteria for FASD should continue to be imperatives in the diagnostic process."* As demonstrated in the current study, strict diagnostic cutoffs (e.g., 3 facial features rather than 2, PFL 3rd percentile rather than 10th , lip Rank 4 rather than Rank 2; OFC 3rd percentile rather than 10th) associated with increased specificity did not lead to under-diagnosis of affected children when using the 4-Digit Code. The 4-Digit Code uses stringent cutoffs for the FAS facial phenotype to achieve diagnostic accuracy/validity. If the face is not specific to (caused only by) alcohol, one cannot validly label the condition FAS (or PFAS) because one cannot link the patient's adverse outcomes to their alcohol exposure. High specificity does not prevent individuals at risk for FASD from being identified and diagnosed. The 4-Digit Code is able to document the full continuum of outcomes and exposures (from 1113 to 4444) across the entire age span because it is not constrained by the implication of causation that comes with the term ARND. Aase and colleagues [35] urged "*simple recording of the verifiable conclusions. If prenatal alcohol exposure has taken place, but FAS cannot be substantiated, the exposure still should be indicated, and any nonspecific abnormalities or problems noted.*" This is the approach the FASD 4-Digit Code adopted when it was first introduced in 1997 [14]. This approach ensures no one is missed and no one is misdiagnosed.

The two diagnostic systems produce different outcomes, but which one, if either, is correct? Validation studies are required to confirm the accuracy, reproducibility, and medical validity of a diagnostic system. Validity is the degree to which a tool (or diagnostic system) is measuring what it

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

purports to measure [36]. When the 4-Digit Code was introduced in 1997 [14, 16], it was published as an empirical study confirming its superior performance to the gestalt [37] approach it was designed to replace. Since then, two decades of more extensive laboratory, clinical, and public health empirical studies have comprehensively affirmed the validity of the FASD 4-Digit Code [11]. A clinician's guide for how to fully assess the performance of FASD diagnostic systems was introduced in 2013 [11] and replicated below (Table 2).

The guide proposes 12 questions clinicians should ask to assess the performance of FASD diagnostic systems. The 4-Digit Code's performance meets all 12 criteria. In contrast, the 2005 [38] and 2016 [3] versions of the Hoyme et al. FASD diagnostic systems were introduced without empirical studies confirming its superior performance to other published FASD systems.

The single most important form of validation required of a FASD diagnostic system is confirmation that the FAS facial phenotype is highly specific to (caused only by) prenatal alcohol exposure. As discussed above, in the absence of a highly specific facial phenotype, the validity of the entire FASD diagnostic system collapses. The labels FAS and PFAS are rendered invalid. Diagnoses of FAS and PFAS can no longer be validly rendered when prenatal alcohol exposure is unknown. And FAS and PFAS are no longer distinguishable from ARND. Several published studies have confirmed that the Rank 4 FAS facial phenotype is highly specific (>95% specificity) [11] to prenatal alcohol exposure while the Hoyme et al. FAS Facial phenotype has a reported level of specificity (71% to 75%) [24, 25] that is insufficient to confirm it is caused only by prenatal alcohol exposure. This absence of association between the Hoyme et al. FAS facial phenotype and prenatal alcohol exposure was further confirmed in the current study. To date, the FASD 4-Digit Code is the only FASD diagnostic system that has a published record of validation.

Table 2. As clinicians assess the performance of FASD diagnostic guidelines, clinicians should ask the following questions [11]

1. Have properly designed studies been published to confirm the case definition for the FAS facial phenotype is highly specific (>95%) to FAS and alcohol (e.g. observed only among individuals with prenatal alcohol exposure and FAS)? If the FAS facial phenotype is not highly specific to prenatal alcohol exposure, FAS cannot be diagnosed when prenatal alcohol exposure is unknown.
2. Was data used to empirically derive the diagnostic guidelines? Was the data drawn from a large, representative, population-base?
3. Has the performance of the guidelines been empirically assessed (validated)?
4. Individuals are born with FAS/D. Can the diagnostic system identify FAS/D at birth and across the lifespan?
5. Growth deficiency, the FAS facial phenotype, CNS abnormalities, and alcohol exposure all present along clinically meaningful continuums. The FAS facial phenotype is not just present or absent. The brain is not just normal or abnormal. Do the Guidelines recognize/incorporate these important continuums?
6. Do the guidelines produce clinically distinct subgroups across the full spectrum (FAS, PFAS, SE/AE, ND/AE)?
A. Do brain imaging studies identify statistically significant contrasts between the FASD subgroups?
B. Individuals with FAS have more severe CNS dysfunction than individuals with "ARND". Do the Guidelines generate FAS and "ARND" groups that demonstrate this important contrast?
C. Do individuals who meet the criteria for FAS actually have FAS?
7. Can the guidelines detect unique alcohol exposure patterns between the FASD subgroups?
8. Can the diagnostic system be effectively and efficiently taught to interdisciplinary teams?
9. Are the guidelines confirmed to be reproducible? If two clinics use the guidelines, do they render the same diagnoses?
10. Do families report high satisfaction/confidence with the diagnostic process/outcome?
11. Are the names of the diagnoses (FAS, PFAS, SE/AE, ND/AE) medically valid? Do they imply causality between alcohol and outcome that cannot be confirmed in the individual patient?
12. Do diagnoses under the umbrella of FASD qualify patients for intervention services that lead to improved outcomes?

ADVANCES IN PEDIATRIC RESEARCH

Conclusions

The FASD 4-Digit Code and Hoyme et al. 2016 FASD diagnostic systems produced markedly different outcomes. Only 38% of the 1,392 patients received concordant diagnoses from the two systems. Overall, the Hoyme et al. criteria rendered half as many diagnoses under the umbrella of FASD as the 4-Digit Code (558 and 1,092 respectively) due to more stringent alcohol exposure criteria and the setting of minimum age restrictions. The Hoyme et al. criteria placed a much higher proportion of FASD diagnoses in the FAS and PFAS categories than the 4-Digit Code (53% and 7%, respectively) because of the substantial relaxation of the Hoyme et al. FAS facial phenotype criteria. The Hoyme et al., FAS/PFAS facial phenotype had no correlation with or specificity to prenatal alcohol exposure. In contrast, the 4-Digit Code Rank 4 FAS facial phenotype was highly correlated with and highly specific to prenatal alcohol exposure. The Hoyme et al. North American Lip/Philtrum Guide and 4-Digit Code Lip-Philtrum Guide 1, while similar in appearance, are not equivalent tools. The Rank 4 moderately thin upper lip on the Hoyme et al. Guide is equivalent to the Rank 2 moderately thick upper lip on the 4-Digit Guide. The FASD 4-Digit Code has been extensively validated [11] over the past 20 years. In contrast, the relaxation of the FAS facial phenotype criteria poses a major threat to the validity of the Hoyme et al. 2016 FASD diagnostic system.

Ethical approval

This study was approved by the University of Washington Human Subjects Division.

Author contribution

All authors are members of the interdisciplinary FASD diagnostic team and participated in the interpretation and reporting of the study's outcomes. SJA conducted the statistical analyses.

ARTICLE

An investigation of intra-individual variability in children with fetal alcohol spectrum disorder (FASD)

Sheliza Ali [a], Kimberly A. Kerns[a], Bryce P. Mulligan[a], Heather Carmichael Olson[b,c] and Susan J. Astley[d,e]

ABSTRACT

Intra-individual variability (IIV) is defined as systematic within-person variation in performance either across test sessions (e.g., test/retest performance on the same task) or in one session (e.g., variations in performance on multiple trials of a single task). Higher levels of IIV have been noted as a characteristic of neurodevelopmental disorders such as attention deficit/hyperactivity disorder (ADHD), but IIV is yet to be investigated in fetal alcohol spectrum disorder (FASD). FASD is a term used to describe a range of conditions resulting from prenatal exposure to alcohol. As part of a comprehensive neuropsychological battery, four study groups (1. fetal alcohol syndrome/partial fetal alcohol syndrome; 2. static encephalopathy/alcohol exposed; 3. neurobehavioral disorder/alcohol exposed as diagnosed using the University of Washington FASD 4-Digit Code; 4. typically-developing (TD) age-matched children with no prenatal alcohol exposure) were administered measures of motor response and inhibitory control, attention, and adaptive behavior. The results indicate increased levels of IIV in those with FASD compared to the TD controls. It was found that IIV uniquely contributes to predicting adaptive behavior above and beyond attention, while attention partially mediates the relationship between IIV and adaptive behavior. This is the first study to the authors' knowledge to show the presence of increased IIV in children with FASD. It additionally provides evidence that IIV measures some inherent variability in performance independent of poor attention in children with FASD.

Fetal alcohol spectrum disorder; Prenatal alcohol; Intra-individual variability; Variability; Attention; Adaptive behavior

Fetal alcohol spectrum disorder (FASD) is a broad nonclinical term used to describe several conditions resulting from prenatal exposure to alcohol. FASD has been documented as occurring worldwide and according to Roozen et al. (2016), the prevalence of FASD per 1000 live births in the United States (US) is estimated to be 0.7 for fetal alcohol syndrome (FAS), 2.2 for partial fetal alcohol syndrome (pFAS), 9.1 for alcohol-related neurodevelopmental disorder (ARND), and 2.6 for alcohol-related birth defects (ARBD). Other diagnostic criteria and terminology have been developed for children

with prenatal exposure to alcohol; for example, in Canada "FASD" can now be used as a diagnostic term with specifiers (Cook et al., 2016), rather than a nonclinical umbrella term. This lack of universal criteria and terminology means that children can be given different diagnoses depending on the criteria used. It should be noted that this paper uses terms that are consistent with the University of Washington FASD 4-Digit Code, a case-defined, validated system that characterizes a pattern of growth deficiency, facial dysmorphology, central nervous system (CNS) functional and structural abnormalities, and prenatal alcohol exposure (Astley, 2013). This system derives four diagnoses under the umbrella of FASD: FAS, pFAS, static encephalopathy/alcohol exposed (SE/AE), and neurobehavioral disorder/alcohol exposed (ND/AE). There has been an increasing amount of research conducted on the cause and symptoms of children with FASD—however, the research is still in the early stages of facilitating a clear understanding of the widespread effects of prenatal exposure to alcohol (for reviews, see Guerri, Bazinet, & Riley, 2009; Kable et al., 2016; Mukherjee, 2015). In order to expand the current understanding of the behavioral outcomes of children with FASD, this paper investigates intra-individual variability (IIV) and its relationship with attention and adaptive behavior in children with FASD.

The individual symptoms seen in those with FASD differ depending on circumstances such as the amount of alcohol consumed by the mother, nutrition, maternal age, stage of gestation, etc. (May et al., 2013; Sulik, 2005); therefore, not all symptoms are present in every case, and those that are vary in their degree of severity (Astley, 2013).

Individuals diagnosed with FASD frequently exhibit considerable within-group variability in the presentation of symptoms and are clinically noted to exhibit higher levels of variation in the performance of academic and daily activities when compared to typically-developing (TD) children. For example, variability seen in social communication has been rationalized as being due to children with FASD having deficits in attention and executive function, leading to hyperactivity and a lack of awareness of the displeasure of their peers (Kjellmer & Olswang, 2012; for a review, see Mattson, Crocker, & Nguyen, 2011). Variability has also been seen in motor response times; Simmons, Thomas, Levy, and Riley (2010) found that as the planning demands of a motor task increased, so did the within-group variability and length of response times of their FAS group compared with their control and prenatal alcohol exposed (PAE) groups. There was no difference found between the FASD groups and control group when the response planning required was minimal, suggesting that the variability in performance in individuals with FASD increases with cognitive demand.

Although considerable information about the variability *between* individuals with FASD has been noted, as far as the authors' are aware, to date there have been no studies investigating task performance response variability *within* individuals with FASD—that is, what has been termed IIV, which is defined as systematic within-person variation in performance either across testing sessions (e.g., test/retest performance on the same task) or on a single session (e.g., variations in performance on multiple trials of a single task). Compared to between-person variability, the measurement of IIV adds information related to the consistency or stability of performance over time (where high IIV implies low consistency). This type of variability, though not formally measured in children with FASD, has been noted as a common feature of the disorder. A case study by Timler and Olswang (2001) investigated an

8-year-old boy diagnosed with FAS to determine discrepancies between parent and teacher determinations of the best educational program for him, noting that "behavior was inconsistent from day to day" (Timler & Olswang, 2001, p. 51) and that this was not due to intentional disobedience. Similar statements can be found from support forums where parents and guardians of children with FASD report this inexplicable IIV in their children ranging from social interactions to academic performance. Many forums and information booklets describe these inconsistencies in performance as the child having "on" and "off" days. Malbin (2004) states that inconsistencies in memory or performance are a primary feature of children with FASD and that this is reflective of the functioning of underlying brain structures. Kjellmer and Olswang (2012) further note that children with FASD exhibit higher levels of variability in social communication, elaborating that these inconsistencies in communication make interactions with these children unpredictable—especially when they perform similarly to their TD peers on some days but not on others. A number of studies have documented greater within-participant variability in reaction times—i.e., reaction time *SD* (RTSD)—on sustained attention tasks in children with prenatal alcohol exposure (Olson, Feldman, Streissguth, Sampson, & Bookstein, 1998; Streissguth, Barr, Sampson, and Parrish-Johnson, 1986; Streissguth, Bookstein, Sampson, & Barr, 1995; Streissguth et al., 1994), a finding replicated in studies of animals prenatally exposed to alcohol (Hausknecht et al., 2005).

Intra-individual Variability (IIV)

IIV is defined as a within-person variation in performance either across testing occasions—such as the variability measured for a single person on a single task across multiple sessions spanning the short term (trials) to the long term (days, weeks, etc.)—or in a single session—variability for a single person at a single occasion across multiple trials (MacDonald & Stawski, 2014). Whereas some level of variability is typical due to practice and fatigue effects, when the variability seen is not a random occurrence but becomes trait-like and characteristic of an individual's performance then it is of clinical interest. It should be noted that a distinction is made between systematic and permanent changes over time, often referred to as intra-individual change (Nesselroade, 1991), and reversible changes over short periods of time. For the purpose of this paper, IIV is used to mean the latter definition.

IIV appears to be a sensitive predictor of neural dysfunction. An overall increase in IIV has been documented as occurring in clinical groups with cognitive difficulties, including aging populations (Dykiert, Der, Starr, & Deary, 2012), those with traumatic brain injury (Hill, Rohling, Boettcher, & Meyers, 2013; Stuss, Murphy, Binns, & Alexander, 2003), individuals with dementia (MacDonald, Nyberg, & Bäckman, 2006), and children with attention deficit/hyperactivity disorder (ADHD) and other neurodevelopmental disorders (Geurts et al., 2008). The study of IIV in aging and traumatic brain injury populations is of interest, as it may shed light on the possible changes in neural structures that can account for this variability in performance. Similarly, it is also of interest when studying young children with neurodevelopmental disorders to understand variations in the abilities of these children compared to their TD peers.

IIV is not a consistent aspect of the neural system, but rather appears to have a developmental trajectory. In their review of IIV, MacDonald et al. (2006) discuss the U-shaped function of IIV over the life span – in general, IIV is higher in early childhood, begins to decrease into adolescence and adulthood as the neural system becomes more efficient during the natural pruning and myelination processes, and then begins to increase again in later adulthood, which is associated with lower efficiency and cognitive decline. Given this connection between a decrease in IIV and synaptic pruning, as this process is compromised in children with prenatal alcohol exposure (Lebel et al., 2012; Treit et al., 2013) it is possible that the IIV seen in FASD may be higher than in TD children. Lebel et al. (2012) found that in children with FASD, cortical loss over time is positively related to the amount of alcohol exposure prenatally. Specifically, they found that those with FASD did not have increases in cortical volume *before* synaptic pruning began; these increases are seen in TD controls. They suggest that these trajectories indicate a lack of plasticity, so that when pruning occurs during later years, those with FASD may actually be losing important neural connections, thereby decreasing cognitive efficiency (Lebel et al., 2012).

While there are a number of structural central nervous system symptoms associated with FASD (for reviews, see Moore, Migliorini, Infante, & Riley, 2014; Wilhelm & Guizzetti, 2015), Treit et al. (2013) investigated abnormalities in the white matter tracts of children with FASD using diffusion tensor imaging (DTI). Two measures used in DTI are fractional anisotropy (FA), which measures the direction of proton diffusion, and mean diffusivity (MD), which measures the magnitude of diffusion. As children typically mature, so too do their white matter connections in the brain, allowing for more efficient conduction and a decrease in variability; therefore, in DTI, maturation is associated with an increase in FA and a decrease in MD. Treit et al. (2013) notes that during development, the FASD group showed some expected changes in white matter (increased FA and decreased MD) but not to the degree of the controls, especially in the frontal regions of the brain, suggesting poor myelination as a possible explanation. As IIV is often conceptualized as a metric for efficiency in the neural connections, these findings can be extrapolated to suggest an increase in variability in the FASD group, along with lower efficiency. Indeed, Tamnes, Fjell, Westlye, Ostby, and Walhovd (2012) report a decrease in IIV from childhood into adolescence, rationalized as secondary to improved white matter connectivity and maturity. Research has also found evidence supporting differences in more central regions while using DTI to investigate the integrity of white matter connections in the brain of TD children (Tamnes et al., 2012) and those with FASD (Treit et al., 2013). A recent review by Wilhelm and Guizzetti (2015) consolidates research detailing the negative effect of prenatal exposure to alcohol on glial cells that play an essential role in CNS structural development including myelination and plasticity, which may account for the widespread effect of the teratogen on brain development.

IIV and Attention

As measures of IIV are typically calculated on tasks that require some level of sustained attention over repeated trials (e.g., continuous performance tasks, go/no-go tasks, etc.), it is important to understand the relationship between IIV and aspects of attention. Kelly, Uddin, Biswal, Castellanos, and Milham (2008) investigated two competing networks with regard to IIV and attention in healthy participants: the "task-positive"

network that becomes active during a task and is related to attention, and the "task-negative" network that is deactivated during a task but active at rest, also known as the default mode network (DMN). They found that as the negative correlation between the two networks increases, the variability in performance decreases, meaning that performance stabilizes as more attention is given to the task. However, when both these networks are activated and therefore competing with each other, the variability of performance increases, especially as the task becomes more complex. This suggests that as attention becomes more compromised, so (too) does the response to the stimuli. This provides a possible mechanism whereby disorders affecting attention networks may also be associated with increased variability in performance.

Although research similar to that of Kelly et al. (2008) has not been conducted on an FASD population, there have been resting-state studies investigating the DMN in this population. Specifically, Santhanam et al. (2011) investigated the DMN of adults with prenatal alcohol exposure compared to controls and found, using a resting-state functional magnetic resonance imaging (fMRI), that the level of deactivation in the DMN was lower for the alcohol-exposed group than for the controls. The DMN is more active during rest, so change is measured in levels of deactivation. Based on the findings of Kelly et al. (2008), less deactivation implies increased competition with the task-positive network. Santhanam et al. (2011) similarly suggest that the lower levels of deactivation seen in the clinical groups implies that there is some competition (attentional modulation) between the DMN and cognitive activity, resulting in dysfunctional or poorer performance in the clinical groups. Castellanos, Kelly, and Milham (2009) describe a similar relation between the DMN and IIV in children with ADHD.

There has also been some research conducted on IIV in children with ADHD, a common comorbid diagnosis with FASD, and a population where within-person *variability* in performance is considered by some researchers to be a *stable* between-person characteristic of the disorder (see Castellanos & Tannock, 2002). Additionally, Gmehlin et al. (2014) investigated attention and inhibition in a population of non-medicated adults with ADHD using IIV and errors of commission and omission on a go/no-go task. They argued that their findings of increased IIV and errors of omission suggest deficits in sustained attention—that disruptions in sustained attention that do not ultimately result in errors of omission instead lead to longer response times—and secondarily increased IIV.

Research by Geurts et al. (2008) argues that variability in performance is not specific to ADHD, as their findings support increased IIV in children with high-functioning autism (HFA), with comorbid autism spectrum disorder (ASD) and ADHD, as opposed to those with ADHD alone or TD children. They support their findings with the argument that previous studies have not controlled for comorbidity in their participants; this conclusion is also echoed by studies investigating similar responses in children with HFA, ADHD, and Tourette's syndrome (Verté, Geurts, Roeyers, Oosterlaan, & Sergeant, 2006).

IIV and Adaptive Behavior

Burton, Strauss, Hultsch, and Hunter (2009) investigated the relationship between IIV and everyday problem-solving in older adults. They point out that everyday problem-solving is an ecologically valid way of measuring an individual's abilities (as opposed to IQ), and determined that those with more inconsistent reaction times

(that is, higher IIV) have poorer everyday problem-solving abilities, thereby suggesting that the IIV measure has some "functional" relevance. Additionally, studies have pointed to the link between the frontal lobes and adaptive behavior (Schoenbaum, Roesch, Stalnaker, & Takahashi, 2009), as well as the frontal lobes and IIV (Bellgrove, Hester, & Garavan, 2004; MacDonald et al., 2006; Simmonds et al., 2007), thus suggesting a relationship between IIV and adaptive behavior. However, it should be noted that although Burton et al. (2009) highlight that everyday problem-solving is a more ecologically valid way of measuring ability than IQ, a relationship between the two constructs does exist. This is not surprising given the overlap in these constructs, and definitions of IQ such as "intelligence is the aggregate or global capacity of the individual to act purposefully, to think rationally and to *deal effectively with his environment*" (Wechsler, 1944, p. 3). Indeed, IQ is typically found to be predictive of adaptive behavior in children with developmental disorders, especially in lower-functioning groups (Bölte & Poustka, 2002; Duncan & Bishop, 2013; Liss et al., 2001).

Children with FASD have also been documented as exhibiting deficits in adaptive behavior when compared to controls on communication, daily living skills, and socialization domains (Crocker, Vaurio, Riley, & Mattson, 2009; Jirikowic, Kartin, & Olson, 2008; Rasmussen, Andrew, Zwaigenbaum, & Tough, 2008) and these deficits are significantly more impaired than in children with ADHD. Crocker et al. (2009) highlight that even though there are shared symptoms between children with ADHD and those with FASD, the latter are more impaired on daily living skills, and while children with ADHD tend to improve with age, such a relation is not seen in those with FASD, suggesting an "arrest" in development in these skills versus a "delay" (Crocker et al., 2009, p. 22).

Aim and Hypothesis

The current study aims to investigate IIV in children with FASD compared to TD controls with no prenatal exposure to alcohol. Based on the existing literature, children with FASD are anticipated to have higher levels of IIV when compared to controls. The relationship between IIV and attention has been outlined in previous studies (e.g., Kelly et al., 2008) as well as the relationship between attention and adaptive behavior (e.g., Clark, Prior, & Kinsella, 2002), and between IIV and adaptive behavior (e.g., Burton et al., 2009). These relationships also lead to the question of how, and if, the assessment of IIV provides any information that is distinct from the assessment of attention, for example in relation to behavioral outcomes such as accounting for adaptive behavior. In other words, is IIV a unique or sensitive measure in an FASD population, as has been proposed in older populations (Hultsch, Strauss, Hunter, & MacDonald, 2008)? As such, this study also aims to investigate the relationship between IIV, attention, and adaptive behavior: specifically, it was hypothesized that IIV would account for additional variability in adaptive behavior independent of attention. Finally, it was hypothesized that attention would be found to mediate the relationship between IIV and adaptive behavior.

Method

Participants

The protocol was approved by the University of Washington Human Subjects Review Board. The individuals involved in this study were participants in the FASD MRI/MRS (magnetic resonance spectroscopy)/fMRI study conducted by Astley and colleagues in 2007 (Astley, Aylward, et al., 2009a, 2009b; Astley, Olson, et al., 2009; Astley, Richards, et al., 2009). Three FASD groups were chosen from 1200 patients who were previously diagnosed by an interdisciplinary team in the WA State FAS Diagnostic & Prevention Network (FAS DPN) or clinics using the FASD 4-Digit Code (Astley, 2013, 2004).

The first group, FAS/pFAS (n = 20), is comprised of children with severe cognitive/behavioral dysfunction and/or CNS structural/neurological abnormalities, and the FAS facial phenotype. These groups were combined because the primary clinical difference between FAS and pFAS is the presence of growth deficiency in the former. The second group, SE/AE (n = 24), is comprised of children with severe cognitive/behavioral dysfunction and/or CNS structural/neurological abnormalities, but without the FAS facial phenotype (the main distinguishing feature from group 1). The FASD 4-Digit Code defines severe cognitive/behavioral dysfunction as three or more domains of function (e.g., cognition, memory, language, etc.) that are two or more *SD*s below the mean based on standardized psychometric tools administered by clinicians. The 4-Digit Code ranks severe dysfunction as CNS Rank 3. CNS structural/neurological abnormalities may include microcephaly, structural abnormalities detected on MRI, and/or a seizure disorder. These structural/neurological abnormalities are assigned a CNS Rank 4. The third clinical group, ND/AE (n = 21), is comprised of children with prenatal alcohol exposure and moderate cognitive/behavioral dysfunction. The children in this group did not present with CNS structural/neurological abnormalities or the FAS facial phenotype. Moderate dysfunction is defined by the FASD 4-Digit Code as cognitive/behavioral function or development that is impaired but insufficient to receive a CNS Rank 3 classification. Moderate dysfunction is classified as CNS Rank 2. The fourth group, TD controls (n = 16), is comprised of children with no prenatal alcohol exposure who were healthy and did not present with academic concerns. They were chosen from a large cohort of children who, at birth, were enrolled in a University of Washington study of typical development conducted via the Department of Speech and Hearing Sciences. This registry of children has been maintained over the years to serve as a source of healthy controls for studies conducted across the university.

The children in all four groups were balanced on age (within 6 months), gender, and race. See Table 1 for demographic information and Astley et al. (2009b) and Astley, Olson, et al. (2009) for additional neuropsychological profile data not used in the current study.

IIV Measurement

While there are multiple ways of measuring IIV, including simple measures of intra-subject variability such as the intra-individual coefficient of variation (ICV) and the

Table 1. Demographic Profiles and Performance on Measures of IQ, Attention and Adaptive Behavior.

	Group			
	FAS/pFAS	SE/AE	ND/AE	Control
Characteristics	*n* = 20	*n* = 24	*n* = 21	*n* = 16
Female, *n* (%)	10 (50.0)	8 (33.3)	10 (47.6)	8 (50.0)

Race, *n* (%)				
Caucasian	12 (60.0)	11 (45.8)	12 (57.1)	13 (81.3)
African American	6 (30.0)	4 (16.7)	6 (28.6)	2 (12.6)
Native American	2 (10.0)	7 (29.2)	2 (9.5)	0 (0.0)
Other	0 (0.0)	2 (8.3)	1 (4.8)	1 (6.3)
FSIQ[1]*, *M* (*SD*)	77.5 (14.4)	79.3 (10.5)	99.2 (11.3)	123.9 (6.5)
Attention[2]*, *M* (*SD*)	59.8 (20.1)	70.9 (22.9)	81.9 (24.7)	103.6 (15.5)
Adaptive Behavior[3]*, *M* (*SD*)	59.0 (17.5)	55.0 (14.2)	65.4 (21.1)	95.3 (12.3)

Note. *Standard score: *M* = 100, *SD* = 15; [1]Wechsler Intelligence Scale for Children – Third Edition (WISC-III; Wechsler, 1991); [2]Full-Scale Attention Quotient, Integrated Visual and Auditory Continuous Performance Test; [3]Adaptive Behavior Composite, Vineland Adaptive Behavior Scales – Interview Format. FAS/pFAS = fetal alcohol syndrome/partial fetal alcohol syndrome; ND/AE = neurobehavioral disorder/alcohol exposed; SE/AE = static encephalopathy/alcohol exposed.

raw-score intra-individual *SD* (raw-score ISD), in the current study the IIV is calculated using a residual ISD method (Bielak, Hultsch, Strauss, MacDonald, & Hunter, 2010; Geurts et al., 2008; Hultsch et al., 2008). In their discussion of methods of calculating IIV using measurements of reaction times (RTs) to simple motor tasks, Hultsch et al. (2008) state that this ISD method provides information about either the amount of IIV (analyses investigating short-term variability in behavior) or the form of the IIV (analyses aimed at investigating systematic changes over time); the present study seeks to examine the *amount* of IIV. For the "amount" calculations, Hultsch et al. (2008) describe residual ISD (among others) as a preferred method. The residual ISD method (see the Statistical Procedures section below) for calculating IIV on RT involves saving residual scores for the RT of each individual trial (unpredictable variation) following a regression partialing out confounding variables (e.g., mean RT, systematic time-based effects related to practice or learning), thus leaving only unsystematic trial-to-trial variation. The within-person, across-trial *SD* of these residual values is known as the residual ISD (Geurts et al., 2008; Hultsch et al., 2008).

Hultsch et al. (2008) highlight the advantages of using the residual ISD method over the raw-score ISD for the calculation of IIV. One benefit of the residual ISD is that it accounts for the correlation typically observed between the intra-individual mean and the raw-score ISD. For example, unlike the raw-score ISD method, which may be impacted by between-group variations in performance (e.g., group differences in mean RT), the residual ISD method adjusts for between-group differences in mean RT with linear regression, eliminating this as a potential source of bias. Secondly, residual ISD also allows IIV scores to be adjusted for differences due to systematic within-person variation (variation due to a known mechanism), such as from the effects of fatigue or practice; this is the rationale for including trial sequence as a predictor in the regression model. In summary, residual ISD can be thought of as a "purer" and therefore more construct-valid measure of IIV than raw-score ISD. While raw-score ISD reflects both unsystematic and systematic trial-to-trial variations in RT, residual ISD reflects only that within-person variation in RT which is not systematically related to linear change across trials or to group

differences in mean RT. The raw score ISD does not adequately capture the phenomenon of interest (seemingly random fluctuations in RT across trials) because it does not isolate unsystematic variance from that which is systematic (i.e., related to differences across trials or between groups).

IIV Tasks

All participants completed two tasks (Letters Game & Arrows Game) aimed at assessing unique components of inhibitory control during a task requiring sustained attention. These tasks include a control continuous performance condition (typically simple detection of a stimulus) and an inhibitory condition (requiring participants to attend to salient but irrelevant stimuli). Specifically, in the Letters Game (a go/no-go paradigm), in the control condition single capital letters appear on a computer screen and the participants are required to hit the space bar for the "X" trials. In the inhibitory condition, the participants hit the space bar for all letters except "X", that is, they are asked to inhibit the response when "X" is on-screen (Figure 1(a)). In the Arrows Game (a game requiring overcoming prepotent motor response), an arrow appears on-screen requiring participants to either push the arrow key pointing in the same direction (control condition) or the opposite direction (inhibitory condition) as the displayed arrow (Figure 1(b)).

Attention Task

All participants completed the Integrated Visual and Auditory (IVA; Tinius, 2003) continuous performance test (CPT). The IVA CPT is a standardized go/no-go-type

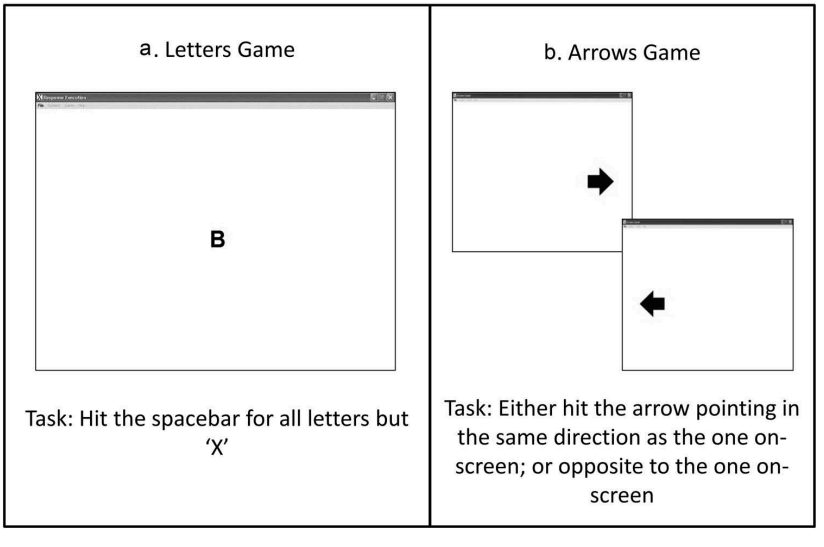

Figure 1. Screenshots of a task for (a) the Letters Game and (b) the Arrows Game.

computerized test that simultaneously assesses both visual and auditory aspects of attention, providing measures of vigilance, focus, and speed. During the task, participants either see or hear the numbers "1" and "2". They are then expected to respond by clicking a button or mouse when a "1" is seen or heard and to inhibit that response when a "2" is seen or heard. This measure thus produces separate scores for visual and auditory attention that are combined into a "full-scale attention quotient". For the purposes of this study, the full-scale attention quotient is used in the analyses (see Table 1; additional IVA scores are published in Astley, Olson, et al., 2009).

Adaptive Behavior Measure

The Vineland Adaptive Behavior Scales – Interview Format (VABS; Sparrow, Balla, & Cicchetti, 1984) was completed by a parent or guardian of each participant. Adaptive behavior represents the typical performance of an individual—that is, it is meant to assess what an individual actually does, behaviorally, on a daily basis. The VABS is a standardized age-based parent questionnaire containing statements that are rated as *usually*, *sometimes*, or *never* based on the target individual's abilities. The statements fall into three major domains (Communication, Daily Living Skills, and Socialization) that combine into the overall Adaptive Behavior Composite that is used in the present analyses (see Table 1; additional VABS scores are published in Astley, Olson, et al., 2009). The VABS is a common measure that is used to assess an individual's deficits in adaptive functioning in order to assist in diagnosis (such as intellectual disability or ASD), to understand the impact of a diagnosis, or to advise intervention planning, since it is deemed to be directly applicable to the skills that an individual will use in daily living (Cicchetti, Carter, & Gray, 2013).

Statistical Procedures

Preparation.

The data for each task (the Letters Game and the Arrows Game) were analyzed separately for ease of operation. They were firstly prepared by removing participants where there are missing data due to equipment failure or incomplete tasks. As a result, one participant from the SE/AE group was removed from the Arrows Game, while no participants were removed from the Letters Game analyses. As is standard for the calculation of IIV, implausible outliers in the response times were removed, such as extremely fast responses (less than 150 ms, generally indicative of anticipatory errors). Extremely slow responses are thought to be due to distraction from the task and were also removed for the calculation of IIV. These upper boundaries for slow responses were computed separately for each task; the games differ in presumed complexity and therefore it is thought that the mean RT for each task will reflect this. The upper boundary for each task was equated to the mean RT for the task plus three times its *SD*. The removal of these outliers in the RTs allows for a more conservative estimation of IIV. In total, for the Letters Game approximately 4% of trials were removed, while 2% were removed for the Arrows Game.

Intra-Individual Variability (IIV).

IIV was indexed by computing ISDs (see Bielak et al., 2010). The ISD represents the variability of each individual's RT across the individual task trials. Separate ISDs were

computed for each condition (control and inhibition) within each task. Because the means and *SD*s of raw RTs are correlated within persons, the ISD method involves saving the residuals from a regression to partial out effects of possible confounding variables (including trial, condition, and group) to parse the unique variance of each individual. This residual was then converted to a standardized *t*-score ($M = 50$, $SD \approx 10$) to allow for comparison across tasks. The final IIV measure is the *SD* across the trials of these *t*-scores, which is the ISD per individual, per condition, per task.

Results

Mean Reaction Times (RTs)

A mixed analysis of variance (ANOVA) was undertaken to compare the main effects of group (between-subjects variable) and condition (within-subjects variable), as well as to determine if an interaction exists between group and condition. For both the Letters Game and the Arrows Game, an investigation of the mean RT between groups for each condition indicated a main effect of condition where, as expected, the mean RT of the inhibition condition, $F(1, 77) = 49.44$, $p < .001$, partial $\eta^2 = .39$, is significantly slower than the control condition, $F(1, 76) = 28.23$, $p < .001$, partial $\eta^2 = .27$.

A main effect for group is also present for the Letters Game, $F(3, 77) = 3.36$, $p < .05$, partial $\eta^2 = .12$, and the Arrows Game, $F(3, 76) = 5.03$, $p < .01$, partial $\eta^2 = .17$. There is no significant interaction effect. Significant group differences were further explored via the Duncan post hoc test that essentially identifies which group means differ (see Table 2 for mean values and Duncan post hoc groupings).

IIV

IIV estimates per task per condition were compared using a mixed ANOVA to examine the main effects of group and condition and their interaction. Investigation of the IIV for the Letters Game revealed main effects for both group, $F(3, 77) = 4.33$, $p < .01$, partial $\eta^2 = .14$, and condition, $F(1, 77) = 52.51$, $p < .001$, partial $\eta^2 = .41$. No significant interaction effect was found. The variability in the inhibition condition was higher than that of the control condition across all groups (see Table 2).

Table 2. Means for Reaction Times (RTs) and IIV.

		Letters Game			Arrows Game		
Group	Condition	*n*	RT (ms)	IIV	*n*	RT (ms)	IIV
FAS/pFAS	Control	20	385.275	6.263	20	537.366	7.963
(1)	Inhibition		437.828	10.163		651.772	8.453
SE/AE	Control	24	434.738	7.624	23	516.719	9.263
(2)	Inhibition		480.838	11.806		628.128	9.618
ND/AE	Control	21	393.475	6.399	21	456.592	5.764
(3)	Inhibition		447.009	10.337		543.288	6.485
Control	Control	16	367.744	4.560	16	383.491	5.400
(4)	Inhibition		404.654	7.052		439.032	5.483
Duncan Post Hoc Tests			134, 123	123, 4		123, 34	12, 134

Note. FAS/pFAS = fetal alcohol syndrome/partial fetal alcohol syndrome; ND/AE = neurobehavioral disorder/alcohol exposed; SE/AE = static encephalopathy/alcohol exposed.

Investigation of the IIV for the Arrows Game revealed a main effect for group, $F(3, 76) = 2.90$, $p < .05$, partial $\eta^2 = .10$. There is no significant main effect for condition, nor is there an interaction effect (see Table 2).

Attention and Adaptive Behavior

A one-way ANOVA revealed significant differences between group performance on attention measures, $F(3, 76) = 13.39$, $p < .001$, $\eta^2 = .35$, and adaptive behavior measures, $F(3, 75) = 21.12$, $p < .001$, $\eta^2 = .46$.

IIV, Attention, and Adaptive Behavior

Hierarchical regression was utilized to analyze the relationship between these variables, specifically whether IIV accounts for more variation in adaptive behavior above and beyond attention. The total attention quotient was entered into the first block, followed by the IIV for the Letters Game. This specific IIV score was chosen due to the simplicity of the Letters Game task, thus resulting in a pure baseline measure of IIV.

A hierarchical regression for the full sample was completed. The results indicate an overall significant regression, $F(2, 77) = 12.66$, $p < .001$, where attention and IIV together account for 25.2% of the variance in adaptive behavior. Attention significantly accounts for 16.8% of the variance in adaptive behavior, while IIV significantly accounts for an additional 8.4% of variance in adaptive behavior (see Table 3). Alternatively, entering IIV into the hierarchical regression first results in it significantly accounting for 15.0% of the variance in adaptive behavior, while attention significantly accounts for 10.3% of the variance above and beyond the IIV. This suggests that there is a shared variance between IIV and attention (approximately 6%), as well as unique contributions, with regard to predicting adaptive behavior.

An additional hierarchical regression analysis was carried out where IQ was controlled by entering it into the equation first, followed by attention, then IIV. The results indicate a significant regression model, $F(3, 77) = 25.61$, $p < .001$, where overall 50.9% of the variance in adaptive behavior is accounted for by IQ, attention, and IIV. Interestingly, after IQ is entered, attention and IIV no longer account for any unique significant variation in adaptive behavior. Specifically, IQ accounts for 49.1% of the variance in adaptive behavior in this model (see Table 3).

Table 3. Hierarchical Regression Analyses for Adaptive Behavior.

Variable	β	R^2 change	F change
Model 1			
Attention	0.332	0.168**	15.389
IIV	−0.300	0.084*	8.430
Model 2			
IIV	−0.300	0.150**	13.392
Attention	0.332	0.103*	10.294
Model 3			
IQ	0.622	0.491**	73.349
Attention	0.051	0.003	0.426
IIV	−0.135	0.015	2.314

Note. *Correlation significant at the .01 level (two-tailed); **Correlation significant at the .001 level (two-tailed).

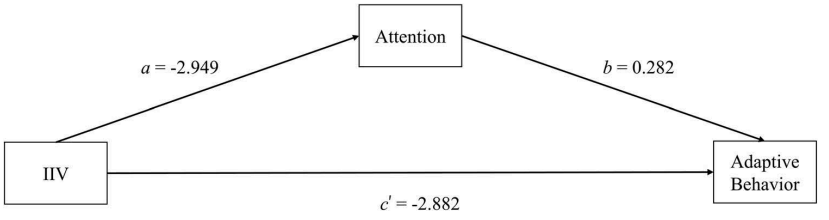

Figure 2. Simple mediation model of the direct and indirect effects of IIV on adaptive behavior.

Table 4. Model Outcomes for Test of Mediation: Does Attention Mediate the Relationship between IIV and Adaptive Behavior?

		Consequent						
		Attention				Adaptive Behavior		
Antecedent		Coefficient	*SE*	*p*		Coefficient	*SE*	*p*
IIV	*a*	−2.949	1.249	<.05	*c′*	−2.882	0.993	<.01
Attention		—	—	—	*b*	0.282	0.088	<.01
		R^2 = .068				R^2 = .252		
		$F(1, 76) = 5.573$, $p < .05$				$F(2, 75) = 12.662$, $p < .001$		

Mediation Analysis

A simple mediation analysis was carried out using ordinary least-squares path analysis. The results indicate that IIV indirectly affects levels of adaptive behavior through its effect on levels of attention. As noted in Figure 2 and Table 4, IIV has a negative effect on attention levels ($a = -2.949$), while attention levels have a positive effect on adaptive behavior ($b = 0.282$). A bias-corrected bootstrap confidence interval for the indirect effect of IIV on adaptive behavior through its effect on attention ($ab = -0.832$), based on 10,000 bootstrap samples, does not include zero (−2.021 to −0.096), thus indicating a significant indirect effect. There is also evidence that IIV influences adaptive behavior independent of its effect through impacting attention ($c' = -2.882$).

Discussion

The present study investigates the mean RT and IIV of three distinct groups of children with FASD (FAS/pFAS, SE/AE, and ND/AE) and one control group comprised of TD children with no prenatal alcohol exposure, using two different tasks. Mean RT and IIV were calculated for each task, group, and condition. The results indicate that overall, the control group was both faster and had lower IIV than the FASD groups.

As expected, the mean RT for the inhibition condition of each task was found to be significantly higher, meaning that the participants responded more slowly when alternating between an activation and inhibition task. This finding is consistent with this condition, as it is more challenging—even if only slightly—than the control condition. The differences in mean RT between groups, across trials and tasks, are reflective of the control group being significantly faster than the FASD groups. Additionally, similar to the

report of Simmons et al. (2010), the overall RT of both the clinical and control groups increases as the difficulty of the task increases, secondary to the greater cognitive processing required for response planning. For this study, not only is the mean RT of both tasks higher on average in the inhibition condition for each group, but it is higher overall for the Arrows Game, which requires the participant to decide between two differing motor responses (consistent with differences seen in simple versus choice reaction times; Simmons et al., 2010). Simmons et al. (2010) suggest that for children with FASD, the additional RT increase in motor tasks that require a response selection (such as the Arrows Game) may be due to alcohol-related changes affecting the CNS (related to planning time) and peripheral nervous system (related to motor response time).

It is well established that children tend to be more variable in cognitive performance when compared to adolescents and adults (MacDonald et al., 2006). The present findings on IIV suggest that children on the fetal alcohol spectrum tend to be even more variable than their age-matched TD peers on a go/no-go paradigm requiring a motor response. The higher IIV in the clinical groups compared to the controls possibly adds to the understanding of how prenatal exposure to alcohol can affect the developmental trajectory of the brain. The IIV findings indicate group effects for both tasks where the control group is typically less variable. Whereas Simmons et al. (2010) report that as the cognitive demands of a task increase so does the response variability within an FASD group, the present findings take this a step further in their indication that as the cognitive demand increases so too does the variability *within* an individual with FASD IIV. The present findings are consistent with those of Geurts et al. (2008), who note that both the mean RT and IIV of their clinical populations were higher than those of the controls. Visual inspection of the IIV data in the present study also reveals that within the clinical groups, the SE/AE group had on average the highest level of IIV compared to the FAS/pFAS and ND/AE groups.

To the authors' knowledge, this is the first study to investigate IIV in individuals with FASD, but it is by no means the only neurodevelopmental disorder with this feature; similar findings have been reported in children with ADHD, ASD, and Tourette's syndrome (Geurts et al., 2008; Verté et al., 2006). This leads to the question of whether the IIV noted in these populations is any different; that is, is the IIV seen in children with FASD any different from that of children with ADHD, or even those with co-morbid diagnoses, and is it possible to distinguish between these groups based on their levels of variability? This is an area that clearly requires further investigation.

A common conclusion in the literature is that IIV is reflective of the integrity of brain structures and may additionally be due to competition between the DMN and the task-oriented network in other populations (Castellanos et al., 2009; Kelly et al., 2008). Although the DMN in those with FASD has been investigated (e.g., Santhanam et al., 2011), there has yet to be a direct comparison with levels of IIV in this population. Additionally, the negative impact of alcohol on the developing brain includes impairments in neuronal migration (e.g., Guerri et al., 2009; Wilhelm & Guizzetti, 2015) and synaptic pruning (e.g., Lebel et al., 2012; Treit et al., 2013), to name a few. Impairment in these neurodevelopmental processes may additionally contribute to the expression of IIV in this population.

In order to investigate the clinical utility of IIV compared to attention, analyses were carried out to determine whether IIV accounts for variability in adaptive behavior

above and beyond that due to poor attention. With regard to IIV, attention, and adaptive behavior, the initial regression results across all groups indicate that attention and IIV together account for 25.2% of the variance in adaptive behavior. Attention and IIV share approximately 6% of this variance, while they also contribute uniquely. Specifically, IIV accounts for an additional 8.4% of the variance in adaptive behavior after the variance accounted for by attention and the shared variance between attention and IIV (totaling 16.8%) is removed, suggesting that IIV does in fact measure something different than basic attention deficits and is not simply a result of poor attention. While it has been suggested that attention and IIV are related (Gmehlin et al., 2014; Kelly et al., 2008), the present findings also highlight a unique contribution from each to real-life functioning, as assessed by an adaptive behavior measure. This finding is similar to that reported by Burton et al. (2009) in an aging population, where higher IIV was determined to be a useful predictor of activities of daily living. If the RT IIV is related to disruptions in underlying neural processes (e.g., Kelly et al., 2008) then it can similarly lead to inconsistency in activities of everyday living (e.g., Timler & Olswang, 2001) reflected as lower levels of adaptive behavior.

On the other hand, previous studies have highlighted the predictive power of IQ regarding adaptive behavior (Bölte & Poustka, 2002; Duncan & Bishop, 2013; Liss et al., 2001). In the present study, when the impact of IQ on adaptive behavior is controlled (regressed out), neither attention nor IIV account for additional variance in adaptive behavior. Therefore, while IIV and attention have unique contributions when predicting adaptive behavior, it appears that IQ remains the best predictor. This may not be surprising given the overlap between these latter two constructs. The focus of adaptive behavior tests is on the measurement of abilities such as being able to cope with environmental changes, learn new everyday skills and demonstrate independence, which to some extent likely overlap with the ability to "deal effectively with the environment" as assessed by IQ. Regressing IQ onto adaptive behavior first would indeed remove the "shared" aspects of adaptive behavior and intellectual ability, perhaps the variability that is most related to IIV and attention. Indeed, Dennis et al. (2009) state that statistically covarying or controlling for a demographic trait that is relevant to and characteristic of a group is misleading and often provides anomalous and counterintuitive findings. In addition, the lack of meaningful relationship between IIV and adaptive behavior when IQ is controlled does not suggest that there is no utility to understanding the role of IIV as it relates to processes such as attention. In fact, IIV has been noted to anticipate the onset and trajectory of changes in the cognitive performance in an aging population (Bielak et al., 2010) and may be useful in predicting the same in a younger population. Additionally, it may be worthwhile to investigate whether the role of IIV in predicting adaptive behavior is different in an aging FASD population.

A simple mediation analysis was undertaken to further explore the relationship between IIV and attention when predicting adaptive behavior. Both direct and indirect relationships were found where IIV directly accounts for variance in adaptive behavior and also indirectly accounts for variance in adaptive behavior through its influence on attention. While attention does not fully mediate the relationship between IIV and adaptive behavior, it does play a partial role in the relationship (Figure 2). For this analysis, the assumption was that IIV precedes both attention and adaptive behavior in time—that is, IIV influences attention. While some researchers discuss IIV as a result of

impaired attention (Kelly et al., 2008), evidence of IIV being associated with developmental disorders such as ADHD (Castellanos & Tannock, 2002; Gmehlin et al., 2014) and aging (MacDonald et al., 2006) suggests that it may be due to a lack of development or breakdown of processes that are more basic than levels of attention, and may be a cause rather than an outcome of poor attention.

Limitations and Future Directions

Along with the possible directions outlined throughout the discussion, it would be of worth to investigate the trajectory of IIV in children with FASD over time. It has previously been mentioned that IIV in a TD population presents in the form of a U-shaped curve over the life span (for a review, see MacDonald et al., 2006). The question remains as to whether a similar decrease in IIV is seen in children with FASD when they approach adolescence and adulthood, and additionally whether the difference in variability compared to TD individuals will hold, which it is hypothesized—based on the findings in the present study—is likely.

Assessing longitudinally the outcome of a targeted intervention in clinical groups with varying levels of IIV would add more information with regard to the benefits of measuring IIV early on, especially for an age group where IQ testing is unavailable or unfeasible (e.g., younger than 6 years of age, or impaired language). As children become older their requirements and demands for daily living increase, which is where there tends to be a departure of clinical groups from TD children (Crocker et al., 2009). If there is additional differentiation in this adaptive behavior between groups with varying levels of IIV it may prove useful in determining the level of care required. Finally, other studies investigating IIV have looked at neural and cognitive correlates (e.g., Bellgrove et al., 2004), and this is a proposed future direction for this clinical population.

Another important issue to consider is the fact that children with FASD tend to have higher levels of environmental instability, such as an increased number of placements in foster care (Streissguth et al., 2004), and this likely has an effect on brain development. As a result, this environmental instability, in addition to the teratogenic effects of alcohol, may contribute to the varying levels of IIV seen in clinical populations. Conversely, due to an unclear cause and effect relationship, high levels of IIV in these children may present an additional challenge when providing care resulting in frequent changes to their living environment. While the current study does not investigate specific contributors to IIV, this may be a future direction worthy of investigation.

A limitation of the current study is that IIV is measured from the motor RT of a basic task that is reflective of a continuous performance test of attention that indeed is similar to the way in which the measure of attention was administered. As a result, future investigations of IIV in this population may benefit from using an RT measure that is not as closely tied to measures of attention. Secondly, after cognitive testing, the control group was found to have cognitive abilities that are in the above average range, which may not represent the population of TD children; however, this may also be the result of excluding participants from the control group if there was any uncertainty of alcohol being consumed prenatally. Thirdly, due to the low sample size of each group, regression analyses were undertaken for all participants and the study lacked sufficient power for looking at whether the impact of IIV in

each group was similar. Additionally, a cause and effect relationship cannot be guaranteed based on the simple mediation analyses carried out in this study, which include specific variables that do not rule out the possible impact of other unmeasured variables. Finally, the correlation found between the variables measured is dependent on the reliability of those measures—that is, how accurately they measure the true score.

Conclusion

The results of this study are the first to demonstrate an increased level of IIV in children with FASD compared to TD children, and add further information on the effect of prenatal exposure to alcohol. It is additionally established that IIV does contribute uniquely above and beyond attention when predicting the variance in daily adaptive behaviors, and that attention acts as a partial mediator between IIV and adaptive behavior.

Listening Difficulties in Children With Fetal Alcohol Spectrum Disorders: More Than a Problem of Audibility

Susan A. McLaughlin,[a] John C. Thorne,[b] Tracy Jirikowic,[c] Tiffany Waddington,[a] Adrian K. C. Lee,[a,b] and Susan J. Astley Hemingway[d,e]

Purpose: Data from standardized caregiver questionnaires indicate that children with fetal alcohol spectrum disorders (FASDs) frequently exhibit atypical auditory behaviors, including reduced responsivity to spoken stimuli. Another body of evidence suggests that prenatal alcohol exposure may result in auditory dysfunction involving loss of audibility (i.e., hearing loss) and/or impaired processing of clearly audible, "suprathreshold" sounds necessary for sound-in-noise listening. Yet, the nexus between atypical auditory behavior and underlying auditory dysfunction in children with FASDs remains largely unexplored.
Method: To investigate atypical auditory behaviors in FASDs and explore their potential physiological bases, we examined clinical data from 325 children diagnosed with FASDs at the University of Washington using the FASD 4-Digit Diagnostic Code. Atypical behaviors reported on the "auditory filtering" domain of the Short Sensory Profile were assessed to document their prevalence across FASD diagnoses and explore their relationship to reported hearing loss and/or central nervous system measures of cognition, attention, and language function that may indicate suprathreshold processing deficits.
Results: Atypical auditory behavior was reported among 80% of children with FASDs, a prevalence that did not vary by FASD diagnostic severity or hearing status but was positively correlated with attention-deficit/hyperactivity disorder. In contrast, hearing loss was documented in the clinical records of 40% of children with fetal alcohol syndrome (FAS; a diagnosis on the fetal alcohol spectrum characterized by central nervous system dysfunction, facial dysmorphia, and growth deficiency), 16-fold more prevalent than for those with less severe FASDs (2.4%). Reported hearing loss was significantly associated with physical features characteristic of FAS.
Conclusion: Children with FAS but not other FASDs may be at a particular risk for hearing loss. However, listening difficulties in the absence of hearing loss—presumably related to suprathreshold processing deficits—are prevalent across the entire fetal alcohol spectrum. The nature and impact of both listening difficulties and hearing loss in FASDs warrant further investigation.

Fetal alcohol spectrum disorder (FASD) is an umbrella term used to describe the range of physical, functional, and neurological abnormalities caused by prenatal alcohol exposure. It has been estimated that FASDs affect at least 1% of children and perhaps more (Sampson et al., 1997), with prevalence estimates varying by geographic location and diagnostic methodology (Roozen et al., 2016). Among all FASDs, fetal alcohol syndrome (FAS) is the most visibly evident diagnosis, characterized by growth deficiency and a specific set of facial features (i.e., thin upper lip, smooth philtrum, and small eyes), in the presence of significant central nervous system (CNS) abnormality (Astley, 2004, 2013; Bertrand et al., 2005). However, the majority of people with an FASD lack these observable physical markers yet still experience a wide and variable range of functional impairments. These typically include learning, attention, impulse control, communication, and social skill deficits (Astley, 2004; Kodituwakku & Kodituwakku, 2014; Streissguth et al., 2004; Thorne, 2017).

A small body of classic literature suggests that the teratogenic effects of prenatal alcohol exposure may involve insults to the auditory system potentially resulting in hearing loss (i.e., decreased sensitivity to low-level sound) and/or "suprathreshold" deficits affecting the processing of clearly audible sound essential for picking out sound targets in noise. A complex hierarchy of suprathreshold processing operations originating in the CNS and the auditory periphery is involved in separating out and making sense of the myriad acoustic signals generated by competing sound sources. Key mechanisms include the extraction of spatial information and precise encoding of the spectrotemporal features unique to each sound source, perceptual separation of sound streams and formation of distinct "auditory objects," and selective attention to the target auditory object (reviewed in Bizley & Cohen, 2013; Carlyon, 2004; Griffiths & Warren, 2004; B. C. J. Moore & Gockel, 2012; Shinn-Cunningham, 2008, 2017; Shinn-Cunningham, Best, & Lee, 2017). Suprathreshold processing deficits can arise, for example, as a consequence of inadequate sensory encoding (e.g., broad frequency tuning on the basilar membrane [Kortlang, Mauermann, & Ewert, 2016] or temporal coding infidelities [Bharadwaj, Masud, Mehraei, Verhulst, & Shinn-Cunningham, 2015]), binaural/spatial processing deficits (Ross, Fujioka, Tremblay, & Picton, 2007), or impaired cognitive control processes (e.g., attention deployment) in the absence of auditory coding deficits (Lee, Larson, Maddox, & Shinn-Cunningham, 2014). Damage to these or other suprathreshold processes can compromise sound-in-noise listening abilities and—like hearing loss—can impact daily function (Hillock-Dunn, Taylor, Buss, & Leibold, 2015; Shinn-Cunningham, 2017). Such auditory dysfunction may contribute significantly to some of the communication impairments observed in FASDs. In the complex acoustic environments common to daily life (e.g., classrooms, restaurants), both hearing loss and suprathreshold listening deficits in the absence of hearing loss have the capacity to negatively impact speech perception (reviewed in Bronkhorst, 2015). Such degradation of the speech signal may limit the auditory information children rely on to decipher and learn fundamental linguistic rules (White-Schwoch et al., 2015).

In terms of processes associated with audibility, impairments in mechanisms and structures involved in detecting low-level sound have been observed in individuals with FAS and in laboratory animals with extensive prenatal alcohol exposure. Prenatally exposed rats were found to have significantly prolonged and/or reduced-amplitude auditory brainstem responses and damaged hair cell receptors indicative of sensorineural (inner ear/auditory nerve) hearing loss (Church et al., 1987; Church & Kaltenbach, 1997). Consistent with this, hearing loss of both sensorineural and conductive (middle ear) origin has been shown to be more prevalent in children with FAS than their typically developing counterparts (Church, Eldis, Blakley, & Bawle, 1997; Church & Gerkin, 1988; Rössig, Wässer, & Oppermann, 1994). Conductive hearing loss related to recurrent otitis media has been commonly observed in children with craniofacial anomalies, including those with FAS, at rates ranging from 38% to 93% (reviewed in Church & Kaltenbach, 1997). Importantly, however, there is little research exploring sensorineural or conductive hearing loss in individuals who have FASDs but do not have the sentinel physical findings (i.e., facial dysmorphia and/or growth deficiency) of FAS. Cohen-Kerem, Bar-Oz, Nulman, Papaioannou, and Koren (2007) observed hearing loss and otitis media to be no more prevalent in those with diagnoses across the fetal alcohol spectrum than is found in the general population, but confirmatory data are lacking. This potential divergence in prevalence of hearing loss in FAS versus other FASDs may be due to an embryonic neuroectodermal syndrome hypothesized to underlie the craniofacial and ocular anomalies seen primarily in FAS; inner ear dysfunction may be associated with this syndrome (Church & Kaltenbach, 1997).

Research investigating the suprathreshold processing sequelae of prenatal alcohol exposure is even more limited and again has been restricted primarily to human subjects with FAS or laboratory animals exposed prenatally to moderate-to-heavy levels of alcohol. Slowed transmission of neural impulses in the auditory brainstem (Church, Abel, Kaltenbach, & Overbeck, 1996), delayed auditory event-related potentials (Kaneko, Riley, & Ehlers, 1993), and a reduction in the size of key auditory brainstem structures (Church & Kaltenbach, 1997) have been seen in prenatally exposed rats. Similarly, attenuated auditory event-related potentials have been observed in children with FAS (Kaneko, Ehlers, Phillips, & Riley, 1996; reviewed in Church & Kaltenbach, 1997). Data regarding the functional consequences of suprathreshold deficits due to prenatal alcohol exposure are particularly sparse. In one of the sole behavioral studies to date, Church et al. (1997) observed listening deficits in 100% of children with FAS (n = 12) tested on sound-in-noise dichotic listening tasks; however, most of these individuals had comorbid hearing loss, rendering it difficult to disentangle the relationship between functional impairment, hearing loss, and suprathreshold deficits. Moreover, as with hearing loss, little is known about the prevalence of listening difficulties (defined by D. R. Moore, 2018, as problems with hearing or listening despite normal audiometry) or the potential for suprathreshold processing deficits in individuals with FASDs but without FAS (cf. Stephen et al., 2012).

To date, there has been no systematic investigation of auditory dysfunction across the fetal alcohol spectrum. The limited data available suggest that individuals who have FASDs but not FAS may be less likely to experience hearing loss due to the absence of structural impairments associated with an embryologic neuroectodermal syndrome. We therefore predict that atypical auditory behaviors on the Short Sensory Profile (SSP; McIntosh, Miller, Shyu, & Dunn, 1999)—a norm-referenced caregiver report questionnaire used clinically to assess sensory processing dysfunction—will be present in children with FASDs and will be unrelated to hearing loss. It is not obvious, a priori, whether such listening difficulties—which presumably derive chiefly from suprathreshold deficits associated with particular CNS processes that may or may not be coupled to those measures

of CNS dysfunction used to inform FASD diagnoses—will vary according to diagnostic severity.

To investigate this hypothesis and to more generally explore the prevalence and nature of auditory dysfunction across FASDs, we leveraged existing information about auditory-related behaviors and reported hearing status, in addition to other diagnostic and neurobehavioral variables (including standardized measures of cognition/IQ, attention, and language function) present in a clinical database collected by the Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network (FAS DPN). Information about peripheral hearing status was obtained from caregiver-provided records and reports submitted to the database. Data regarding auditory behaviors were gleaned from caregiver ratings of child auditory function on the SSP, which assesses multiple "domains" of sensory processing. In this study, we focused on the "auditory filtering" domain, which consists primarily of five items on which caregivers are asked to rate their child's behavior in situations that require either attending to or tuning out sound stimuli (see Jirikowic, Thorne, McLaughlin, Lee, & Astley, 2018, for full analysis and discussion of results in this sample population across all SSP domains). The SSP items were formulated based on neurobehavioral theories of sensory processing and integration (Dunn, 1997) and therefore lack reference to the highly specified auditory processing theories of auditory science. However, the auditory filtering items nonetheless serve to provide a standardized clinical measure of higher order listening behaviors, with a particular focus on attentional processes. The central role of attention in the behaviors probed by these items has been confirmed by principal component analyses showing that ratings on the auditory filtering items (plus one other item from an earlier long-version Sensory Profile) cluster together into a discrete "inattention/distractibility" factor (Dunn & Brown, 1997).

Despite prior reports that auditory filtering is consistently one of the SSP domains on which children with FASDs are most often rated as demonstrating a "definite difference" (> 2 *SD*s below the normative mean; Abele-Webster, Magill-Evans, & Pei, 2012; Carr, Agnihotri, & Keightley, 2010; Franklin, Deitz, Jirikowic, & Astley, 2008; Hansen & Jirikowic, 2013; Jirikowic, Olson, & Kartin, 2008), there has been little discussion of the potential impairments that may underlie atypical auditory behaviors in children with FASDs (Abele-Webster et al., 2012). This study thus sought to investigate auditory dysfunction in FASDs by exploring auditory behavioral outcomes and their relationship to neurobehavioral measures and reported hearing loss as a means to generate preliminary hypotheses about the underlying mechanisms involved. The study had three specific aims:

- Specific Aim 1: to quantify the prevalence of atypical auditory behaviors—as measured by auditory filtering domain scores on the SSP—across the spectrum of fetal alcohol disorders. We hypothesized that the proportion of children rated with a definite difference in auditory filtering scores would be high across the fetal alcohol spectrum.
- Specific Aim 2: to explore whether atypical auditory filtering domain scores for children with FASDs are related to (a) reported hearing loss and/or (b) measures of cognition/IQ, attention, and language function indicative of CNS impairment. Using neurodevelopmental CNS impairment as a proxy for potential suprathreshold processing deficits, we hypothesized that atypical auditory filtering scores in children with FASDs would be related more strongly to these deficits than to reported hearing loss.
- Specific Aim 3: to quantify the prevalence of hearing loss across the spectrum of fetal alcohol disorders. We hypothesized that children with FAS would have a higher prevalence of reported hearing loss than children with other FASDs.

Method

Participants

Selected data from children seen at FAS DPN clinics between 2000 and 2016 were retrospectively examined. At the time of their diagnostic evaluation, all patients evaluated at these clinics were invited to have their FASD clinical data entered into the FAS DPN research database for use in future research studies. Patient/caregiver consent was obtained in accordance with University of Washington Human Subjects Division oversight and approval.

All patients in the FAS DPN database were evaluated for FASDs using the 4-Digit Diagnostic Code (updated and coded according to criteria from the 2004 version; Astley, 2004), an interdisciplinary approach to diagnosis guided by empirically validated criteria (Astley, 2004, 2013). The four digits of the FASD 4-Digit Diagnostic Code reflect the magnitude of expression of the four key diagnostic features of FAS, in the following order: (a) growth deficiency, (b) FAS facial phenotype, (c) CNS structural/functional abnormalities, and (d) prenatal alcohol exposure. The magnitude of expression of each feature is case defined and ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong and classic presentation of the feature. Each Likert rank is specifically case defined. There are 102 four-digit codes that fall broadly under the umbrella of FASDs. These codes cluster into four clinically meaningful diagnostic subcategories (Astley, 2004): FAS, partial FAS (PFAS), static encephalopathy/alcohol exposed (SE/AE), and neurobehavioral disorder/alcohol exposed (ND/AE).

Data used in this study were from children in the FAS DPN research database who met the following inclusionary criteria: (a) between 3.00 and 10.99 years old at the time of diagnostic clinic visit, (b) diagnosed with FASDs (FAS, PFAS, SE/AE, or ND/AE), and (c) had SSP results available in the research database. Any subjects with missing data on more than one third of the items in any SSP domain were excluded.

Measures

The FAS DPN research database contains more than 2,000 fields of information on each patient evaluated for FASDs. The selected variables used in this analysis were measures related to auditory behavior (auditory filtering scores on the SSP), reported hearing status (hearing loss and history of otitis media), and measures of growth, facial morphology, and CNS structure and function used to derive each child's 4-Digit Diagnostic Code FASD diagnosis. These variables are described in more detail below.

Auditory Behaviors

SSP. The SSP (McIntosh et al., 1999), standardized for ages 3–11 years, is a 38-item caregiver-report questionnaire designed to identify atypical behavioral responses to sensation. A short-form version of the longer Sensory Profile (Dunn, 1999), the SSP encompasses seven domains of sensory processing—tactile sensitivity, taste/smell sensitivity, movement sensitivity, underresponsive/seeks sensation, auditory filtering, low energy/ weak, and visual/auditory sensitivity—with total scores in each domain norm-referenced, based on the performance of 1,037 children without known disabilities (Dunn & Brown, 1997). The SSP is considered to be a reliable and valid measurement tool, with high internal consistency for total score (Cronbach's $\alpha = .96$) and section scores (Cronbach's $\alpha = .82$–$.89$; Cronbach's α for the auditory filtering domain = .87).

Scores from the SSP's auditory filtering domain are the primary focus of this study. The auditory filtering domain comprises six items focused on either attending to or tuning out sound stimuli:

- Item 22: is distracted or has trouble functioning if there is a lot of noise around
- Item 23: appears to not hear what you say (e.g., does not "tune in" to what you say, appears to ignore you)
- Item 24: can't work with background noise (e.g., fan, refrigerator)
- Item 25: has trouble completing tasks when the radio is on
- Item 26: doesn't respond when name is called but you know the child's hearing is OK
- Item 27: has difficulty paying attention

Caregivers rate their child's frequency of atypical sensory behaviors on a Likert scale ranging from 1 (*always exhibits this behavior*) to 5 (*never exhibits this behavior*). Lower scores indicate more atypical behaviors. Total scores across items in each domain are compared to a normative sample in order to derive "cut scores" (Dunn, 1999) that categorize domain scores into classification category groups reflecting either "typical performance" for a domain score $\leq$ 1 *SD* below the normative mean (i.e., auditory filtering cut scores: 23–30), "probable difference" for a domain score > 1 but < 2 *SD*s below the normative mean (i.e., auditory filtering cut scores: 20–22), or "definite difference" for a domain score $\geq$ 2 *SD*s below the normative mean (i.e., auditory filtering cut scores: 6–19).

We conducted our primary analyses on auditory filtering domain total (summed total of scores on the six auditory filtering items) classification categories. We also examined score profiles across the six individual items. Of particular interest were Items 23 and 26, which are the only auditory filtering items explicitly involving auditory-related tasks (hearing what is said/tuning in and responding when name is called, respectively) and therefore most closely approximate measurable sound-in-noise listening behaviors. In contrast, the other auditory filtering items, particularly Items 24 and 25, appear to be more related to sound sensitivity/distractibility than to listening behaviors.

Hearing Status

Hearing loss and history of otitis media. Data on hearing status are obtained by the FAS DPN team based on a careful review of the records available for a given patient, as hearing function is typically not prospectively evaluated as part of the FAS DPN diagnostic assessment. These clinical records yield heterogenous information about hearing function (see Table 1), occasionally including thresholds measured during pure-tone audiograms but more typically consisting of formal reports (e.g., medical office hearing screens, school hearing screens, play-based audiometric procedures) indicating whether or not the individual had "passed" a hearing screen (sometimes at a given sound level[s], sometimes not)—in addition to newborn hearing screens based on auditory brainstem response and sometimes otoacoustic emission testing. Caregiver report on functional hearing levels and/or caregiver report regarding history of otitis media was also included. Due to the varying nature and quality of these data, they were used to assess only reported hearing loss and history of otitis media; reliable information related to presumed etiology of hearing loss was not available in this data set. Reported hearing loss was coded dichotomously, defined as audiometric thresholds > 25 dB HL in one or both ears at any frequency tested and/or formal report documenting hearing loss. Normal/functional hearing was defined as (a) audiometric thresholds of 25 dB HL or better across all frequencies tested and/or formal document with report of hearing screen at a given sound successfully passed or (b) caregiver report of no hearing concerns. Hearing data that were inconclusive or unclear—for example, report of failed infant hearing screen but no indication of any subsequent auditory assessment or audiometric thresholds > 25 dB HL but note of concurrent nasal congestion—were classified as missing in order to keep normal/functional hearing and hearing loss categories distinct and operationally valid. Caregiver report of history of otitis media/middle ear infection was also captured based on the number of reported cases: 0, 1, 2, or 3 or more.

FASD Diagnosis and Measures of Physical Dysmorphia and Alcohol Exposure

4-Digit Diagnostic Code FASD diagnosis (FAS, PFAS, SE/AE, and ND/AE). See full description above, along with Astley (2004) for additional details.

Table 1. Demographic and clinical profiles of the study sample.

Characteristic	*N* (valid %)
Gender	
Female	124 (38.2)
Male	201 (61.8)
Age at diagnosis (years)	
3–5.9	117 (36.0)
6–10.9	208 (64.0)
M (*SD*), range	6.9 (2.1), 3.0–10.9
Race/ethnicity	
Caucasian	157 (48.3)
African American	33 (10.2)
Native American/Canadian	23 (7.1)
Hispanic	14 (4.3)
Other (including mixed race)	98 (30.2)
FASD diagnosis	
FAS	13 (4.0)
PFAS	19 (5.5)
SE/AE	96 (29.5)
ND/AE	197 (60.6)
Type of auditory report	
Threshold info from audiogram	83 (25.5)
Formal report, no thresholds	167 (51.4)
Newborn screening	15 (4.6)
Caregiver report regarding hearing	53 (16.3)
Not reported	7 (2.5)
Short Sensory Profile respondent	
Parent unspecified	170 (52.3)
Foster parent	56 (17.2)
Adoptive parent	27 (8.3)
Legal guardian	15 (4.6)
Other family	47 (14.5)
Not reported	10 (3.1)

Note. Demographic and clinical profiles of the 325 children with fetal alcohol spectrum disorder (FASD) in the clinical study sample. FASD diagnoses were made by an interdisciplinary team using the 4-Digit Diagnostic Code (Astley, 2004), based on four clinically meaningful diagnostic subcategories: FAS = fetal alcohol syndrome; PFAS = partial FAS; SE/AE = static encephalopathy/alcohol exposed; and ND/AE = neurobehavioral disorder/alcohol exposed.

Growth deficiency. This measure ("growth rank": 1 = *none*, 2 = *mild*, 3 = *moderate*, and 4 = *severe*), which yields the first digit in the FASD 4-Digit Diagnostic Code, documents the magnitude of prenatal and/or postnatal growth deficiency (see Astley, 2004, for additional details).

FAS facial phenotype. This measure ("face rank": 1 = *none*, 2 = *mild*, 3 = *moderate*, and 4 = *severe*), which yields the second digit in the FASD 4-Digit Diagnostic Code, documents the magnitude of expression of the FAS facial phenotype, as defined by short palpebral fissure lengths, a smooth philtrum, and a thin upper lip (see Astley, 2004, for additional details).

Likelihood of structural/neurodevelopmental CNS abnormality. This measure ("CNS rank": 1 = *unlikely*, 2 = *possible*, 3 = *probable*, and 4 = *definite*) yields the third digit in the FASD 4-Digit Diagnostic Code. The first three levels (1 = *unlikely*, 2 = *possible*, and 3 = *probable*) document presumed likelihood of CNS structural abnormality as assessed by the interdisciplinary FAS DPN team on the basis of a variety of standardized assessments of function including executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention, and activity level. The fourth level (4 = *definite*) documents potential CNS abnormality of presumed prenatal origin on the basis of structural (e.g., microcephaly or observable brain abnormalities) and/or neurological (e.g., seizures or other hard neurological signs) evidence. To the degree possible, clinical assessment rules out traumatic brain injury or postnatal disease processes unrelated to prenatal alcohol exposure in assigning CNS rank (see Astley, 2004, for additional details).

Microcephaly. Microcephaly (0 = *no*, 1 = *yes*) is defined by the FASD 4-Digit Diagnostic Code as an occipital frontal circumference 2 or more *SD*s below the mean (≤ third percentile; see Astley, 2004, for additional details).

Prenatal alcohol exposure. This measure ("alcohol rank": 1 = *confirmed absence of exposure*; 2 = *unknown exposure*; 3 = *confirmed exposure, level unknown or moderate*; and 4 = *confirmed exposure, level high*), which yields the fourth digit in the FASD 4-Digit Diagnostic Code, documents the magnitude of alcohol exposure. Alcohol exposure is ranked according to the quantity, timing, frequency, and certainty of exposure during pregnancy and is based on best available records and/or direct report from the biological mother/witnesses to the exposure. A diagnosis under the umbrella of FASDs requires a confirmed prenatal alcohol exposure (Rank 3 or 4) with one exception: FAS. A diagnosis of FAS requires the Rank 4 FAS facial phenotype, which is so highly specific to (caused only by) prenatal alcohol exposure that presence of the Rank 4 FAS facial phenotype offsets the need for a confirmed history of alcohol exposure (see Astley, 2004, for additional details).

Measures of CNS Function

In the context of a careful medical review to document any potential postnatal sources of underlying CNS abnormality (e.g., traumatic brain injury, seizure disorder), the FAS DPN clinical assessment of CNS function includes a review of available neurodevelopmental assessments in the medical record, as well as documentation of current CNS function using common behavioral measures. For the current study, the following clinical measures available in the record were used to gauge the presence and severity of neurodevelopmental CNS impairment.

Attention-deficit/hyperactivity disorder diagnosis. This variable (0 = *no*, 1 = *yes*) documents whether the subject has a confirmed previous diagnosis of attention-deficit/hyperactivity disorder (ADHD) from a qualified provider or as a result of the FAS DPN clinical assessment.

Cognition/full-scale IQ and language function. The following domains of function were analyzed using a 3-point severity score: 1 = *within normal limits*, that is, performance no lower than 0.9 *SD* below the mean; 2 = *mildly to moderately impaired*, that is, performance 1.0–1.9 *SD*s below the mean on a standardized measure; and 3 = *severely impaired*, that is, performance 2 or more *SD*s below the mean on a standardized measure. The severity score was derived by the FAS DPN clinical team based on aggregate data in each respective domain, including standardized test

scores administered as part of the diagnostic clinic and/or scores available in the clinical records.

Cognitive data included standardized IQ scores from a variety of norm-referenced tests for intellectual and cognitive abilities, including the Wechsler Intelligence Scale for Children (Wechsler, 2003), the Stanford–Binet Intelligence Scales(Bain & Allin, 2005), and the Differential Ability Scales (Elliott, 2007). Normal cognition was defined as full-scale IQ (FSIQ) > 85, mildly impaired as 70 < FSIQ ≤ 85, and severely impaired as FSIQ ≤ 70.

Language function was quantified by a range of both standardized and structured clinical assessments, including but not limited to the various editions of the Clinical Evaluation of Language Fundamentals (Semel, Wiig, & Secord, 2013), the Preschool Language Scale (Zimmerman, Steiner, & Pond, 2002), and the Comprehensive Assessment of Spoken Language (Carrow-Woolfolk, 1999), and assessment of narrative production. Both direct testing and information from a detailed review of records were used to establish a clinical ranking based on the 3-point severity scale described above.

Analyses

All analyses were conducted using SPSS Version 19.0. Descriptive statistics (means, standard deviations, proportions) were used to profile the study population. Relationships between auditory filtering domain score categories (typical performance, probable difference, and definite difference) and selected clinical variables (Aims 1 and 2) were assessed using chi-squared (χ^2) tests when outcomes were assessed on nominal scales and Mantel–Haenszel linear-by-linear association chi-squared tests of trend (χ^2_{MH}) when outcomes were assessed on ordinal scales. Similarly, relationships between variables related to peripheral hearing status and selected clinical variables (Aim 3) were evaluated using chi-squared, linear-by-linear, and Fisher's exact tests, as appropriate. Results were considered significant at two-sided p values of < .05. The effect sizes of significant results were estimated using Cramer's V (ϕ_C) for chi-squared analyses, Spearman correlation coefficient (ρ) for linear-by-linear trend tests (Agresti, 2007), and phi coefficients (ϕ) for Fisher's exact results. Post hoc tests were performed for significant omnibus chi-squared statistics by estimating the p value of the adjusted residuals (i.e., the z scores). Because of the exploratory nature of the study, p values for post hoc analyses should be interpreted with caution.

Results

The data set analyzed (N = 325) consisted of 124 girls and 201 boys, ranging in age from 3.03 to 10.97 years. Table 1 provides demographic and clinical characteristics and data type/origin. In this sample, the largest proportion of children were diagnosed with ND/AE, followed by SE/AE. As expected, about one of 10 children was diagnosed with FAS or PFAS. This study sample is a good representation of the larger FAS DPN population (see Astley, 2010; see Table 2).

Of the 325 participants who met the inclusionary criteria (which included data available for at least two thirds of the SSP items in any given domain), 43 individuals were still missing some SSP data, nine of whom were missing data in the auditory filtering domain. To handle these missing data, the average of the subjects' remaining scores in the incomplete domain was calculated, and this value replaced the missing score(s) in that domain, for that subject. This approach was selected to control for bias while still fairly representing the child's auditory filtering profile. To maintain the ordinal format of the data, those newly calculated item scores that were not whole numbers were rounded to the closest whole number.

Aim 1: Prevalence of Atypical Auditory Behaviors Across FASD Diagnoses

A majority (80.0%) of children with FASDs in our clinical sample were rated by their caregivers as exhibiting a definite difference (2 *SD*s below the normative mean) on the auditory filtering domain of the SSP (see Figure 1). No significant linear relationship was observed between outcomes on auditory filtering domain score categories and severity of FASD diagnosis; however, the raw cross-tabulation numbers unexpectedly show that the percentage of children diagnosed with FAS who were reported with a definite difference on the auditory filtering items (61.5%) was lower than the equivalent figure for children with either PFAS (78.9%), SD/AE (87.5%), or ND/AE (77.7%). Correspondingly, the percentage of children with FAS rated with typical performance was higher than those with less severe diagnoses (see Table 2, top). When the cross-tabulation was collapsed to assess the prevalence of definite difference reported among FAS (61.5%) versus all other FASD diagnoses combined (80.8%), the contrast remained nonsignificant (Fisher's exact test, p = .19).

Due to this unexpected (albeit nonsignificant) finding in which children with less severe FASD diagnoses were more frequently rated with atypical auditory behaviors than were children with FAS, post hoc analyses were conducted to more closely examine the relationships between auditory filtering outcomes and various physical features of FASDs (i.e., growth deficiency, FAS facial features, likelihood of CNS structural abnormalities and microcephaly), in addition to prenatal alcohol exposure (see Table 2, bottom). The post hoc analyses revealed a similar pattern of association. Atypical auditory behaviors were prevalent across the full spectrum of physical outcomes and tended to be more prevalent among those with less severe physical outcomes, especially those with less severe facial features.

Aim 2: Relationship Between Atypical Auditory Behaviors and Measures Indicative of Reported Hearing Dysfunction or CNS Impairment

No observable relationship was found between outcomes on auditory filtering domain score categories and measures of peripheral hearing status, either reported hearing loss or

Table 2. Prevalence of Short Sensory Profile auditory filtering domain scores across fetal alcohol spectrum disorder (FASD) diagnoses.

	Auditory filtering domain score category

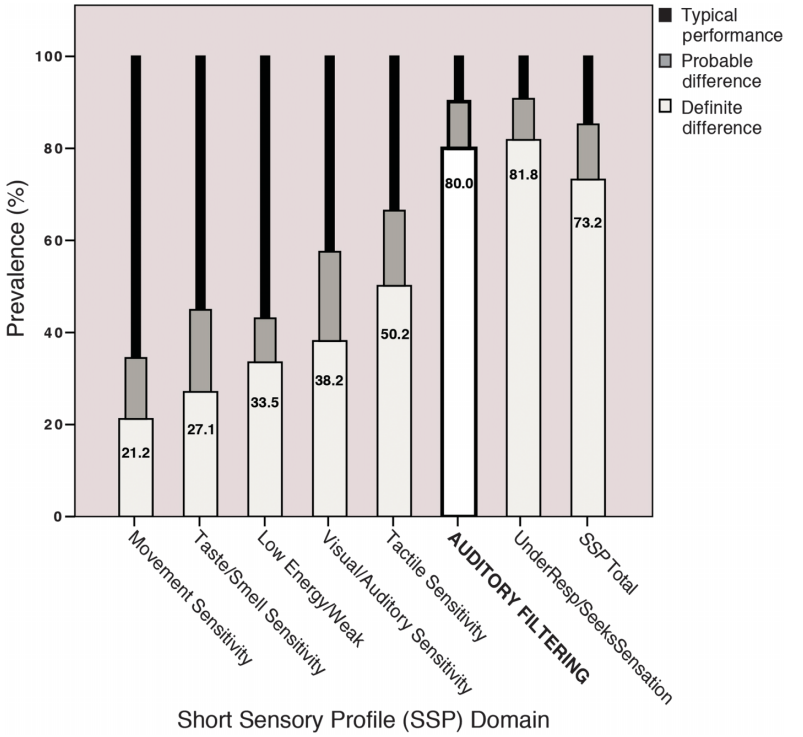
Note. Prevalence of Short Sensory Profile auditory filtering domain scores across FASD diagnoses. No linear relationship between auditory filtering scores ("definite difference": domain score ≥ 2 *SD*s below the normative mean; "probable difference": domain score > 1 but < 2 *SD*s below the normative mean; or "typical performance": domain score ≤ 1 *SD* below the normative mean) and FASD diagnosis was observed (FASD diagnostic abbreviations [Astley, 2004]: fetal alcohol syndrome [FAS], partial FAS [PFAS], static encephalopathy/alcohol exposed [SE/AE], and neurobehavioral disorder/alcohol exposed [ND/AE]). Post hoc analyses of the relationship between auditory filtering scores and physical features of FASD show that atypical auditory behaviors tended to be more prevalent among those with less severe physical outcomes, especially less severe facial features. The four key diagnostic features of FASD (growth deficiency, FAS facial phenotype, CNS abnormalities, and prenatal alcohol exposure) are case defined on 4-point Likert scales (ranks) and comprise the four digits of the FASD 4-Digit Diagnostic Code (Astley, 2004). Alcohol Ranks 1 and 2 are not included here because individuals diagnosed with FASD cannot by definition have Alcohol Rank 1 (confirmed lack of prenatal alcohol exposure) and Alcohol Rank 2 (unknown, indicates unknown prenatal alcohol exposure). SSP = Short Sensory Profile; CNS = central nervous system. Bold values are significant at $p < .05$.

history of otitis media (see Table 3, top). With respect to measures associated with CNS impairment (see Table 3, bottom), there was no observable relationship between auditory filtering outcomes and FSIQ scores or language function; however, a relationship between auditory filtering scores and ADHD diagnosis was observed. Post hoc analyses documented a high prevalence of children with a definite difference in auditory filtering scores among those with (88.3%) and without (72.6%) ADHD, but the prevalence was significantly higher among those with ADHD.

We additionally assessed the effect of age on auditory filtering outcomes in order to ensure that none of the observed relationships was confounded by age. Based on data reported by Dunn (1999) indicating that younger and older children may score differently on some sections of the long-form Sensory Profile (with scores indicating that younger children may perform better on items related to inattention/distractibility), we split the sample into two groups. They were (a) preschool children (3.00–5.99 years old at the time of FAS DPN clinic visit) and (b) school-aged children (6.00–10.99 years old at clinic visit). This split was also motivated by the knowledge that school-aged children may have a wider range of cognitive assessments available in the clinical record to examine the relationships between auditory behaviors and CNS function. A chi-squared test comparing outcomes on auditory filtering domain score categories across groups did show an effect of age, $\chi^2(2, N = 325) = 9.40$, $p = .009$, $\phi_C = .17$, with post hoc comparisons indicating that definite differences in auditory filtering were more likely to be reported ($p = .005$) in the older age group

Figure 1. Profile of Short Sensory Profile domain scores in the clinical study sample of 325 children diagnosed with fetal alcohol spectrum disorders. Represented here is the percentage of children whose total score in each domain (and total score across all domains: "SSP Total") falls into the categories of "definite difference" (light gray bars, except in the case of the auditory filtering domain, which is white for emphasis): domain score ≥ 2 *SD*s below the normative mean; "probable difference" (dark gray bars): domain score > 1 but < 2 *SD*s below the normative mean; or "typical performance" (black bars): domain score ≤ 1 *SD* below the normative mean. Auditory filtering domain scores showed among the highest ratings of children with definite and probable differences.



(85.1% with a definite difference among children 6 years of age and older) than in the younger (70.9% with a definite difference among those less than 6 years of age), consistent with Dunn's findings. Based on this information, we separately assessed the influence of age on the relationship between auditory filtering outcomes and each of the diagnostic, neurobehavioral, and hearing-related variables probed in the study. We found that the presence (or lack thereof) of a linear relationship to auditory filtering outcomes did not differ between the two age groups for any of the variables examined with the exception of language function, where a linear relationship between auditory filtering scores and language function was observed in the older group, $\chi^2_{MH}(1, N = 199) = 6.11$, $p = .013$, but not the younger, $\chi^2_{MH}(1, N = 110) = 1.67$, $p = .194$. The prevalence of older children with a definite difference in auditory filtering scores was highest among those rated as having "severely impaired" language function (92.0%). This is approximately 10 percentage points higher than among those with "mildly to moderately impaired" language function (82.9%) and those without language impairment (79.6%).

Aim 3: Assessing the Relationship Between Hearing Status and FASD Diagnostic Measures

Relationships between measures of peripheral hearing status and FASD diagnosis—including component assessments of the presence of the physical features of FASDs (FAS facial phenotype, growth deficiency, likelihood of CNS structural abnormality, and microcephaly), magnitude of prenatal alcohol exposure, and FSIQ—were assessed (see Table 4). Reported hearing loss (defined as reported audiometric thresholds > 25 dB HL in one or both ears at any frequency tested or formal report documenting hearing loss) was 16-fold more prevalent among the children diagnosed with FAS (40%: four individuals with reported hearing loss out of the 10 individuals with FAS with sufficient hearing/audiometric information in the data set) than among the children diagnosed with other FASD diagnoses (2.4%: seven with reported hearing loss out of 286 individuals [PFAS = 17, SE/AE = 88, ND/AE = 181]; see Figure 2, left). The prevalence of hearing loss increased linearly with increasing severity of FASD diagnosis. In contrast, no significant

Table 3. Short Sensory Profile auditory filtering domain scores: association with reported hearing status and central nervous system (CNS) function.

	Auditory filtering domain categories

Mildly impaired	82 (83.7)	9 (9.2)	7 (7.1)	
Severely impaired	92 (81.4)	12 (10.6)	9 (8.0)	

Note. Association between Short Sensory Profile auditory filtering domain scores ("definite difference": domain score ≥ 2 *SD*s below the normative mean; "probable difference": domain score > 1 but < 2 *SD*s below the normative mean; or "typical performance": domain score ≤ 1 *SD* below the normative mean) and reported hearing status and CNS function. Hearing loss defined as thresholds > 25 dB HL at any frequency tested and/or formal report documenting hearing loss. Whereas atypical auditory behaviors were more prevalent among children with attention-deficit/hyperactivity disorder (ADHD), no linear relationships between auditory filtering scores and measures of hearing status were observed. See text for operational definitions of the three language function categories. Bold values are significant at $p < .05$.2

relationship between history of otitis media and FASD diagnosis was observed (see Table 4 and Figure 2 [right]).

The prevalence of reported hearing loss increased significantly and linearly with increasing severity of growth deficiency, FAS facial phenotype, likelihood of CNS structural abnormality, and FSIQ deficit. Reported hearing loss was also significantly more prevalent among children with microcephaly. Although the prevalence of reported hearing loss among the children with high alcohol exposure was twofold greater than among children with moderate exposures, this contrast was not statistically significant. With respect to reported history of otitis media, no significant associations were observed with any of the FASD diagnostic variables examined.

Discussion

The present results were obtained from a retrospective examination of data collected from children who were diagnosed with FASDs at Washington State FAS DPN clinics. They indicate that a large proportion of children with FASDs exhibit atypical, higher order auditory behaviors involving attending to or tuning out sound stimuli, as measured by caregiver ratings on the auditory filtering domain of the SSP. The prevalence of atypical auditory behaviors in this population was not observed to be significantly related to severity of FASD diagnosis; that is, a comparably high proportion of children were reported with a definite difference in auditory filtering across fetal alcohol diagnoses. No relationship was observed between atypical auditory behaviors and reported estimates of peripheral hearing function—including hearing loss and history of otitis media potentially indicative of conductive hearing issues—based on data obtained from caregiver-provided records and reports. There was a relationship, however, between atypical auditory behaviors and ADHD diagnosis, presumably reflective of underlying CNS impairment. Children with ADHD were more likely to be reported with atypical behaviors in the auditory filtering domain. The prevalence of atypical auditory behaviors was not observed to be correlated across the sample with other measures of CNS function, including measures of cognition and language function.

Reported hearing loss was found to be related to FASD diagnosis; that is, hearing loss was 16-fold more prevalent among children with FAS (40%) than among children with other FASDs (2.4%), for whom the prevalence of hearing loss was similar to that estimated for the general U.S. adolescent population (2.3%; Lin, Niparko, & Ferrucci, 2011). An increased prevalence of reported hearing loss was also correlated with the presence of physical features associated with FAS: growth deficiency, facial dysmorphia, likelihood of CNS damage, and microcephaly. Reported hearing loss was also related to lower FSIQ scores but was not observed to be significantly related to the reported

Table 4. Association between reported hearing loss, otitis media, fetal alcohol spectrum disorder (FASD) diagnosis, and FASD features.

FASD diagnostic features	Reported hearing loss (one or two ears)		Reported cases: otitis media (OM)

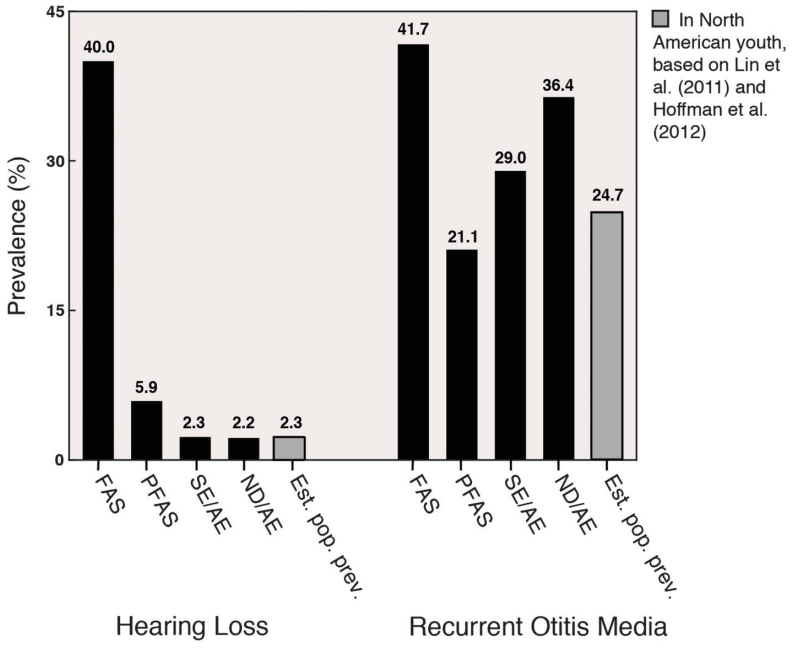
Note. Association between hearing status (reported hearing loss and otitis media) and FASD diagnosis (abbreviations: ND/AE = neurobehavioral disorder/alcohol exposed; SE/AE = static encephalopathy/alcohol exposed; PFAS = partial FAS; and FAS = fetal alcohol syndrome [Astley, 2004]) and diagnostic physical features of FASDs. Reported hearing loss (see text for operational definition) was more prevalent among children diagnosed with FAS than with other FASD diagnoses, whereas no significant relationship between history of otitis media and FASD diagnosis was observed. (Values for *n* and valid % are shown here only for 3+ cases of otitis media, but analyses related to otitis media are conducted across three categories: 0 cases, 1–2 documented cases, and 3+ cases.) The prevalence of reported hearing loss increased with increasing severity of growth deficiency, FAS facial phenotype, likelihood of central nervous system (CNS) structural abnormality, microcephaly, and full-scale IQ deficit. No such relationships were observed with respect to reported history of otitis media; no significant associations were observed with any of the FASD diagnostic variables examined. The four key diagnostic features of FASD (growth deficiency, FAS facial phenotype, CNS abnormalities, and prenatal alcohol exposure) are case defined on 4-point Likert scales (ranks) and comprise the four digits of the FASD 4-Digit Diagnostic Code (Astley, 2004). Alcohol Ranks 1 and 2 are not included here because individuals diagnosed with FASD cannot by definition have Alcohol Rank 1 (confirmed lack of prenatal alcohol exposure) and Alcohol Rank 2 (unknown, indicates unknown prenatal alcohol exposure). Bold values are significant at $p < .05$.

magnitude of prenatal alcohol exposure. In contrast, reported history of otitis media did not differ according to any of the above measures, including FASD diagnosis or the physical features of FAS. It is important to note that reported hearing loss was based on retrospective record review, not prospective audiologic assessment. Moreover, a relatively small number of individuals in the study sample were reported with hearing loss. Based on these two limitations, the present findings related to hearing loss should be interpreted with caution.

Auditory Dysfunction in Children With FASDs

The observed prominence of auditory filtering as one of the SSP domains in which caregivers rated their children with the highest frequencies of problem behaviors is consistent with previous findings in children diagnosed with FASDs (Abele-Webster et al., 2012; Carr et al., 2010; Franklin et al., 2008; Hansen & Jirikowic, 2013). Although there is evidence to suggest that one of the teratogenic effects of alcohol is insult to the developing auditory periphery that may impact audiometric hearing thresholds (Church & Kaltenbach, 1997), less is known about damage to other mechanisms—potentially centrally mediated—that may be implicated in the sound-in-noise listening and sound sensitivity/distractibility behaviors probed by the SSP. The present finding that the prevalence of atypical auditory behavior reported on the SSP is comparably high across the fetal alcohol spectrum is consistent with data from Carr et al. (2010) showing that 88% of children

Figure 2. Reported hearing loss (see text for operational definition) and recurrent otitis media (3+ occurrences) across fetal alcohol spectrum disorder (FASD) diagnoses (FASD diagnostic abbreviations [Astley, 2004]: fetal alcohol syndrome [FAS], partial FAS [PFAS], static encephalopathy/alcohol exposed [SE/AE], and neurobehavioral disorder/alcohol exposed [ND/AE]) and diagnostic/physical features of FASDs. Reported hearing loss was 16-fold more prevalent among children diagnosed with FAS (four out of 10 individuals with FAS were reported with hearing loss) than with other FASD diagnoses (seven out of 286 individuals reported with hearing loss; a prevalence similar to that observed in the general U.S. adolescent population [Lin et al., 2011]). History of recurrent otitis media was not observed to vary significantly across FASD diagnoses.



with alcohol-related neurodevelopmental disorder (analogous to ND/AE and SE/AE) and 80% of those with PFAS were rated with definite auditory filtering differences. Together, these findings suggest that these atypical auditory behaviors are widespread in individuals with FASDs, even those without the observable physical markers of FAS or PFAS. Although the prevalence of FAS itself is estimated to be one to three per 1,000 live births in the general population (Stratton, Howe, & Battaglia, 1996), individuals with fetal alcohol-related disorders across the entire spectrum are far more numerous (see Astley, 2010; Sampson et al., 1997), underscoring the clinically driven imperative to better characterize and understand auditory dysfunction across FASDs.

It is notable, however, that the atypical auditory behaviors seen on the SSP are not specific to FASDs. Whereas low auditory filtering scores do not appear to be common in typically developing children (for whom Tomchek and Dunn [2007] observed the lowest ratings of definite differences [3.1%] across domains to be in auditory filtering), children with a variety of neurodevelopmental disorders are frequently rated with atypical auditory filtering scores. In particular, 78% of toddlers (Tomchek & Dunn, 2007) and 70% of older children (Green, Chandler, Charman, Simonoff, & Baird, 2016) with autism spectrum disorder (ASD) were rated with a definite difference in the auditory filtering domain (see also Al-Heizan, AlAbdulwahab, & Kachanathu, 2015; Ashburner, Ziviani, & Rodger, 2008; Baker, Lane, Angley, & Young, 2008; Chen, Rodgers, & McConachie, 2009; O'Donnell, Deitz, Kartin, Nalty, & Dawson, 2012; Tomchek, Huebner, & Dunn, 2014). For children with Down syndrome (Bruni, Cameron, Dua, & Noy, 2010), Williams syndrome (John & Mervis, 2010), and moderate intellectual developmental disabilities (Engel-Yeger, Hardal-Nasser, & Gal, 2011), SSP profiles in which definite differences in auditory filtering scores deviate from typical (43%, 59%, and 50%, respectively), but not notably more so than other domains, have also been observed.

Hearing Loss Versus Listening Difficulties in Children With FASDs

The lack of any observed relationship between low auditory filtering scores in children with FASDs and reported hearing status (either hearing loss or general conductive hearing concerns as represented by episodes of otitis media) preliminarily suggests that audibility was not a factor in the atypical auditory behaviors reported on the SSP. The finding that audibility issues (i.e., reported hearing loss) were no more prevalent in children diagnosed with an FASD

other than FAS compared to the general U.S. adolescent population (Lin et al., 2011), but were elevated in children with FAS, is consistent with previous data (Church & Gerkin, 1988; Church et al., 1997; Cohen-Kerem et al., 2007; Rössig et al., 1994). Church and Kaltenbach (1997) hypothesized that there may be a relationship between the craniofacial abnormalities seen in FAS and inner ear dysfunction, based on shared embryological origins in ectodermal tissue potentially susceptible to damage from prenatal alcohol exposure. The present finding that reported hearing loss is related to the severity of facial dysmorphia supports this hypothesis. However, hearing loss was additionally related to all of the other physical markers of FAS—including growth deficiency, likelihood of CNS structural abnormality, and microcephaly—which may or may not be associated with neuroectodermal impairments. It is possible that the gross structural sequelae of prenatal alcohol exposure—including structural deficits involving the inner ear—are somehow related. Notably, no significant relationship was seen between hearing loss and magnitude of prenatal alcohol exposure, although the lack of relationship observed may be due to potential unreliability of the data.

In contrast, reported episodes of otitis media typically associated with middle ear function were not observed to vary across FASD diagnoses. Rates of recurrent otitis media did not appear to differ greatly than would be expected in typically developing American children (Hoffman et al., 2013), contrary to past observations of increased otitis media in FAS (Church et al., 1997; Rössig et al., 1994). This difference may be due to the widespread adoption of the pneumococcal conjugate vaccine beginning in the early 2000s (Qureishi, Lee, Belfield, Birchall, & Daniel, 2014), which is reported to have precipitated a 28% drop in the annual prevalence of otitis media diagnoses in the United States between 1997 and 2007 (Hoffman et al., 2013).

Due to the reliance on retrospective record review rather than direct audiologic assessment at the time of the FAS DPN clinic visit, the above findings are preliminary. However, they do suggest that audibility is not a factor in the atypical auditory behaviors reported in children with FASDs. These listening difficulties—namely, problems with hearing or listening despite normal audiometry—are prevalent across FASDs. Listening difficulties, which have been linked to the controversial clinical diagnosis of (central) auditory processing disorder ([C]APD; American Academy of Audiology, 2010; American Speech-Language-Hearing Association, 2005), are frequently reported in children with a variety of developmental disorders, including specific language impairment, dyslexia, and ADHD (reviewed in de Wit et al., 2018), in addition to children without any known neurodevelopmental disorders. Depending on the diagnostic criteria they used, Wilson and Arnott (2013) found that anywhere from 7% to 96% of a sample of typically developing children could be said to have listening difficulties potentially indicative of CAPD.

There is a vast array of distinct but interrelated, centrally mediated suprathreshold auditory processes that support sound-in-noise listening, including accurate lower order encoding of temporal and spatial attributes of the sound signal (reviewed in Bharadwaj et al., 2015; Stecker & Gallun, 2012) and intact spatial hearing processes (Cameron, Dillon, Glyde, Kanthan, & Kania, 2014). Each of these processes is critical to higher order operations by which the brain segregates the multitude of sound signals arriving at the ear into meaningful "auditory objects" (Griffiths & Warren, 2004; Shinn-Cunningham, 2008). Moreover, as detailed by D. R. Moore (2018), complex listening tasks such as those probed by some of the SSP auditory filtering items and other more auditory-specific tests depend not only on this interrelated network of central auditory processes but also on mechanisms more traditionally associated with the auditory periphery (e.g., high-threshold auditory nerve fiber synapses; see Kujawa & Liberman, 2015) and on central processes typically considered cognitive (e.g., attention, memory, and emotion). These cognitive processes interact with but may or may not involve auditory-specific components. Attention and other cognitive control processes are necessary to focus cognitive resources on the sound target (Anderson & Kraus, 2010; Eckert, Teubner-Rhodes, & Vaden, 2016; Fritz, Elhilali, David, & Shamma, 2007). In addition, they facilitate the quick switching of attention between spatiotemporal acoustic cues in order to enhance focus on relevant sound sources/speakers (an operation termed *active listening*, which is essential to following conversations in noisy, multitalker settings: see Larson & Lee, 2013, 2014; Shinn-Cunningham et al., 2017). All of these suprathreshold mechanisms are susceptible to breakdown and may be implicated in the listening difficulties observed in children with FASDs.

Although it is beyond the scope of this study to investigate the mechanisms of impairment underlying listening difficulties in children with FASDs, the preliminary finding that ADHD was related to atypical auditory filtering scores suggests that attention may play an important role in such auditory dysfunction. A relationship between the features of ADHD and presumed (C)APD has been previously reported (reviewed in de Wit et al., 2018), leading to a suggestion that (C)APD may, in some cases, simply reflect amodal attentional deficits (absent any auditory-specific processes) already captured by ADHD diagnosis. Of three studies reviewed by de Wit et al. that compare performance on various standardized assessments between children diagnosed with presumed (C)APD and those with ADHD, one observed auditory and visual duration pattern test performance differences between groups (Bellis, Billiet, & Ross, 2011). Although it is not possible based on the present results to ascertain whether auditory-specific or more general attentional deficits are related to listening difficulties in FASDs, previous evidence suggests that auditory filtering ratings do capture a construct distinct from ADHD. In a study of 46 children with FASDs, Carr et al. (2010) found that some auditory filtering scores differed according to FASD diagnosis, yet only one participant had ADHD, although all had received formal assessment. Moreover, Abele-Webster et al. (2012) found no correlation between the attention-deficit/hyperactivity index of the Conners' Parent Rating

Scales and any SSP domain scores and concluded that sensory processing problems in children with FASDs are distinct from ADHD. Although rates of comorbid ADHD and FASDs are typically high—53.9% of the larger FAS DPN population was diagnosed with ADHD (Astley, 2010, Table 11), and other researchers have estimated that up to 95% of children with FASDs have ADHD (Fryer, McGee, Matt, Riley, & Mattson, 2007)—Kodali et al. (2017) report that patterns of brain activity related to executive function differ between the two disorders. A meta-analysis by Kingdon, Cardoso, and McGrath (2016) also showed distinct patterns of executive function behavior deficits, with more extensive set-shifting impairments in FASDs. Such set-shifting impairments may be associated with attentional switching deficits that could negatively impact active listening behaviors.

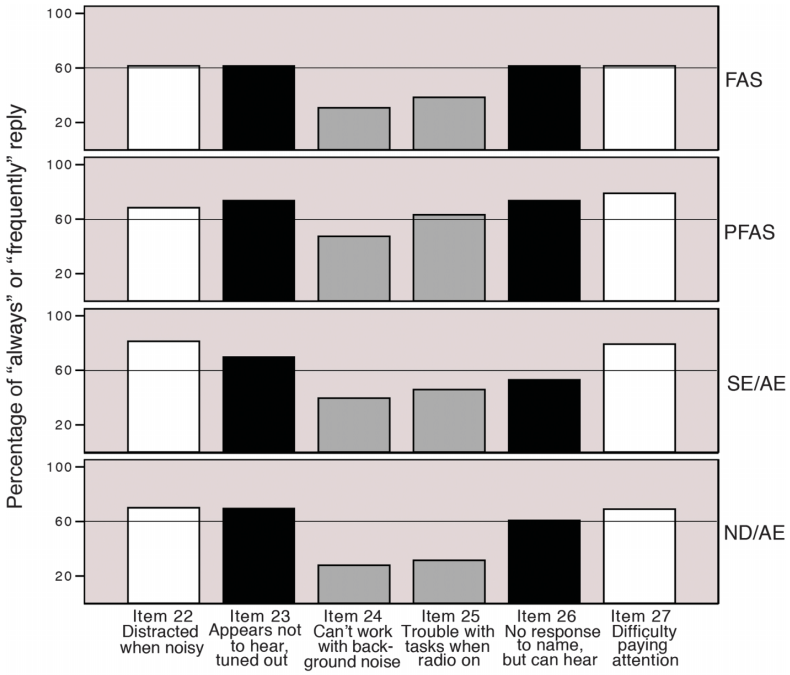
To get a better sense of the specific behaviors driving the low auditory filtering scores observed in this study, we explored the overall caregiver-response profile across individual auditory filtering items (22–27; see Figure 3). Although not formulated to specifically probe sound-in-noise listening, some of the SSP items at least partially capture these behaviors. Items 23 ("appears to not hear what you say [for example, does not 'tune in' to what you say, appears to ignore you]") and 26 ("doesn't respond when name is called but you know the child's hearing is OK") do explicitly assess listening behaviors, and although there is no mention of the acoustic environment, it is reasonable to assume that noise may play a role in the scenarios caregivers envision when rating their child's behavior. In contrast, Items 24 ("can't work with background noise [for example, fan, refrigerator]") and 25 ("has trouble completing tasks when the radio is on") appear to interrogate behaviors related to sound sensitivity or distractibility. As can be seen in Figure 3, the percentage of caregivers responding that their child "always or 'frequently" exhibits the described negative behavior was higher for Items 23 and 26 (black bars) than for Items 24 and 25 (gray bars), across FASD diagnoses. This suggests that problematic listening behaviors more strongly impacted the low auditory filtering ratings observed than did sound sensitivity/distractibility. Interestingly, Tomchek and Dunn (2007) reported similar results in children with ASD, with 73% and 51% responding "always/frequently" to Items 23 and 26, respectively, versus 13% and 16% to Items 24 and 25. Other auditory filtering items that consistently received atypical ratings for the children with FASDs in the study sample were Items 27 ("has difficulty paying attention") and 22 ("is distracted or has trouble functioning if there is a lot of noise around"), neither of which explicitly probes listening or even (in the case of Item 27) sound-related behavior but does clearly address attentional abilities. Negative behaviors on these items were also similarly elevated in Tomchek and Dunn's sample of children with ASD, with 79% responding "always/frequently" to Item 27 and 58% to Item 22.

No relationship was observed across the sample between auditory filtering scores and the other putative measures of CNS-mediated processing examined: cognition (FSIQ) and language function. The lack of correlation with IQ is consistent with previous studies, which reported that overall SSP scores are independent of IQ outcomes (Carr et al., 2010; Jirikowic et al., 2008). However, the lack of observed relationship across the sample between auditory filtering scores and language function is more surprising but is potentially related to the aggregate nature of the data used to derive this measure. "Language" is a complex behavioral domain, and the relatively gross clinical rankings of language function in the data set (based on available clinical measures that differed depending on the examined age range) potentially lacked appropriate resolution to capture the impact of problematic, higher order auditory behaviors on language functioning, particularly in younger children. It is also possible, as suggested by our findings, that the relationship between atypical auditory filtering behaviors and language function is not apparent until children are old enough that higher order, more subtle aspects of language are expected to be mastered. For example, Thorne and colleagues (Thorne, 2017; Thorne & Coggins, 2016) have observed impaired cohesive referencing—which, in English, relies on correct use of the articles "a" and "the," two similar sounding terms that can require subtle auditory processing to discriminate—to be highly prevalent in older children with FASDs. If, as we suggest, degraded linguistic input due to impaired sound-in-noise listening processes (reviewed in Bronkhorst, 2015) makes it challenging to learn the fundamental linguistic rules (White-Schwoch et al., 2015) involved in functional use of these two terms, atypical auditory filtering behaviors may have an impact on language functioning that is not captured by a global clinical ranking of language function in younger children but reveals itself when children are older. Prospective research that systematically explores the relationship between auditory function in FASDs and more specific measures of language function, particularly those that rely on subtle auditory processing, and particularly in older children, is needed.

Potential Limitations

This study represents a preliminary step in investigating auditory dysfunction in children with FASDs using retrospective SSP auditory filtering data, clinical measures of CNS function, and caregiver-provided peripheral hearing information. These existing data served as expedient but imperfect proxies for more targeted, objective, and systematic assessments of suprathreshold listening abilities and prospective audiologic evaluations. Due to the observational nature of the data, it is possible that hearing loss in the sample was underreported and that the imprecise behavioral measures available representing sound-in-noise listening and language function obscured the observation of important relationships. Moreover, the subjective caregiver ratings on the SSP were susceptible to bias, as with any caregiver rating, although it is important to note the caregivers completed the SSP prior to their child's FASD diagnostic evaluation, so their responses were not biased by knowledge of their child's FASD diagnosis. Systematic, prospective investigation

Figure 3. Profile of caregiver ratings on Short Sensory Profile auditory filtering items across fetal alcohol spectrum disorder diagnoses (abbreviations [Astley, 2004]: fetal alcohol syndrome [FAS], partial FAS [PFAS], static encephalopathy/alcohol exposed [SE/AE], and neurobehavioral disorder/alcohol exposed [ND/AE]). The percentage of "always" or "frequently" ratings with respect to the described negative behavior was higher, across fetal alcohol spectrum disorder diagnoses, for items related to sound-in-noise listening (Items 23 and 26: black bars) than for items related to sound sensitivity/distractibility (Items 24 and 25: gray bars).



employing carefully controlled objective measures of sound-in-noise listening abilities, detailed audiologic assessment, and more targeted neuropsychological testing in children with FASDs, grouped by different age bands, is needed.

Conclusions and Future Directions

Results from this study indicate that, although children with FAS exhibit a higher-than-normal prevalence of hearing loss, it is listening difficulties in the absence of hearing loss, likely related to suprathreshold processing deficits, that are strikingly prevalent across the spectrum of fetal alcohol disorders. Such listening difficulties are impactful—affecting life function adversely and potentially contributing to lifelong difficulties with linguistic exchange and/or social interaction—and are likely widespread, given that prenatal alcohol exposure is the leading preventable cause of birth defects and intellectual and neurodevelopmental disabilities (Williams & Smith, 2015). The present results related to listening difficulties in FASDs point to the importance of systematic clinical assessment of this domain of functioning whenever prenatal alcohol exposure is part of the clinical profile of an individual being assessed, so that common and relevant impairment is not missed.

Although it is unclear whether listening difficulties in FASDs derive from the similar etiologies as listening difficulties observed in children with other neurodevelopmental disorders or in children presumed to be typically developing, the physiological bases of listening difficulties, in general, remain unclear (DeBonis, 2015; D. R. Moore, 2018). FASD offers a unique opportunity to explore their etiology relative to the involvement of a known and well-characterized teratogen, alcohol. The present results suggest an important role for attention-related processes in listening difficulties in children with FASDs. However, a detailed and systematic investigation of auditory dysfunction in FASDs is needed before firm conclusions are reached. It will be important to characterize auditory behavior and objectively assess suprathreshold listening abilities in FASDs, using detailed audiologic and psychoacoustic assays, along with advanced multimodal neuroimaging methods to assess the functional integrity of the auditory pathway—from periphery to cortex—in order to better parse out the physiological bases of auditory dysfunction from among the multitude of candidate auditory and cognitive processes. Although there are few evidence-

based interventions available to date to ameliorate listening difficulties related to suprathreshold deficits, enhanced understanding of the physiological underpinnings of auditory dysfunction will ultimately improve diagnoses and better inform therapy options available to these listeners.

Acknowledgments

The Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network has been supported by the Division of Alcohol and Substance Abuse of the Washington State Department of Social and Health Services through the passage of Senate Bill SB5688 (1997–present) and the Center on Human Development and Disability, University of Washington, since 1993 (National Institute of Child Health and Human). This research was supported by a University of Washington Alcohol and Drug Abuse Institute grant, "Characterizing Auditory Processing in Individuals with Fetal Alcohol Spectrum Disorder," awarded to S. A. M., A. K. C. L., and S. J. A. H.

ALCOHOLISM CLINICAL & EXPERIMENTAL RESEARCH

Are Low-to-Moderate Average Alcohol Consumption and Isolated Episodes of Binge Drinking in Early Pregnancy Associated with Facial Features Related to Fetal Alcohol Syndrome in 5-Year-Old Children?

Ulrik Schiøler Kesmodel, Siv Steffen Nygaard, Erik Lykke Mortensen, Jacquelyn Bertrand, Clark H. Denny, Alex Glidewell, and Susan Astley Hemingway

Background: Fetal alcohol syndrome (FAS) typically is observed among individuals with high prenatal alcohol exposures (PAE), but exposure histories obtained in clinical diagnostic settings are often inaccurate. The present analysis used the Lifestyle During Pregnancy Study (LDPS) to assess the potential effects of low-to-moderate average weekly alcohol consumption and binge drinking in early pregnancy on facial features associated with FAS among children 5 years of age.

Methods: The analysis is a prospective follow-up study of 670 women and their children sampled from the LDPS cohort based on maternal alcohol consumption during pregnancy. The 4-Digit Code FAS Facial Photographic Analysis Software was used to measure the magnitude of expression of the 3 diagnostic facial features of FAS from standardized digital photographs. Logistic regression was used to estimate the odds of presenting with the FAS/partial fetal alcohol syndrome (PFAS) facial phenotypes relative to different patterns of prenatal alcohol exposure.

Results: Ten children presented with the FAS/PFAS facial phenotypes. None of the children sampled met the central nervous system (CNS) criteria for FAS or PFAS at age 5 years. All remained at risk for PFAS since some types of CNS dysfunction associated with this diagnosis may only be assessed at older ages. The FAS/PFAS facial phenotypes were 8.5-fold more likely among children exposed to an average of 1 to 4 drinks/wk and 2.5-fold more likely among children with a single binge exposure in gestational weeks 3 to 4 compared to children with no such exposures. The magnitude of expression of the FAS facial phenotype was significantly correlated with all other diagnostic features of FAS: growth deficiency, microcephaly, and measures of CNS dysfunction.

Conclusions: These findings suggest that low-to-moderate levels of PAE or isolated binge exposures may place some fetuses at risk for FAS/PFAS. Thus, conservative advice is still for women to abstain from alcohol consumption during pregnancy.

Key Words: Alcohol, Alcohol Binge Drinking, Pregnancy, Fetal Alcohol Syndrome, Fetal Alcohol Spectrum Disorders.

FETAL ALCOHOL SYNDROME (FAS) is a permanent birth defect and developmental disability caused by in utero exposure to alcohol. FAS is characterized by growth deficiency, a unique constellation of minor facial anomalies, and structural, neurological, or functional central nervous system (CNS) abnormalities (Astley and Clarren, 2000; Bertrand et al., 2004; Stratton et al., 1996). Not all individuals exposed to and damaged by prenatal alcohol exposure have FAS, the most involved diagnosis under the umbrella of fetal alcohol spectrum disorders (FASDs). Prenatal exposure to alcohol can also result in more subtle adverse effects and diagnoses. The growth, facial, and CNS abnormalities can all present along separate continua from mild to severe (Stratton et al., 1996).

A number of FASD diagnostic schemes have been posed and applied worldwide (Astley, 2004; Bertrand et al., 2004; Bower and Elliott, 2016; Cook et al., 2016; American Psychiatric Association, 2013; Hoyme et al., 2016). All promote an interdisciplinary approach to diagnosis and broadly agree that FASDs are characterized by growth, facial, and CNS abnormalities. But, the specific criteria

used to define each diagnosis under the umbrella of FASDs do differ across the diagnostic systems (Astley, 2011; Astley et al., 2017; Coles et al., 2016). It should be noted that all schemes assess facial features for an FAS diagnosis since these features reflect anomalies in prenatal brain development. The current analysis used criteria as outlined in Astley (2004), also known as the 4-Digit Code. Briefly, these criteria require all of the following:

1. Growth deficiency: prenatal and/or postnatal height and/or weight at or below the 10th percentile;
2. Facial dysmorphia: all 3 of the following: (i) short palpebral fissure lengths (PFLs; less than or equal to third percentile); (ii) smooth philtrum (Rank 4 or 5 on the University of Washington Lip-Philtrum Guide); and (iii) thin upper lip (Rank 4 or 5 on the University of Washington Lip-Philtrum Guide);
3. Evidence of severe CNS structural, neurological, and/or functional abnormalities;
4. Prenatal alcohol exposure: a confirmed or unknown history of exposure. FAS can be diagnosed in the absence of a confirmed prenatal alcohol exposure history if the 3 facial features (as defined by the Rank 4 facial phenotypes in the 4-Digit Code) are present. Empirical evidence confirms the Rank 4 facial phenotypes are so highly specific to (caused only by) prenatal alcohol exposure. Its presence can be used to confirm exposure when an exposure history is unavailable (Astley, 2013).

The FAS facial phenotype is not simply present or absent. It presents along a clinically meaningful continuum from mild to moderate to severe (Astley and Clarren, 2000). The magnitude of expression of the FAS facial phenotype not only increases with increasing prenatal alcohol exposure, but also correlates significantly with increasing severity of growth deficiency, microcephaly, and CNS dysfunction (Astley, 2013). These significant correlations serve to validate a causal association between prenatal alcohol exposure and the growth, facial, and CNS abnormalities currently used to define FAS (Astley, 2013; Astley and Clarren, 2001).

FAS is typically observed among individuals with reportedly high prenatal alcohol exposures (PAE; ≥6 drinks/d or 5 to 6 drinks within a short period of time) (O'Leary and Bower, 2012), but exposure histories obtained in clinical diagnostic settings often are inaccurate. For example, the average reported exposure among 154 individuals diagnosed with FAS or partial fetal alcohol syndrome (PFAS) at the University of Washington FAS Diagnostic & Prevention Network (FASDPN) using the 4-Digit Code was 8 to 12 drinks per drinking occasion, 5 to 6 days per week (Astley, 2010). This average exposure pattern, however, spanned a wide range. At the low end of the range, 1 of every 14 children with FAS or PFAS had a reported exposure of no more than 1 drink/d. Are these 1 in 14 cases especially vulnerable to the adverse effects of prenatal alcohol exposure, or were their lower exposures inaccurately reported? The Lifestyle During Pregnancy Study (LDPS) (Kesmodel et al., 2010, 2012) provided just such a dataset that addressed this issue by collecting prenatal alcohol exposure history during early pregnancy and using standardized measures of growth, face, and CNS.

The LDPS has previously provided data on the association between low-to-moderate alcohol intake and alcohol binge drinking and neuropsychological development, including intelligence, attention, psychomotor function, executive function, and behavior (Bay et al., 2012; Kesmodel et al., 2010, 2012, 2013). The objective of the present analysis was to use the LDPS to assess the potential effects of low-to-moderate average weekly alcohol consumption and binge drinking in early pregnancy on facial features associated with FAS among children 5 years of age. Specifically, we (i) document the occurrence of the individual FAS facial features and overall FAS facial phenotype in the study sample; (ii) assess the association between prenatal alcohol exposure and the magnitude of expression of the FAS facial features and phenotype; and (iii) assess the association between the magnitude of expression of the FAS facial phenotype and other diagnostic features of FAS, including cognitive impact, reduced head circumference, and growth deficiency.

MATERIALS AND METHODS

Study Sample

This study was part of the LDPS, which has been described in detail elsewhere (Kesmodel et al., 2010, 2012). Briefly, the study is a prospective follow-up study based on a subsample from the Danish National Birth Cohort (DNBC; Olsen et al., 2001).

A total of 1,628 mother–child pairs participated in the follow-up. Inclusion was based on a stratified sample with oversampling of women with low-to-moderate alcohol intake and binge drinking (Kesmodel et al., 2010, 2012). Exclusion criteria were inability to speak Danish, impaired hearing or vision causing inability to complete the cognitive tests, multiple pregnancies, and congenital diseases likely to cause mental retardation (Kesmodel et al., 2010). Data collection for the follow-up study took place from September 2003 to June 2008 (Kesmodel et al., 2010).

Of the 1,628 participants' images available for measurement, 670 met the inclusion criteria for this study and had at least 1 of the 3 facial features measured (see details in Appendix).

Exposure Assessment

Information on alcohol intake during pregnancy was derived from the first prenatal DNBC interview. Among the subsample of women participating in the follow-up, the median week of gestation for completing the prenatal interview was 17 weeks (range: 7 to 39 weeks). During the interview, the women were asked about their average number of beers, glasses of wine, and glasses of spirits they currently consumed at the time of the interview over the course of a week, and based on this information, the total number of weekly drinks was calculated. These alcohol exposure questions have been shown to yield valid estimates of alcohol consumption throughout pregnancy (relative to other methods) and reliable information among pregnant Danish women (Kesmodel and Olsen, 2001). Information on binge drinking during pregnancy included data on the number of binge episodes (defined as intake of ≥5 drinks on a single occasion) and the timing (gestational week) of these episodes (Kesmodel, 2001) up until the time of the interview. A number of women

in the current sample reported 1 or more binge episodes during early weeks of pregnancy, although their average number of drinks per week at the time of interview was zero (Kesmodel et al., 2012). These women were classified accordingly as consuming zero average drinks per week during pregnancy, but with 1 or more previous binge episodes. The definition of a drink followed the definition from the Danish National Board of Health, with 1 standard drink being equal to 12 g of pure alcohol. The sampling stratification for average weekly consumption and binge consumption in the first trimester has been described previously (Kesmodel et al., 2010, 2012). This stratification resulted in 5 sampling categories used in this analysis.

Outcome Measures

Facial Features. The follow-up assessments were conducted at 4 sites located in Copenhagen, Aarhus, Odense, and Aalborg. The assessment comprised a comprehensive neuropsychological test battery which is described in detail elsewhere (Kesmodel et al., 2010, 2012).

Following the test session, standardized digital facial photographs were taken of each mother and child to allow subsequent measurement of (dysmorphic) facial features, including the philtrum, the upper lip, and PFL. Specific procedures for taking and coding photographs are described in Appendix. All testers were blind to the exposure status of the participants, and all tests were administered in Danish.

Briefly, the University of Washington FAS Facial Photographic Analysis Software (Astley, 2016) was used to measure the magnitude of expression of each of the 3 diagnostic facial features of FAS (short PFLs: 2 or more standard deviations (SD) below the mean; smooth philtrum (Rank 4 or 5 on the University of Washington Lip-Philtrum Guide) and thin upper lip (Rank 4 or 5 on the Lip-Philtrum Guide (Fig. 1), lip circularity ≥75.5) as defined by the University of Washington FASD 4-Digit Code (Astley, 2016). For the 366 children with photographs of sufficient quality to allow accurate measurement of all 3 facial features, the magnitude of expression of the overall FAS facial phenotype (Face Rank) was ranked on a 4-point Likert scale (Rank 1: normal phenotype; Rank 2: mild FAS phenotype; Rank 3: moderate FAS phenotype; and Rank 4: severe FAS phenotype) in accordance with the FASD 4-Digit Code (Astley, 2004). The Scandinavian PFL growth charts (Stromland et al., 1999) and University of Washington Lip-Philtrum Guide 1 were used for this Danish population.

Cognitive Function. Child intelligence was assessed using the Wechsler Preschool and Primary Scale of Intelligence-Revised (WPPSI-R) (Wechsler, 1990) covering the age span 3 to 7 years. The WPPSI-R includes 5 verbal and 5 performance subtests that are used to calculate an overall verbal intelligence quotient (VIQ), overall performance IQ (PIQ), and full-scale IQ (FSIQ). In this test battery, only 3 of the verbal (arithmetic, information, and vocabulary) and 3 of the performance (block design, geometric design, and object assembly) subtests were carried out to facilitate the child's cooperation throughout the testing. Standard procedures were used to prorate scores from the shortened test.

Child attention was assessed with the Test of Everyday Attention for Children at Five (TEACh-5; Underbjerg et al., 2012, 2013) covering the age span 5 years to 5 years and 3 months. For this study, 2 subtests assessing selective attention ("Great Balloon Hunt" and "Hide and Seek II") and 2 subtests assessing sustained attention ("Barking" and "Draw a line") were used. Each subtest score was standardized to a mean of 0 and a SD of 1. To calculate composite scores for overall, selective, and sustained attention, the means of the respective standardized subtest scores for each individual were calculated and restandardized to a mean of 0 and SD of 1.

Executive function was assessed using the Behavior Rating Inventory of Executive Function (BRIEF) questionnaire (Gioia et al., 2000) covering the age span 5 to 18 years. The questionnaire consists of 2 versions, 1 for parents and 1 for teachers. The parent version was used for these analyses because of higher participation. Each questionnaire evaluates 8 domains of executive functioning and forms the Global Executive Composite (GEC). Three of the 8 domains form the Behavioral Regulation Index (BRI), and 5 of the domains form the Metacognition Index (MI). Since the 8 domains do not follow a normal distribution, we performed a normalizing *t*-score transformation to standardize each domain to a mean of 50 and SD of 10. To compute the GEC, BRI, and MI, the means of the respective domains for each individual were calculated and restandardized to a mean of 50 and SD of 10. For all BRIEF scores, a higher score indicates more executive function difficulties.

Covariates

Factors demonstrated in previous research to influence child neurodevelopment were selected as covariates. The following covariates were obtained in the prenatal interview and subsequently coded as follows: parity (0, 1, ≥2); prenatal smoking (yes/no); and maternal prepregnancy body mass index (BMI) (weight in kg/[height in m]^2). At the time of the 5-year follow-up, the following variables were recorded: maternal marital status (single at either the prenatal interview or follow-up/with partner at both times) and parental education in years (total duration of attained education averaged for both parents or maternal only if information on the father was missing). Additional information on collection of covariate information is provided elsewhere (Kesmodel, 2012; Kesmodel et al., 2010).

Maternal age was obtained from the unique Danish personal identification number, as were sex and age of the child. Birthweight in grams, head circumference, and gestational age in days were obtained from the Danish Medical Birth Registry (Bliddal et al., 2018).

Data Analysis

Descriptive statistics (i.e., means, SDs, and proportions) were used to profile the sociodemographics of the study population, the maternal drinking patterns, and the magnitude of expression of the FAS facial features and phenotype. Logistic regression was used to document the odds of presenting with the FAS/PFAS facial phenotype (Face Rank 3 or 4), short PFLs (ABC-Score = C, 2 or more SDs below the mean), smooth philtrum (Rank 4 or 5), or thin upper lip (Rank 4 or 5) relative to 4 different patterns of prenatal alcohol exposure: (i) average number of drinks/week during pregnancy (0, 1 to 4, ≥5), (ii) binge drinking (yes/no), (iii) number of binge drinking episodes (0, 1, 2 ≥ 3), and (iv) gestational timing of the single binge drinking episode (no binge, weeks 1 to 2, weeks 3 to 4, weeks 5+; multiple episodes). Odds ratios were adjusted for predefined covariates (parity; prenatal smoking; maternal prepregnancy BMI; maternal marital status; parental education in years; maternal age at the birth of the index child; sex and age of the child).

Not all photographs were of sufficient quality (e.g., facial expression, rotation, and focus) to generate accurate measures of all 3 facial features. As a result, participants were divided into 2 groups. Group A (N = 366) consisted of children whose photographs were of sufficient quality to measure all 3 facial features. Group B (N = 670) consisted of children whose photographs were of sufficient quality to measure 1 to all 3 of the facial features. Group A is a subset of Group B. Group B was used for analyses focused on the individual facial features. Group A was used for analyses focused on the overall facial phenotype.

All analyses were conducted in SAS and Stata 12 (StataCorp LP, College Station, TX, USA) and weighted by sampling probabilities. Statistical tests were 2-sided and deemed significant at the 5% level. Estimates are accompanied by 95% confidence intervals.

RESULTS

Sample Characteristics

Although the 2 subsets, Group A and Group B, were not randomly selected from the 1,628, the sociodemographic profiles (Table 1) and maternal drinking patterns (Table 2) confirm that both subgroups were highly reflective of one another and highly representative of the 1,628 participants from which they were drawn. Of the 366 women in Group A, 308 (84%) reported, on average, low-to-moderate alcohol consumption with isolated episodes of binge drinking, and 58 reported no alcohol consumption during pregnancy. Of the 670 women in Group B, 561 (84%) reported, on average, low-to-moderate alcohol consumption with isolated episodes of binge drinking, and 109 reported no alcohol consumption during pregnancy (Table 2).

Occurrence of the FAS and PFAS Facial Phenotypes

Among the 366 participants with all 3 facial features measured, 308 had confirmed exposure to alcohol. Nine of the 308 (2.9%) met the 4-Digit Code criteria for the moderate

expression of the FAS facial phenotype (Face Rank 3), and 1 (0.3%) met the criteria for the severe expression of the FAS facial phenotype (Face Rank 4) (Table 3). Measures of growth, CNS structure and function, and maternal drinking patterns are presented in Table 4 to document whether any of these 10 children met the diagnostic criteria for FAS or PFAS in accordance with the FASD 4-Digit Code. All children were alcohol-exposed. Their mothers reported an average intake of 0 to 7 drinks/wk before pregnancy, 0 to 2 drinks on average per week during pregnancy, and a maximum of 1 binge episode during the first 20 weeks of pregnancy. All children were born at term. Five of the 10 presented with growth, head circumference, and/or IQ measures between 1 and 2 SDs below the mean. None of the children presented with growth measures at or below the 10th percentile. One child presented with a head circumference at the 10th percentile. In the absence of microcephaly (head circumference less than or equal to third percentile), FAS and PFAS require evidence of brain dysfunction. The level of brain dysfunction required for FAS or PFAS (CNS Rank 3) is defined by the 4-Digit Code as 3 or more domains of brain function, 2 or more SDs below the mean based on a comprehensive assessment of language, memory, executive function, cognition, motor, attention, and adaptation, using validated instruments administered by clinical professionals (Astley, 2004). To confirm or rule out this level of brain dysfunction, these assessments must be administered when a child is old enough (typically >8 years) to engage in assessments of more complex, mature brain function (Astley, 2004). None of the 10 children met the above criteria for brain dysfunction based on the WPPSI-R IQ test. Thus, at 5 years of age, none of the 10 children met the 4-Digit Code CNS criteria for FAS or PFAS, but all remain at risk for PFAS because CNS dysfunction (CNS Rank 3) cannot be confirmed or ruled out at this young age.

Among the 304 children in which only 1 or 2 facial features could be measured, the full FAS facial phenotype (Face Rank 4) could effectively be ruled out in 96% and the moderate expression of FAS facial phenotype (Face Rank 3) could be ruled out in 77%. When combined with the facial outcomes of the 366 children with all 3 facial features measured, the FAS/PFAS facial phenotypes (Face Ranks 3 to 4) could be ruled out in 96.7% of the 670 children.

[b]Lifestyle During Pregnancy Study 2012.

Occurrence of the Individual FAS Facial Features

Among the 670 participants with 1, 2, or all 3 of the facial features measured, 4% presented with PFLs 2 or more SDs below the mean (PFL ABC-Score = C), 11% presented with moderately-to-completely smooth philtrums (Philtrum Ranks 4 and 5; ABC-Score = C), and 41% presented with moderately-to-severely thin upper lips (Lip Ranks 4 and 5; ABC-Score = C; Table 3; Fig. 1). The prevalence of each FAS facial feature was nearly identical in the smaller subset of 366 participants that had all 3 facial features measured.

Association Between FAS/PFAS Facial Features and Prenatal Alcohol Exposure

Table 5 shows the odds of presenting with the FAS/PFAS facial phenotypes (Face Rank 3 or 4) across different patterns of quantity, frequency, and timing of prenatal alcohol exposure. Exposure to 1 to 4 drinks/wk on average during gestation was associated with a significant 8.5-fold increased odds for presenting with the FAS/PFAS facial phenotypes compared to participants with no average drinks per week. Exposure to a single binge drinking episode was associated with a significant 1.9-fold increased odds for the FAS/PFAS facial phenotypes. When the timing of the single binge exposure was in gestational weeks 3 to 4, participants were 2.5-fold more likely to present with the FAS/PFAS facial phenotypes than participants with no binge exposure. Single binge exposures occurring before or after gestational weeks 3 to 4 did not result in a significantly increased odds of the FAS/PFAS facial phenotypes.

Table 5 also presents the odds of presenting with each of the individual facial features of FAS (short PFL: ≤−2 SDs, ABC-Score = C), smooth philtrum (Rank 4 or 5, ABC-Score = C), and thin upper lip (Rank 4 or 5, ABC-Score = C) across the different patterns of prenatal alcohol exposure.

PFL. The odds of presenting with short PFLs (ABC-Score = C) increased significantly from 1.8-fold to 3.7-fold as the average number of drinks per week during pregnancy increased from 1 to 4 to ≥5. The odds of short PFLs increased significantly as the timing of binge exposure

occurred earlier in gestation. The odds were highest when binge(s) occurred in weeks 1 to 2 and lowest when binge(s) occurred during or after gestational week 5, although not statistically significant. The odds of short PFLs was highest with a single binge exposure and significantly lower with 2 or more binge episodes.

Philtrum. Odds of a smooth philtrum (ABC-Score = C) appeared to be more dependent on the timing of binge exposure than the number of binge exposures. The odds were significant and highest (1.3-fold higher) when binge drinking occurred in weeks 1 to 2. Odds decreased linearly as binge drinking occurred later in gestation. Intake of 1 to 4 drinks/wk on average and 2 binge episodes in early pregnancy were associated with significantly lower odds of a smooth philtrum.

Lip. Odds of upper lip thinness (ABC-Score = C) also appeared to be more dependent on the timing of binge exposure rather than the number of binge exposures. Participants with 1 binge exposure were at significantly higher odds (Odds ratios [OR] 1.19) for thin upper lip than participants with no binge exposures. When binge exposure occurred in weeks 3 to 4, odds of a thin upper lip was greatest (OR 1.66). When binge exposure occurred in week 5 or later, children were significantly less likely to present with a thin upper lip (OR 0.83).

Associations Between the Magnitude of Expression of the FAS Facial Phenotype and Other Diagnostic Features of FASD

Individuals with short PFLs (≤−2 SDs) had significantly lower mean FSIQ and PIQ scores (5 to 7 points lower) than

[a]Anthropometric measures originally reported in grams (birthweight), kg (weight at age 5 years), or cm (length at birth, height at age 5 years, head circumference at birth and at age 5 years). Presented as deviations from the mean in SD (Danish standard growth curves) in order to avoid identification of individuals.
[b]FSIQ measured with WPPSI-R on standard IQ-scale (mean of 100, SD = 15). Attention measured with TEACh-5 (Test of Everyday Attention for Children at Five). Executive function measured with BRIEF (Behavior Rating Inventory of Executive Function). Presented as deviations from the mean: *N* = −1 SD to +1 SD from population means to avoid identification of individuals.
[c]Calculated in days and converted to completed weeks as presentation in days potentially allows for identification of individuals.

the reference group with normal PFLs (>−1 SD) (Table 6). Individuals with smooth philtrums (Rank 4 or 5) had significantly lower mean FSIQ and VIQ scores (3 to 4 points lower) than individuals with deep philtrums (Rank 1 or 2). Individuals with thin upper lip (Rank 4 or 5) had a significantly higher mean VIQ score (2.5 points higher) than individuals with thicker upper lips (Ranks 1 and 2). When the 3 facial features were assessed together, individuals with the Rank 3 or 4 FAS/PFAS facial phenotypes presented with mean FSIQ and PIQ scores that were 4 to 7 points lower than the individuals with normal facial phenotypes (Ranks 1 and 2). Although the magnitude and direction of association were equivalent to those observed for the individual facial features, the contrasts were not statistically significant. The smaller sample sizes resulted in insufficient power (<80%) to identify the 4 to 7 point contrasts as statistically significant.

We found no significant or clinically relevant differences between children with different facial phenotypes or different measures of individual facial features and executive function and attention (data not presented).

Mean birthweight, birth length, and birth head circumference decreased significantly with increasing magnitude of expression of the FAS facial phenotype (Face Ranks 1 to 4) among the 366 participants in Group A (Fig. 2).

DISCUSSION

Summary

There were 3 core findings in this study with a sample of 670 children in which 109 had no prenatal alcohol exposure and 561 had low-to-moderate exposure with isolated binge episodes. First, 10 children presented with the FAS/PFAS facial phenotypes (Face Rank 3 or 4). All 10 were alcohol-exposed. None met the diagnostic criteria for FAS or PFAS at 5 years of age. All 10, however, remain at risk for PFAS because they were too young at age 5 years to engage in the battery of neuropsychological assessments required to confirm or rule out brain dysfunction. Second, children exposed to 1 to 4 drinks/wk were 8.5-fold more likely to present with the FAS/PFAS facial phenotypes (Rank 3 or 4) than children with no prenatal alcohol exposure. Risk of the FAS/PFAS facial phenotypes was also significantly increased (2.5-fold) among children with a single binge exposure in gestational weeks 3 to 4 compared to children with no binge exposures. And third, the magnitude of expression of the FAS facial phenotype was significantly correlated with all other diagnostic features of FAS: growth deficiency, microcephaly, and measures of CNS dysfunction, even if measures of these features were within the normal range in this sample.

A primary objective of this study was to determine whether adverse outcomes typically observed among populations with high PAE could be found in a population with much lower exposure. Since the facial features that define FAS/PFAS were measured using the same software (Astley, 2016), personnel, and FASD diagnostic system (Astley,

2004) used to measure facial features in the University of Washington FASDPN clinical population, relevant comparisons can be made between the 2 populations. The FASDPN dataset includes over 3,000 individuals with prenatal alcohol exposure who received an interdisciplinary FASD diagnostic evaluation using the FASD 4-Digit Diagnostic Code (Astley, 2010). The alcohol exposures reported in the current study population (83% reported no more than 1 to 8 drinks/wk and/or isolated binge episode [drinking categories 1a to 4c; Table 1]) were considerably lower than the alcohol exposures reported in the FASDPN clinical population (76% report greater than 1 to 8 drinks/wk; average exposure is 7 to 9 drinks per occasion, 4 to 5 d/wk) (Astley, 2010).

Prevalence of FAS Facial Features and Correlation with Prenatal Alcohol Exposure

In the current study population with low-to-moderate prenatal alcohol exposure, 3.2% (10/308) presented with the FAS/PFAS facial phenotypes (Rank 3 or 4). All were exposed to no more than 7 drinks/wk and no more than a single episode of binge drinking. In contrast, a much higher proportion of individuals (19%) present with the FAS/PFAS facial phenotypes in the FASDPN patient population (Astley, 2010). Although individuals in the FASDPN patient population are, on average, highly exposed, 1 of every 14 diagnosed with FAS/PFAS has a reported exposure of no more than 7 drinks/wk. This is similar to the 10 children with the FAS/PFAS facial phenotypes in the current study. Although prenatal alcohol exposure may have been underreported for these 1 in 14 cases, it is also possible that these children are particularly vulnerable to lower levels of exposure. Future research may want to examine this possibility. The outcomes in the current study suggest that lower exposures may, in fact, be sufficient to produce the FAS/PFAS facial phenotypes in a small proportion of children. Timing of exposure also appears to be important. Perhaps one of the most compelling findings in the current study was a significant 2.5-fold increased odds of the FAS/PFAS facial phenotypes among children with a single binge exposure in gestational weeks 3 to 4. Gestational weeks 3 and 4 reflect the primitive streak and gastrulation stage of embryogenesis—a critical period of induction of alcohol-induced craniofacial alterations (Astley, 2013; Astley et al., 1999; Sulik, 1984).

FAS and PFAS require more than just the Rank 3 or 4 facial phenotype. Although 10 children in the current study presented with the Rank 3 or 4 FAS/PFAS facial phenotypes, none met the diagnostic criteria for FAS or PFAS (in accordance with the 4-Digit Code) at the young age of 5 years. FAS is defined by growth ≤10th percentile, a Rank 4 facial phenotype, and microcephaly (less than or equal to third percentile) and/or brain dysfunction (3 or more domains of brain function 2 or more SDs below the mean) (Astley, 2004). PFAS is defined by normal growth,

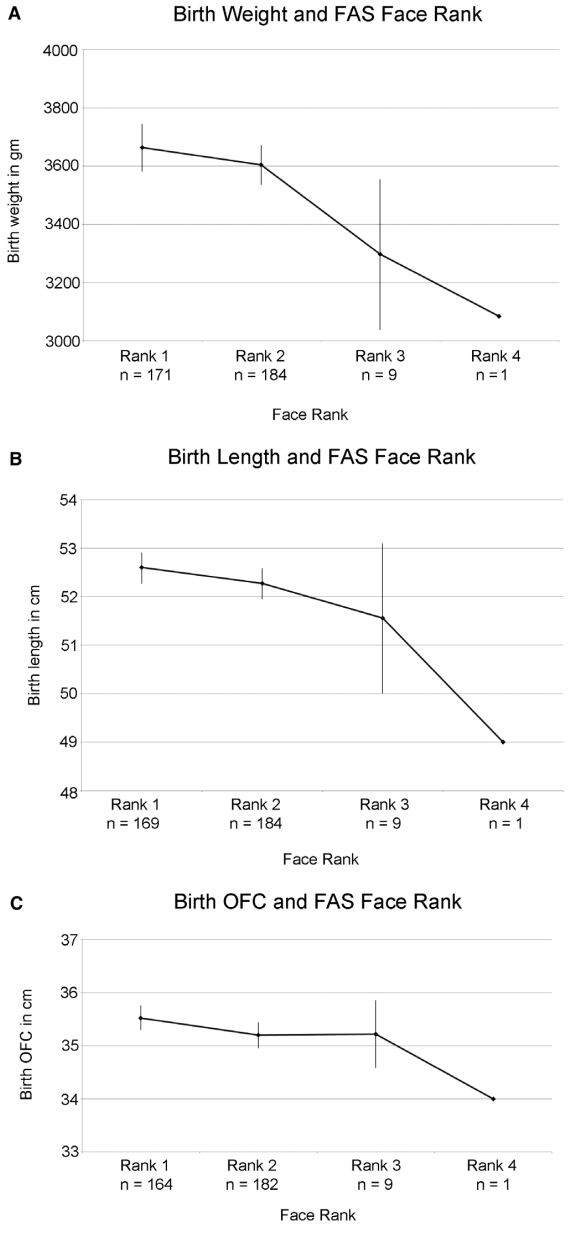

Fig. 2. Mean birthweight, birth length, and birth head circumference decreased significantly with increasing magnitude of expression of the FAS facial phenotype (Face Ranks: 1, normal; 2, mild; 3, moderate; and 4, severe) among the 366 participants in Group A. Error bars reflect 95% CIs. One-way ANOVA test for linear trend *p*-values: birth length 0.04, and birthweight and head circumference 0.001.

a Rank 3 or 4 facial phenotype, and microcephaly and/or brain dysfunction (3 or more domains of brain function 2 or more SDs below the mean). Since no child presented with growth ≤10th percentile, no child met the criteria for FAS. In contrast, all 10 children met the growth and facial criteria for PFAS. None of them presented with microcephaly; therefore, CNS dysfunction would be required to meet the CNS criteria for PFAS. Nevertheless, at 5 years of age, all were too young to participate in the battery of assessments required to confirm or rule out CNS dysfunction. As documented in the FASDPN clinical population, most children with FAS or PFAS do not present with severe brain dysfunction until later in childhood. For example, among 87 children ≤5 years of age at the time of their FAS/PFAS diagnosis at the FASDPN, only 24% met the criteria for severe CNS dysfunction (3 or more domains of function 2 or more SDs below the mean). Among 152 children >5 years of age at the time of their FAS/PFAS diagnosis, 84% met the criteria for severe CNS dysfunction. In addition, recent research (Astley et al., 2016) documents that 67 and 70% of young children with prenatal alcohol exposure that present with the Rank 3 or 4 FAS facial phenotypes, respectively, will present with severe CNS dysfunction (3 or more domains of brain function 2 or more SDs below the mean) when they are old enough (>8 years of age) to engage in more sophisticated assessments of brain function. Thus, if any of the 10 children with the Rank 3 or 4 FAS/PFAS facial phenotypes present with brain dysfunction (3 or more domains of brain function 2 or more SDs below the mean) later in childhood, they would meet the diagnostic criteria for PFAS.

Prenatal alcohol exposure was significantly correlated with the FAS facial phenotype and the 3 individual features that comprise the FAS facial phenotype. The strongest correlations with alcohol (ORs of 1.9 to 8.5) were observed when the 3 features appeared together to produce the Rank 3 or 4 FAS/PFAS facial phenotypes (Table 5). Since the Rank 4 FAS facial phenotype is confirmed to be highly specific to prenatal alcohol exposure (Astley, 2013; Astley and Clarren, 1996), it is highly likely that the FAS/PFAS facial phenotypes observed in these 10 children were caused by their prenatal alcohol exposure. Weaker, but statistically significant, correlations (ORs of 1.2 to 3.7) were observed between prenatal alcohol exposure and each individual FAS facial feature. This would be expected since alcohol is not the only factor influencing the length of a palpebral fissure, the depth of a philtrum, or the thickness of an upper lip. Perhaps one of the strongest factors other than alcohol influencing the physical presentation of these 3 facial features is familial genetics. A unique strength of the current study was the opportunity to measure the birth mothers' facial features. Among the 10 children who presented with the Rank 3 or 4 FAS facial phenotypes, all of their birth mothers presented with normal facial phenotypes (Face Ranks 1 and 2).

Correlations Between the FAS Facial Phenotype and Growth Deficiency, Microcephaly, and CNS Dysfunction

The correlations between face, growth, and CNS abnormalities observed in the current study (Fig. 2) are nearly

identical to those documented in the FASDPN clinical population (figures 8 and 9 in Astley, 2013). This study extends understanding of these correlations to a population of children with low-to-moderate prenatal alcohol exposure.

Strengths

The sample of women and children used for this study form part of a well-described, prospective cohort (Kesmodel et al., 2010; Olsen et al., 2001). While information bias is always a potential problem in observational studies (Kesmodel, 2018), the risk of information bias was minimized. Information on alcohol drinking patterns was collected directly from the birth mothers during pregnancy using validated instruments (Kesmodel, 2001; Kesmodel and Olsen, 2001), and all facial measures were performed by the inventor of the software system (Astley, 2016) used in this paper, thereby eliminating any interobserver variability and reducing the likelihood of measurement error. Further, facial measurements were taken blind to the child's exposure history. Because of the detailed information available on all participants, confounding could be addressed by adjusting for a priori selected potential confounders (Howards, 2018), following the same criteria as previous papers based on this cohort (Kesmodel et al., 2012). Also, it has previously been shown that despite selection problems in the DNBC, the external validity of measures of association seems to be good (Nohr and Liew, 2018).

Weaknesses

The DNBC represents only approximately 30% of all Danish pregnant women and hence is not a representative sample (Olsen et al., 2001). Further, the LDPS sample is a stratified sample within the DNBC (Kesmodel et al., 2010), making the current sample even less representative of the background population. While such selection may make the sample less suitable for firm statements about the overall prevalence of specific traits, inferences based on measures of association have been shown to be valid within the cohort (Nohr and Liew, 2018). Finally, since only 10 children presented with the Rank 3 to 4 facial phenotypes, the representativeness of this small group may be limited, but the statistical power was sufficient to identify significant associations with level and timing of prenatal alcohol exposure.

CONCLUSION

In conclusion, we found that approximately 3% (10/308) of the children whose mothers reported low-to-moderate alcohol intake, not usually associated with the full FAS, met the criteria for moderate-to-severe expression of the FAS facial phenotypes, Face Ranks 3 to 4. None met the diagnostic criteria for FAS or PFAS at 5 years of age. However, all 10 remain at risk for PFAS because they were too young at age 5 years to engage in the battery of neuropsychological assessments required to confirm or rule out severe brain dysfunction. The risk of FAS/PFAS facial phenotypes (Ranks 3 to 4) was significantly increased among both women with average alcohol intake of 1 to 4 drinks/wk and women with isolated episodes of binge drinking, particularly during gestational weeks 3 to 4. These findings suggest that low-to-moderate levels of prenatal alcohol exposure or isolated binge exposures may place some fetuses at risk for FAS, PFAS, or other FASDs. Thus, conservative advice is still for women to abstain from alcohol consumption during pregnancy.

ACKNOWLEDGMENTS

Primary support for this study was provided by the Centers for Disease Control and Prevention (CDC), Atlanta, Georgia, USA. The Danish National Research Foundation has established the Danish Epidemiology Science Centre that initiated and created the DNBC. The cohort was furthermore a result of a major grant from this Foundation. Additional support for the DNBC was obtained from the Pharmacy Foundation, the Egmont Foundation, the March of Dimes Birth Defects Foundation, the Augustinus Foundation, and the Health Foundation. The authors would like to thank all the participants for their time and efforts.

CONFLICT OF INTEREST

None.

ETHICS

The LDPS was approved by the DNBC Board of Directors, the DNBC Steering Committee, the Regional Ethics Committee, the Danish Data Protection Agency, and the Institutional Review Board at the Centers for Disease Control and Prevention. Signed informed consent was obtained for the LDPS. The current analyses were approved by the DNBC Steering Committee and the Danish Data Protection Agency.

APPENDIX • DETAILED PROCEDURES FOR TAKING AND SELECTING PHOTOGRAPHS FOR FACIAL CODING:

To examine the association between facial features used to diagnose FAS/PFAS and low-to-moderate prenatal alcohol exposure, digital photographs were obtained, selected, and categorized for FAS/PFAS criteria according to the FASD 4-Digit Code (Astley, 2004). Details of these procedures are described in this appendix.

Taking Digital Photographs

Each participant had a standardized frontal, oblique, and lateral digital facial photograph taken in accordance with the FAS Facial Photographic Analysis Software instructions (Astley, 2016). Briefly, the child had a relaxed facial expression (no smile, lips gently closed, eyes fully open with no eyeglasses), and the digital images had proper rotation, exposure, and focus. A 19.05-mm-diameter round paper sticker was placed between the participant's eyebrows as an internal measure of scale. Photographs were taken according to the protocol outlined in Astley (2016), and lead psychologists received in-person training on how to take the photographs by SA.

Selection of Photographs for Facial Coding

Resources and photograph quality did not permit the complete analysis of all 1,628 participants' photographs. Thus, a stepwise approach was used to identify those children with clear or suggestive indication of facial dysmorphia for further measurement. The goal was to identify all individuals that presented with 1, 2, or all 3 of the FAS facial features as defined above. The photographs were measured by authors AG and SA in a 2-step process, masked to the participant's alcohol exposure.

- Step 1: AG measured the PFLs and lip circularities of all 1,628 participants regardless of the quality of the feature in the photograph (e.g., the eyes were not fully open, the child was smiling, or the sticker curled). If the eyes are not fully open, the child is smiling, or the sticker is slightly curled, the direction of error will always be in 1 direction; the PFLs will be shorter, the lip thinner, and the philtrum smoother than they truly are. SA reviewed the subset from Step 1 that appeared to have short PFLs ≤ -1.5 SDs and/or thin upper lips (lip circularities ≥ 70) and identified the subset that had sufficient image quality to ensure the PFL and lip circularity measures could be accurately measured. SA then remeasured the PFLs and lip circularities of this subset to ensure the highest level of consistency and accuracy across all facial measures.
- Step 2: SA also reviewed the philtrum of all 1,628 participants and ranked only the subset with philtrum images of sufficient image quality and met criteria for Rank 4 or 5.

Final FAS/PFAS Determination

For all viable photographs, whenever a participant was identified as having at least 1 facial feature in the FAS range, the other 2 facial features were also measured if the quality of the image was sufficient. Once measurement of the 3 facial features was complete, the software generated a 4-Digit Code Facial ABC-Score and Face Rank (Fig. 1). For example, if a child presented with PFLs 2.6 SDs below the mean, a Rank 3 philtrum, and a Rank 2 upper lip, they would receive a Facial ABC-Score of CBA and a Face Rank of 2 (mild). If 1 or 2 of the 3 facial features could not be measured, an "X" was placed in the ABC-Score to signify its absence (e.g., the ABC-Score XCA signifies that the PFL could not be measured, but the philtrum was a "C" and the lip was an "A" [see Fig. 1*B*]). A Face Rank could not be generated if 1 or 2 of the 3 features could not be measured, but Facial ABC-Scores with 1 or 2 missing features could be used to accurately rule out 1 or more of Face Ranks 1 to 4. For example, if a Facial ABC-Score was XXA, Face Ranks 3 and 4 can be accurately ruled out despite not knowing the outcome of the PFL or philtrum, because neither can include a feature with a Rank A.

Alcoholism: Clinical and Experimental Research Vol. 43, No. 6 June 2019

Global DNA Methylation and Histone Posttranslational Modifications in Human and Nonhuman Primate Brain in Association with Prenatal Alcohol Exposure

Jessica S. Jarmasz, Hannah Stirton, Duaa Basalah, James R. Davie, Sterling K. Clarren, Susan J. Astley, and Marc R. Del Bigio

Background: Based upon experimental animal studies, the neurodevelopmental abnormalities associated with prenatal alcohol exposure (PNAE)/fetal alcohol spectrum disorder (FASD) have been attributed, at least in part, to epigenetic modifications. However, there are no direct analyses of human brain tissue.

Methods: Immunohistochemical detection of global epigenetic markers was performed on temporal lobe samples of autopsied fetuses and infants with documented PNAE. They were compared to age-, sex-, and postmortem delay-matched control cases (18 pairs; 20 to 70.5 weeks postconception). Temporal lobe tissue from a macaque monkey model of PNAE was also studied (5.7 to 6 months of age). We used antibodies targeting 4 DNA cytosine, 4 histone methylation, and 6 histone acetylation modifications and assigned scores based upon the semiquantitatively graded intensity and proportion of positively labeled nuclei in the ventricular and subventricular zones, ependyma, temporal cortex, temporal white matter, dentate gyrus (DG), and CA1 pyramidal layer.

Results: Temporal changes were identified for almost all marks according to the state of maturation in the human brain. In the DG (and 3 other brain regions), a statistically significant increase in H3K9ac was associated with PNAE. Statistically significant decreases were seen among 5mC, H3K4me3, H3K9ac, H3K27ac, H4K12ac, and H4K16ac in select regions. In the macaques, H3K36me3 decreased in the DG, and the ependyma showed decreases in 5fC and H3K36me3.

Conclusions: In human brain, global intranuclear epigenetic modifications are brain region and maturation state-specific. These exploratory results support the general hypothesis that PNAE is associated with a global decrease in DNA methylation, a global decrease in histone methylation, and a global increase in histone acetylation. Although the human and monkey subjects are not directly comparable in terms of brain maturation, considering the rapid temporal changes in global epigenetic modifications during brain development, interspecies comparisons may be extremely difficult.

Key Words: Acetylation, Methylation, Epigenetics, Human Brain, Prenatal Alcohol.

AN ESTIMATED 10 to 15% of women in North America consume alcohol (ethanol) during pregnancy (Popova et al., 2017). Prenatal alcohol exposure (PNAE) is associated with spontaneous abortion, sudden unexplained death of an infant (SUDI), and fetal alcohol spectrum disorder (FASD). Individuals with FASD demonstrate neurodevelopmental malformations, cognitive deficits, and social and behavioral problems (Carson et al., 2010; Reynolds et al., 2011). The global prevalence of FASD is estimated to be 7.7 per 1,000 people (Lange et al., 2017), and it is considered one of the most common causes of neurodevelopmental abnormalities (Popova et al., 2012).

In individuals diagnosed with FASD, neuroimaging studies (MRI) have demonstrated a wide range of brain

abnormalities including micrencephaly, abnormal gyral patterns, corpus callosum abnormalities, cortical thinning, and reductions in regional brain volume (e.g., basal ganglia, diencephalon, and cerebellum; Donald et al., 2015; Jacobson et al., 2017; Moore et al., 2014; Nardelli et al., 2011; Norman et al., 2009). In our recent descriptive study of 174 human autopsy cases (fetuses, infants, children, teens, and adults) with PNAE or FASD, we identified 31 cases with micrencephaly, 6 cases with simple hydrocephalus, 6 with corpus callosum defects, 5 with neural tube defects, 5 with prenatal ischemic lesions, and 4 cases with heterotopias (Jarmasz et al., 2017).

The pathogenesis of PNAE/FASD-associated brain anomalies is not well understood. Many molecular studies in animals suggest that epigenetic modifications are involved (Chater-Diehl et al., 2017; Lussier et al., 2017). Epigenetics includes a range of acquired and inheritable chemical modifications found within and surrounding (i.e., histones) the genome that influences gene expression without direct changes to the nucleotide sequence of DNA (Feinberg, 2018). Epigenetics plays a substantial role in DNA replication and transcription, genomic imprinting, cellular differentiation, and cell death. Epigenetic processes include chromatin remodeling, RNA interference (micro RNAs), and covalent reversible chemical modifications to DNA (DNA cytosine modifications) or to histones (posttranslational modifications—PTMs; Feinberg, 2018). Recent reviews have summarized the epigenetic effects, mainly DNA methylation and histone posttranslational modifications (PTMs), in the brains of rodents exposed to alcohol in the pre- and postnatal (human third trimester equivalent) periods (Chater-Diehl et al., 2017; Laufer et al., 2017; Lussier et al., 2017). For a summary of PNAE epigenetic studies that studied the brain specifically, see Appendix S1.

Within the central nervous system, differentiation of neural stem/precursor cells into neurons, astrocytes, and oligodendrocytes is epigenetically driven (Coskun et al., 2012; Hirabayashi and Gotoh, 2010; Liu et al., 2016). For example, neural genes are activated through histone acetylation, whereas pluripotent genes and nonneural genes are repressed through histone methylation and DNA methylation (Hirabayashi and Gotoh, 2010).

To the best of our knowledge, PNAE-associated epigenetic changes have not been directly assessed in human brain tissue. In this study, temporal lobe and hippocampus samples from 18 prenatal alcohol-exposed fetuses and infants who had undergone autopsy (Jarmasz et al., 2017) were compared to age-matched controls using immunohistochemical detection of 4 DNA cytosine modifications, 4 histone methylation modifications, and 6 histone acetylation modifications. In parallel, we studied the temporal lobes from macaque monkey infants that had been exposed in utero to alcohol (Clarren et al., 1987, 1990). We hypothesized that PNAE is associated with global epigenetic changes that persist postnatally in the nuclei of brain cells.

MATERIALS AND METHODS

Human Autopsy Cases

Ethics approval was obtained from the University of Manitoba Research Ethics Board (#HS1311 – H2011:213). Details of the full PNAE/FASD autopsy cohort (N = 174) were described previously (Jarmasz et al., 2017). Because our hypothesis concerns epigenetic changes associated with PNAE, and because epigenetic changes can occur during postnatal life (Kundakovic and Champagne, 2015), we restricted our study to fetuses and infants <1 year. Exclusion criteria were as follows: documented in utero alcohol consumption by the mother in the clinical history of the autopsy report (see Jarmasz et al., 2017; for more details), no availability of formalin-fixed paraffin-embedded (FFPE) brain sample(s), extensive autolysis of brain tissue, severe hypoxic damage, cases dated <1988 (inconsistent FFPE), known gene mutations or chromosomal abnormalities, major brain malformations, bacterial meningitis, and a postmortem delay (PMD) > 48 hours. In our recent study, a PMD of >48 to 72 hours in pig and mouse brain tissue had adverse effects on histone acetylation marks (Jarmasz et al., 2019). When these histone acetylation marks were tested in a human brain microarray containing brain samples with PMDs of 96 and 120 hours, stability was >96 hours (Jarmasz et al., 2019). Age- and sex-matched controls were selected from the same autopsy database. Sex matching is important because there are documented differences in brain size, neurological disease prevalence, epigenetics, and stress response (Dekaban, 1978; Kigar and Auger, 2013; Menger et al., 2010; Shen et al., 2015). Inclusion criteria for age- and sex-matched controls were as follows: The case year had to be accrued within 10 years of the PNAE case, suffered little to no brain trauma, had no brain abnormalities, had no clinical history of prenatal alcohol or drug exposure, and had a PMD of ≤48 hours. A recent fetal case not described in the previous publication (Jarmasz et al., 2017) was included because the documented PNAE exposure was high despite not meeting the ≤48-hours PMD inclusion criteria. The PNAE cohort consisted of 9 fetuses or premature births with gestational age < 42 weeks and 9 infants age 43 to 70.5 weeks PC, along with controls. PNAE cohort epidemiologic and pathologic details are described in Table 1. PNAE and control pairings are described in Table 2. FFPE medial temporal lobe blocks stored at the pathology department (Health Sciences Centre, MB) were cut by microtome (5 to 6 μm thick) and mounted onto charged slides for immunohistochemistry.

Nonhuman Primate PNAE Brains

The *Macaca nemestrina* PNAE study was conducted in the 1980s (Bonthius et al., 1996; Clarren et al., 1987, 1988, 1990; Sheller et al., 1988), in compliance with University of Washington Administrative Policy for the humane treatment of animals used in research. Briefly, 48 pregnant adult female pig-tailed macaques received once-weekly nasogastric doses of ethanol ranging from 0.3 to 4.1 g/kg bodyweight; the highest dose is roughly equivalent to 16 standard distilled liquor drinks in a human (i.e., a binge exposure). High doses (2.5, 3.3, and 4.1 g/kg weekly) of alcohol were started at 33 to 46 days of gestation, rather than the time of fertilization, to reduce the risk of spontaneous abortion (Clarren et al., 1987). Controls received isocaloric sucrose. Thirty-three viable infants were born and subsequently assessed for overall health and features of the fetal alcohol syndrome phenotype (Clarren et al., 1988). The monkeys were killed at 5.7 to 7.2 months of age (Clarren et al., 1990), which is the human brain development equivalent of 2.7 to 3.5 years of age (http://translatingtime.org/translate). The cerebral hemispheres were bisected along the midsagittal plane and further dissected to produce multiple brain regions of interest for various studies. The right hemisphere was placed in 10% neutral buffered formalin for neuropathological study. After fixation (duration not documented),

Table 1. Clinical Details of Fetuses and Infants with Prenatal Alcohol Exposure

Case no.	Sex	Age	Cause of death	Brain weight (percentile)[a]	PNAE	Physical anomalies	Cardiac defects	Brain abnormalities
1	F	20 weeks' gestation	Stillborn/intrauterine death	≥10th to <50th	Alcohol abuse	–	–	None
2	F	21.5 weeks' gestation	Stillborn/intrauterine death	<5th	Rubbing alcohol 2nd trimester	None	None	Micrencephaly
3	M	27 weeks' gestation	Stillborn/intrauterine death	≥10th to <50th	Alcohol abuse	Facial anomalies, low-set ears, bilateral neck webbing	None	None
4	F	29 weeks' gestation	Stillborn/intrauterine death	Not indicated	Alcohol abuse	Low-set ears	None	None
5	M	34 weeks' gestation	Stillborn/intrauterine death	≥5th to <10th	Drank until pregnancy was determined	Low-set ears, palmar creases unusual	None	Micrencephaly
6	F	34 weeks' gestation	Intrapartum death with prematurity	<5th	Drank heavily throughout pregnancy	Facial anomalies, bilateral club foot and partial webbing of toes	Absent superior vena cava, large ASD	Micrencephaly, ventricle wall fusion (partial), periventricular heterotopia (rare), retarded laminar development cerebral cortex and hippocampus, hypoplasia pons
7	M	36 weeks' gestation	Stillborn/intrauterine death	≥10th to <50th	Occasional alcohol during the first trimester	None	Right coronary ostium	None
8	F	40 weeks' gestation	Stillborn/intrauterine death with placental abnormalities	<5th	Drank heavily during the third trimester	None	None	Micrencephaly
9	M	41 weeks' gestation	Stillborn/intrauterine death	<5th	History of alcohol abuse	None	None	Micrencephaly
10	M	21 days (43 weeks PC)	Bacterial + viral infection	<5th	Drank throughout pregnancy	None	None	Micrencephaly
11	F	23 days (43.5 weeks PC)	SUDI with unsafe sleeping environment	≥5th to <10th	Drank throughout pregnancy	None	None	Micrencephaly
12	M	6 weeks (46 weeks PC)	SUDI with congenital anomalies	≥10th to <50th	Drank during pregnancy (known alcoholic)	Thin upper lip	ASD with PDA	Recent mild hypoxic neuron change.
13	F	8 weeks (48 weeks PC)	SUDI with congenital anomalies	Not Indicated	Drank heavily during pregnancy	None	Small VSD	None
14	M	2 months (48.5 weeks PC)	SUDI with unsafe sleeping environment	≥10th to <50th	Drank during pregnancy	Low-set ears	Subaortic VSD	None
15	M	3 months (53 weeks PC)	SUDI	≥10th to <50th	Binged during pregnancy	None	None	None
16	F	4 months (57.5 weeks PC)	SUDI	≥10th to <50th	Drank during the first and second trimester	None	None	Periventricular leukomalacia, subacute (small foci in parietal white matter)
17	F	6 months (66 weeks PC)	SUDI	≥50th to <90th	Fetal alcohol syndrome	None	None	Polygyria
18	M	7 months (70.5 weeks PC)	SUDI	>95th	Mother alcoholic	Facial anomalies	None	None

PC, postconception; SUDI, sudden unexpected death of an infant.

[a]Liveborn; died within minutes to hours of birth.

the hemisphere was divided into 5 mm coronal slices and embedded in paraffin (Clarren et al., 1990). Blocks of FFPE tissue, which had been archived at the University of Washington, were transferred to the senior author's (MRD) laboratory. The available samples consisted of 6 to 8 coronal slices of 1 cerebral hemisphere extending from the occipital lobe tip to the frontal lobe at the level of the posterior striatum. In all cases, at least 1 slice included temporal lobe, hippocampus, thalamus, and posterior putamen. Because the paraffin was brittle, tissue blocks of interest were heated at 60°C for 30 minutes and reembedded in new paraffin. We used only the 3 highest PNAE levels (2.5, 3.3, and 4.1 g/kg; $N = 6$) along with controls (sucrose exposure only; $N = 5$; Appendix S2).

Antibodies to Epigenetic Modifications

We selected antibodies that detect epigenetic modifications known to occur in the brain, and/or have been reported to be affected by alcohol exposure in the prenatal, postnatal immature, or adult periods in either human brain cell lines or rodent brains (Chater-Diehl et al., 2017; Laufer et al., 2017; Lussier et al., 2017). These include 5-methylcytosine (5mC), 5-hydroxymethylcytosine (5hmC), 5-formylcytosine (5fC), 5-carboxycytosine (5caC), histone trimethylated at lysine 4 (H3K4me3), H3K9me2/K9me3, H3K27me3, H3K36me3, histone acetylated at lysine 9 (H3K9ac), H3K14ac, H3K27ac, H4K5ac, H4K12ac, and H4K16ac. We also included antibodies targeting total histone H3 and H4, as well as pan-acetyl H3 and H4. Rationale for inclusion of DNA/histone modifications in this study and technical details of the epigenetic antibodies are presented in Appendix S3 and Table 3. Antibody specificity and epitope tolerance to postmortem degradation is described in detail in a recent publication (Jarmasz et al., 2019).

Immunohistochemistry

Human and macaque brain tissue sections (5 to 6 μm thickness) were subjected to immunohistochemistry, which is described in detail in a recent publication (Jarmasz et al., 2019). Optimal primary antibody concentration was determined by running a series of dilutions greater and less than the manufacturers' suggestions (Appendix S4). Briefly, paraffin was melted at ~60°C, and tissue samples were rehydrated through multiple xylenes and graded ethanol solutions (100, 90, and 75%). Slides were subjected to antigen retrieval, as well as endogenous peroxidase blocked before incubation with 10% serum. The primary antibody was applied, followed by application of the secondary antibody, followed by application of peroxidase-conjugated streptavidin (with multiple 4-minute washes in-between each application). DAB (3,3′ diaminobenzidine) chromogen was used to develop the slides. The slides were counterstained with Harris hematoxylin solution, dehydrated through graded ethanol and multiple xylene solutions, coverslipped with Permount, and left to air-dry overnight.

Imaging of Immunohistochemical Results

Human and macaque slides were imaged using a standard upright microscope with digital camera (Olympus BX51TRF microscope, Olympus Scientific Solutions, Waltham, MA; Qimaging 32-0110A-568 MicroPublisher 5.0, Model LH100HG, Teledyne

Table 3. Details and Sources for the Antibodies to Epigenetic Marks

Antibody	Immunogen/target	Isotype	Species	Type	Company details	Lot no.
5mC	Recognizes 5-methylcytidine in vertebrate DNA	IgG	Mouse	Monoclonal (clone 33D3)	Active Motif, #39649	24516019
5hmC	Raised against 5-hydroxymethylcytosine conjugated to KLH	Serum	Rabbit	Polyclonal	Active Motif, #39769	06116002
5fC	Raised against 5-formylcytidine conjugated to KLH	Serum	Rabbit	Polyclonal	Active Motif, #61223	34711001
5caC	Raised against 5-carboxycytosine conjugated to KLH	Serum	Rabbit	Polyclonal	Active Motif, #61225	32115002
H3K4me3	Raised against a peptide including trimethyl-lysine 4 of histone H3.	Serum	Rabbit	Polyclonal	Active Motif, #39159	12613005
H3K9ac	Synthetic peptide corresponding to Human Histone H3 aa 1-100 (N-terminal) (acetyl K9) conjugated to KLH	IgG	Rabbit	Polyclonal	Abcam, #ab10812	GR287797-1
H3K9me2, K9me3	Synthetic peptide within human histone H3 aa1-100 (tri methyl K9); exact sequence is proprietary	IgG1	Mouse	Monoclonal (clone 6F12-H4)	Abcam, #ab71604	GR117765-1
H3K14ac	Synthetic peptide within human histone H3 (acetyl K14); exact sequence is proprietary.	IgG	Rabbit	Monoclonal (clone EP964Y)	Abcam #ab52946	GR302893-8
H3K27ac	Synthetic peptide corresponding to human histone H3 aa 1-100 (acetyl K27) conjugated to KLH	IgG	Rabbit	Polyclonal	Abcam, #ab4729	GR288020-1
H3K27me3	Synthetic peptide within human histone H3 aa 1-100 (tri methyl K27) conjugated to KLH; exact sequence is proprietary	IgG	Mouse	Monoclonal (clone 6002)	Abcam, #ab6002	GR275911-7
H3K36me3	Synthetic peptide within human histone H3 aa 1-100 (tri methyl K36) conjugated to KLH; exact sequence is proprietary	IgG	Rabbit	Polyclonal	Abcam, #ab9050	GR3177961-1
H4K5ac	Synthetic peptide within human histone H4 aa 1-100 (N-terminal) (acetyl K5); exact sequence is proprietary	IgG	Rabbit	Monoclonal (clone EP1000Y)	Abcam, #ab51997	GR295999-7
H4K12ac	Synthetic peptide corresponding to human histone H4 aa 10-15 (acetyl K12)	IgG	Rabbit	Polyclonal	Abcam, #ab61238	GR325039-3
H4K16ac	Synthetic peptide corresponding to human histone H4 (acetyl K16); exact sequence is proprietary	IgG	Rabbit	Monoclonal (EPR1004)	Abcam, #ab109463	GR187780-8
H3panAc	Peptide including acetyl-lysines contained in the N-terminal tail of human histone H3	IgG	Rabbit	Polyclonal	Active Motif, #61637	28915002
Total H3	Peptide containing the N-terminus of histone H3.	IgG2b	Mouse	Monoclonal (clone MABIO3O1)	Active Motif, #39763	34614001 5217020
Total H4	Synthetic peptide containing human histone H4.	IgG2b	Mouse	Monoclonal (clone MABI0400	Active Motif, #61521	7715006

KLH, keyhole limpet hemocyanin.

Qimaging, Surrey BC, Canada). Images were captured at 40×, 200×, or 400× total magnification using QCapture software (v2.8.1, 2001 to 2005, Qimaging Corp., Teledyne Qimaging, Surrey BC, Canada). The dentate gyrus (DG), CA1 neurons of the hippocampal formation (CA1), ependymal cells along the floor of the temporal horn of the lateral ventricle, temporal neocortex (CX) in the parahippocampal gyrus, and temporal white matter (WM) were evaluated. In human fetuses 34 weeks and younger, the germinal region along the roof of the lateral ventricle, including the ventricular zone (VZ) and subventricular zones (SVZ), was also evaluated. Two previously validated (Jarmasz et al., 2019) semiquantitative scales were used to score the estimated proportion of immunoreactive nuclei (graded 0 to 4; corresponding to approximately 0, 25, 50, 75, and 100% positive) and the graded intensity of immunoreactivity in comparison with a standard image set (graded 0 to 3.5 in 0.5 steps; see Additional file 13, in Jarmasz et al., 2019). Morphologic features of nuclei were used as a surrogate for probable brain cell type. Cells with large round nuclei and prominent nucleoli were considered as probable neurons; cells with medium-sized round or irregular nuclei were considered probable astrocytes (in WM) or possible small neurons in cortex; cells with small round nuclei were considered probable oligodendrocytes; cells with small elongated and irregular nuclei were considered probable microglia; cells with small elongated smooth-contoured nuclei near a vascular lumen were considered endothelial; and cells wrapping vascular endothelia were considered to be smooth muscle. First, control cases were examined in order to establish a general developmental pattern of expression for the epigenetic marks. Second, matched pairs of control and PNAE cases were compared in all brain regions. Not all epigenetic marks were evaluated in every single case. For example, focal tissue damage or imperfections in the immunostaining would preclude proper evaluation. The immunoreactivity scores (proportion and intensity grades) for every brain region were recorded in a Microsoft Excel spreadsheet.

Statistical Analyses

The multiplied proportion and intensity scores were graphed as a function of age for each anatomical region and presented as bar graphs using Microsoft Excel (Y-axis = total multiplied rank, X-axis = postconception age in weeks). Third-order polynomial trendlines ($y = (m_3{*}x^3 + m_2{*}x^2 + m_1{*}x) + b$) were superimposed to the graphed values to depict the general pattern of developmental expression for each epigenetic mark. PNAE data curves were added

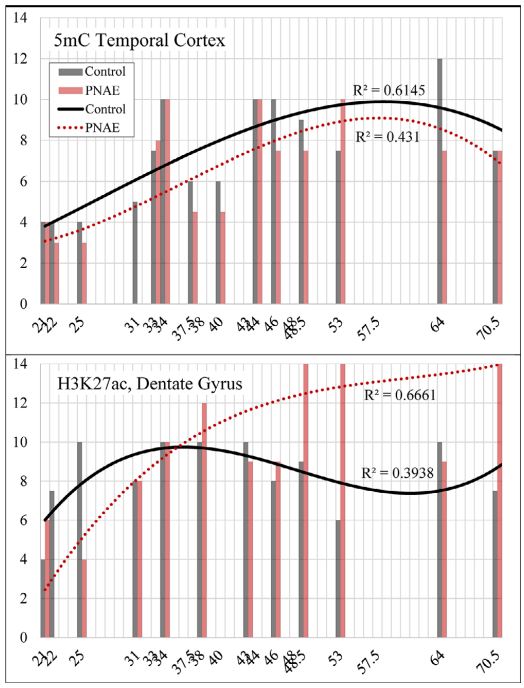

Fig. 1. Examples of human control and PNAE immunostaining scores with third-order polynomial curve fit with R^2 values. The gray bars and black solid curve represent controls, and the red bars and dotted curve represent PNAE cases. The *Y*-axis shows the semiquantitative scores, which is the product of intensity and distribution scores multiplied (maximum score of 14). The *X*-axis is the postconception age in weeks.

to highlight possible differences (Fig. 1). Goodness of fit (R^2) is shown on the graphs; the average R^2 value was 0.5352 ± 0.0246 (mean R^2 ± SEM) for controls and 0.5575 ± 0.0254 for PNAE. However, because the data represent 2 biologically different populations (i.e., stillborn fetuses with uncertain postmortem in utero conditions vs. liveborn infants) a formal polynomial regression fit to compare the curves is likely not valid. Data were subjected to multiple paired *t*-test (2-tailed) comparisons (JMP 14.1 statistical software; SAS Institute, Cary, NC) within 6 age clusters: 21 to 25 weeks PC (n = 3 pairs) and 31 to 34 weeks PC (n = 3 pairs) for the VZ and SVZ; 21 to 25 weeks PC (n = 3 pairs; early fetus), 31 to 40 weeks PC (n = 6 pairs; late fetus), 43 to 48.5 weeks PC (n = 5 pairs; young infant), and 53 to 70.5 weeks PC (n = 4 pairs; infants) for all remaining brain regions. As recommended for exploratory research, all p values are reported without correction for multiple tests (13 antibodies, 5 brain loci), acknowledging that p values marginally <0.05 should be interpreted with caution (Bender and Lange, 2001; Cipriani et al., 2015).

For the macaque brains, images were scored as described above. The Wilcoxon Rank Sums test with chi-square approximation (Kruskal–Wallis) was used to compare control and PNAE groups for each location and each antibody (JMP 14.1 statistical software; SAS Institute). The p values were manually adjusted using the Benjamini–Hochberg formula (Benjamini and Hochberg, 1995): $((i/m)*Q)$ and a false discovery rate (FDR) of 0.1. Those p values that did not remain significant after the Benjamini–Hochberg correction but were still below 0.05 are reported as trends.

RESULTS

General Observations Concerning Immunohistochemical Labeling of Histone Modifications

Most of the antibodies yielded strong and consistent immunolabeling in both human and monkey tissues. We had originally intended to study antibodies targeting total histone H3, total histone H4, pan-acetyl histone H3, pan-acetyl histone H4, H3K9me2, and H3K27me2. For total histone H3 and H4 antibodies, we expected the antibodies to label virtually every nucleus at all stages of maturation. Surprisingly, this was not the case (Appendix S5: Fig. 1). Similarly, we expected that histone H3 and H4 pan-acetyl antibodies would label more cells than any antibody targeting a single acetylated lysine. However, the proportion of cells labeled by anti-pan-acetyl histone H3 and H4 was much less than that labeled by single acetylation marks (Appendix S5: Fig. 1). Consequently, results of these are not reported. The H3K27me2 antibody binding was not blocked by the appropriate peptides. We were unable to get satisfactory cell labeling using the H3K9me2 antibody.

Developmental Expression of Epigenetic Modifications in Control Human Brain

Graphic representations of the human control and PNAE results are shown in Figs 2–6. Polynomial curves were fitted to the data for all location/epitope combinations; they provide a convenient way for visualizing and comparing the data sets.

Ventricular and Subventricular Zones

Developmental expression of epigenetic marks in the VZ varied considerably; 7/13 epigenetic marks (5mC, 5hmC, H3K36me3, H3K9ac, H3K14ac, and H4K5ac) exhibited a "U-" shaped expression curve prior to disappearance of the VZ at 31 to 34 weeks (Figs 2–5, 7; Appendix S5: Fig. 2). Note, however, that the sample sizes are small so we cannot be certain that the transient decline is real. In the SVZ, most marks started at low levels and increased with gestational age (5caC, H3K4me3, H3K36me3, H3K9ac, H4K5ac, and H4K12ac) (Figs 2–5; Appendix S5: Fig. 2). Within the SVZ, an anatomical gradient was evident for 5mC, H3K4me3, H3K36me3, H3K9ac, H3K14ac, H3K27ac, H4K5ac, H4K12ac, and H4K16ac; in the youngest fetuses, only the SVZ adjacent to the VZ was positive, followed by spreading to involve the entire SVZ prior to involution. Within the SVZ, there are different progenitor cell types (Rushing and Ihrie, 2016); however, they could not be easily distinguished due to similarity in size and morphology.

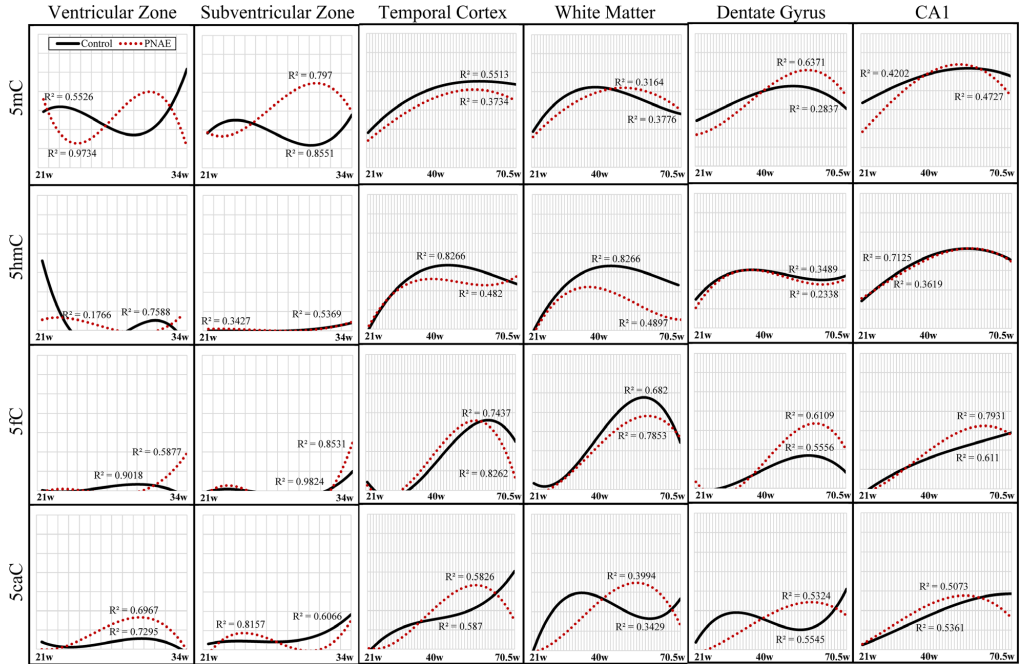

Fig. 2. Graphic representation of semiquantitative score values (maximum 14; *Y*-axis) for DNA cytosine modifications in the human brain regions assessed. The black curve represents the control cases, and the red dotted curve represents PNAE. Curve fit values (R^2) are also shown. The *X*-axis represents the postconception age in weeks. The ventricular (VZ) and subventricular zones (SVZ) are only present in fetal cases up to 34 weeks' gestation. In the VZ and SVZ, 5mC levels were highest, while 5hmC, 5fC, and 5caC levels were low. In the other brain regions, 5mC, 5hmC, and 5caC (white matter only) show a gradual increase, peaking at birth, followed by a plateau or decrease. Although the control and PNAE curves diverged in some circumstances, only 5mC in the CA1 sector of the early fetal PNAE group showed a statistically significant decrease ($p = 0.0198$).

Brain Surface and Temporal Neocortex

Most epigenetic mark antibodies strongly labeled a narrow band of cells along the external surface from the earliest age studied (21 weeks; Fig. 8). This likely represents the marginal zone progenitor layer (Costa et al., 2007). The exceptions were anti-5mC and anti-5hmC, which showed only faint immunoreactivity in this location. In increasing maturity in fetal brains, epigenetic marks expressed in the cortical mantle tended to progress to increasing depths from the surface. Brain cell types were distinguishable through morphology with increasing age. Within the 5th and 6th cortical layers, all but 4 epigenetic marks (5fC, 5caC, H3K14ac, and H4K16ac) demonstrated ~75 to 100% positive staining among large (presumably neuronal) and intermediate-sized nuclei. In WM, small round (presumably oligodendroglial) nuclei demonstrated low positive proportions (≤50%) in the fetuses. In the infant cases, all marks except H3K4me3, H3K27ac, and H4K12ac increased to include ~50 to 100% of the presumptive oligodendrocytes. Epigenetic mark immunoreactivity varied considerably in presumed microglial nuclei. Active transcription marks (H3K4me3, H3K36me3, H3K27ac, H4K5ac, and H4K12ac) were most strongly expressed. Vascular endothelial cells and arterial smooth muscle cells had a seemingly random mix of positive and negative cells for most marks; the exceptions were almost uniform negativity for 5mC, 5hmC, 5fC, 5caC, and H4K16ac (Appendix S5: Fig. 3). Almost every antibody labeled choroid plexus epithelial cell nuclei (Appendix S5: Fig. 3).

White Matter

In presumed oligodendrocytes (small round nuclei), most epigenetic marks were more widespread and more strongly immunoreactive in infants than in fetuses; exceptions were H3K27me3, H3K27ac, and H4K12ac, which decreased in infancy. Among larger irregular (presumed astroglial) nuclei, H4K5ac and H4K12ac were expressed in ~100% of cells at all ages examined. All other epigenetic marks were present in a minority (~0 to 50%) of cells during the fetal stages and increased to a ~50 to 100% in infancy. Among the few very large nuclei of presumed WM neurons, stable immunoreactivity was seen for all epigenetic marks except for 5fC, 5caC, H3K14ac, and H4K16ac, which were negligible in early fetuses (21 to 25 weeks PC) but attained positivity in infancy (53 to 70.5 weeks PC).

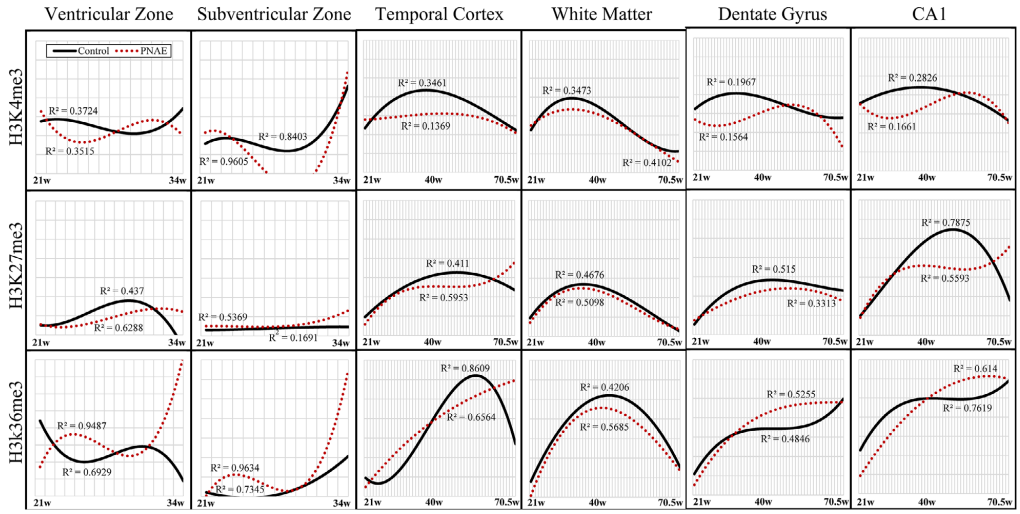

Fig. 3. Graphic representation of semiquantitative score values (maximum 14; *Y*-axis) for histone H3 methylation marks in the human brain regions assessed. The black curve represents the control cases, and the red dotted curve represents PNAE. Curve fit values (R^2) are also shown. In the control VZ, H3K4me3 was relatively stable while the other 2 declined with maturation. In the control SVZ, H3K27me3 was relatively stable while the other 2 increased with maturation. In all other brain regions, most of the marks showed a slight peak near birth. The exception was H3K36me3, which showed a steady increase in the DG and CA1 neurons. None of the histone methylation mark differences were statistically significant between PNAE and controls.

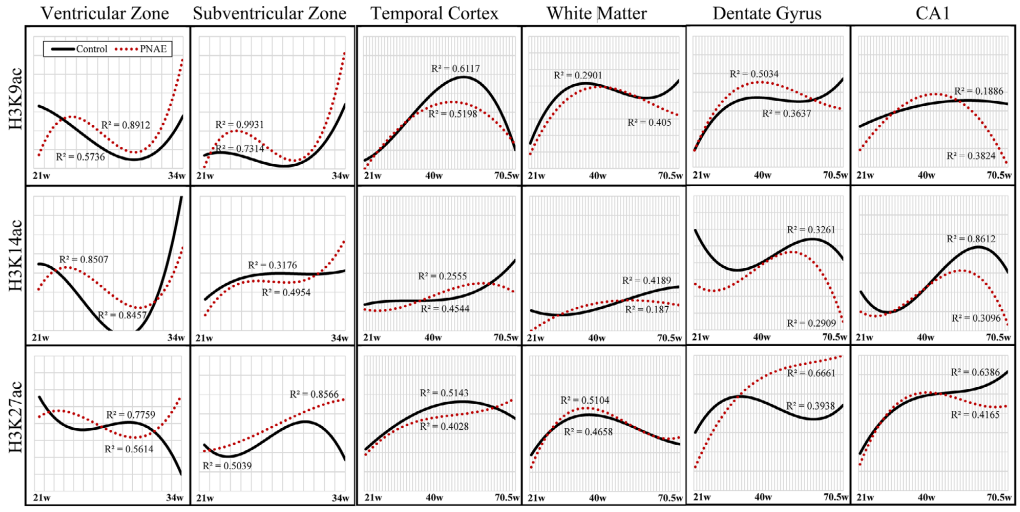

Fig. 4. Graphic representation of semiquantitative score values (maximum 14; *Y*-axis) for histone H3 acetylation marks in the human brain regions assessed. The black curve represents the control cases, and the red dotted curve represents PNAE. Curve fit values (R^2) are also shown. In the VZ and SVZ, H3K9ac and H3K14ac tended to increase with maturation while H3K27ac tended to decline. In the other brain regions, all of the marks tended to increase during the fetal period. Some differences were observed in association with PNAE. In the cortex, H3K9ac ($p = 0.0202$) and H3K27ac ($p = 0.0229$) were lower in young infants with PNAE. In the white matter, H3K9ac was lower ($p = 0.0377$) in the early fetal PNAE group compared with controls. In the dentate gyrus, H3K9ac was higher ($p = 0.0352$) in young PNAE infants. In the CA1, H3K27ac was lower ($p = 0.0414$) in PNAE infants.

Dentate Gyrus Neurons and Pyramidal Neurons of Hippocampal CA1 Region

In human fetuses, granular neurons of the DG were ~50 to 75% positive for all epigenetic marks except for H3K27ac and H4K5ac, which were ~100% positive; the latter 2 are marks of active transcription. Almost all epigenetics marks increased in infancy except for 5hmC, 5fC, H3K4me3, and H4K5ac, which remained consistent. The proportion of CA1

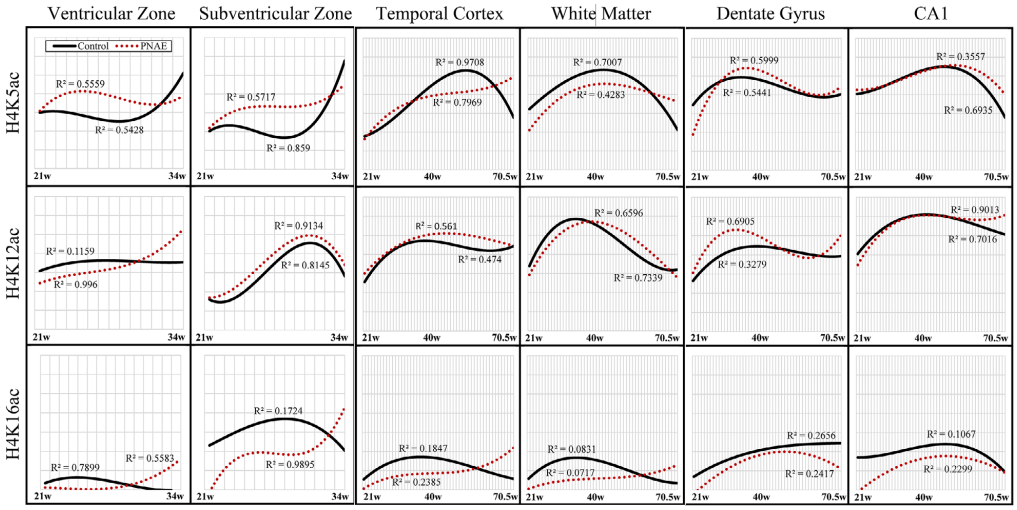

Fig. 5. Graphic representation of semiquantitative score values (maximum 14; *Y*-axis) for histone H4 acetylation marks in the human brain regions assessed. The black curve represents the control cases, and the red dotted curve represents PNAE. Curve fit values (R^2) are also shown. In the VZ and SVZ, H4K5ac tended to increase with maturation. In the other brain regions, most marks tended to increase during the fetal period and decrease during infancy. H4K16ac was significantly lower in the dentate gyrus ($p = 0.0339$) of young infants with PNAE.

pyramidal neurons immunoreactive for 5fC, 5caC, H3K14ac, and H4K16ac was low (~25 to 50%), while all other epigenetic marks were expressed in the majority of cells (~75 to 100%). Immunoreactivity for most epigenetic marks remained consistent from the fetal period to infancy. Exceptions were 5mC, 5fC, H3K4me3, H3K9ac, H3K14ac, and H4K16ac, which all increased (H4K16ac went from ~25% to ~100%).

Temporal Lobe Ependymal Cells

For most epigenetic marks, nuclei of the temporal horn ependymal cells started at ~25 to 50% positive in fetuses and increased to ~75% positive in infants.

Differential Expression of Epigenetic Marks Between Brain Cell Types (see Appendix S6)

In control and PNAE cases, all epigenetic marks except for 5fC, 5caC, H3K9ac, H3K14ac, and H4K16ac were identified in essentially all brain cell types. During the fetal period, almost all epigenetic marks were preferentially expressed in more mature cells that could be identified as neurons. 5hmC and H4K16ac appeared to be relatively specific to large hippocampal and cortical neurons. For 5mC, 5hmC, H3K27me3, H3K36me3, H3K9ac, and H4K16ac, the dentate neurons demonstrated a maturation gradient, where more mature nuclei distant from the germinal layer (i.e., distant from CA4 sector of the hippocampus) were positive, while less mature nuclei near the germinal layer were negative.

Comparison of Epigenetic Marks in Control and PNAE Brains

Statistical comparisons between human control and PNAE pairings are summarized in Table 4. In the young fetuses, the VZ of PNAE cases had less H4K16ac immunoreactivity than controls ($p = 0.0039$). The temporal cortex (a mix of neurons and glial cells) of young infant PNAE cases had less H3K9ac ($p = 0.0202$) and H3K27ac ($p = 0.0229$) immunoreactivity than controls (Fig. 9). For both marks, the difference was reflected in intensity for all cell types, and specifically a loss of immunoreactivity in small round nuclei (presumably oligodendrocytes) for H3K27ac (Fig. 9). H3K9ac showed less immunoreactivity in PNAE WM ($p = 0.0377$; Fig. 10) and among the ependyma cells of the young fetuses ($p = 0.0198$; Fig. 11). Ependymal cells also exhibited decreases in intensity for H3K4me3 ($p = 0.0234$) and a decrease in the number of positive nuclei for H3K27ac ($p = 0.0142$) in the early fetal age group (Fig. 11). In the DG neurons of young infants, an increased intensity was observed for H3K9ac ($p = 0.0352$) (Fig. 10), and a decreased intensity was seen for H4K16ac. In the CA1 neurons of PNAE cases, a smaller proportion were 5mC positive ($p = 0.0198$) and reduced immunoreactivity was seen for H3K27ac ($p = 0.0414$). Overall, H3K9ac exhibited a notable difference in 4 of the 7 brain regions studied and appeared to be the only epigenetic mark affected by PNAE in both the human fetal and infant groups (Figs 9–11).

In the macaque brains, there were few statistically significant differences between the control and PNAE samples (Table 5). In the DG neurons of the PNAE group,

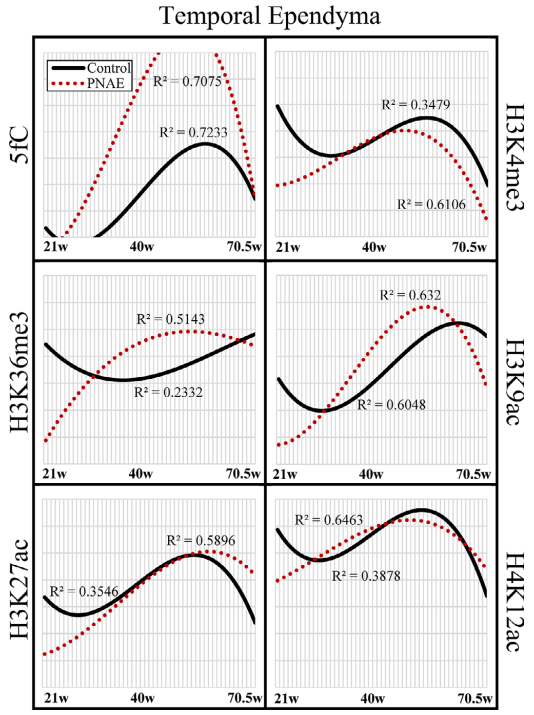

Fig. 6. Graphic representation of semiquantitative score values (maximum 14; *Y*-axis) in the human temporal ependyma. The black curve represents the control cases, and the red dotted curve represents PNAE. Curve fit values (R^2) are also shown. In the early fetal age group, H3K4me3 (p = 0.0234), H3K9ac (p = 0.0198), and H3K27ac (p = 0.0142) were all significantly lower in PNAE compared with controls.

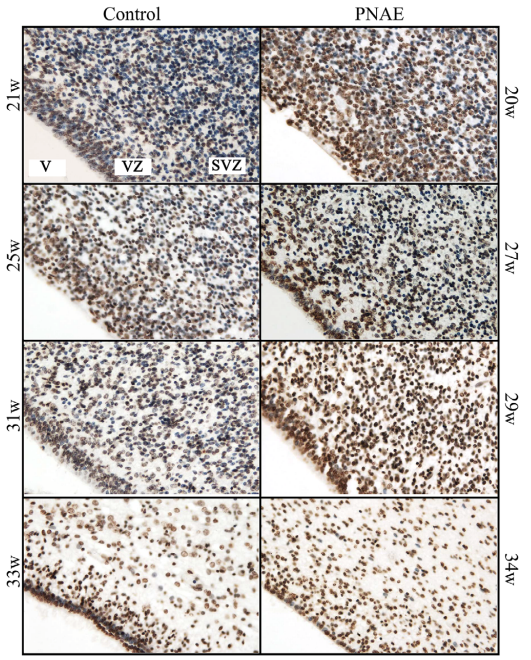

Fig. 7. Photomicrographs showing 5-methylcytosine (5mC) immunoreactivity in human ventricular (VZ) and subventricular zones (SVZ). In controls, most cells of the VZ are strongly positive until it is replaced by the ependymal layer at 31 to 34 weeks. Immunoreactivity in the SVZ increased slightly with fetal maturation. In PNAE cases, 5mC was slightly greater than in controls. Images were taken at 200× magnification. DAB detection of antibody (brown) with hematoxylin counterstain (blue). The postconception age in weeks (w) is indicated for each panel. V = ventricle.

H3K36me3 exhibited less immunoreactivity (p = 0.0054) (Fig. 12). Decreases were observed among the epigenetics marks 5fC (p = 0.0077) and H3K36me3 (p = 0.0058) in the temporal lobe ependyma (Appendix S7).

DISCUSSION

Epigenetic modifications play an important role in brain development, guiding the specification, differentiation, and maturation of neural progenitor cells (NPCs). NPCs in the mouse neural tube gain 5mC during specification, gain 5hmC during differentiation, and then lose 5mC in the later stages of maturation (Zhou, 2012). Similarly, in dentate granule neurons of the developing mouse hippocampus, a methylation gradient correlates with the outside-in pattern of neuronal maturation (Chen et al., 2013). Studies of rat and mouse brains have demonstrated associations between development and histone PTM changes (Cho et al., 2011; Hahn et al., 2013; Podobinska et al., 2017; Resendiz et al., 2014; Zhang et al., 2012). In order for stem cells to change from totipotency to pluripotency, active histone PTMs are present on gene promoters such as H3K27ac and H3K4me3. After NPCs begin to differentiate, many gene promoters are in a bivalent (poised state) with repressive histone PTMs such as H3K27me3 and activating histone PTMs such as H3K4me3 dually expressed, allowing them to rapidly turn on and off. When a brain cell is fully differentiated, repressive histone PTMs such as H3K27me3 are typically dominant (Podobinska et al., 2017). H3K4me2 and histone acetylation levels increase during differentiation of mouse NPCs (Resendiz et al., 2014; Zhang et al., 2012). Compared to NPCs, mature mouse cortical neurons are enriched in histone acetylation marks (Cho et al., 2011). Corresponding to findings in developing rodent brains, regulatory processes are reflected in our developmental expression graphs. For example, in hippocampal CA1 neurons, which can be identified without ambiguity, H3K27me3 (repressive) demonstrates a gradual increase during the fetal period (differentiation), followed by a gradual decrease during infancy. In contrast, H3K27ac (activating) demonstrated a gradual increase during infancy. These findings suggest that human hippocampal neurons have not reached genetic maturity in infancy, which is entirely consistent with observations that neuron size

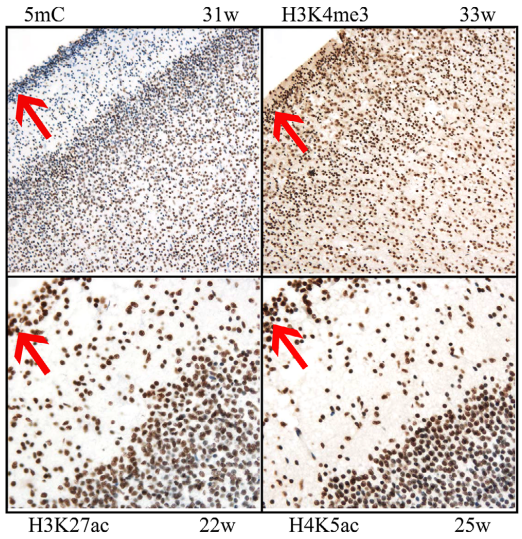

Fig. 8. Photomicrographs showing immunoreactivity for 4 epigenetic marks at the surface of temporal neocortex from normal human fetuses. The narrow band of immature marginal zone cells (red arrows) is positive for H3K4me3, H3K27ac, and H4K5ac, and negative for 5mC. Cells in deeper, more differentiated, layers of the cortex show mixed immunoreactivity. Images were taken at 20× (upper panels) and 200× (lower panels) magnifications. DAB detection of antibody (brown) with hematoxylin counterstain (blue). The gestational age in weeks (w) is indicated in each panel.

increases between 9 months and 16 years (Arnold and Trojanowski, 1996) and that synaptophysin accumulates in the CA1 sector throughout childhood and teenage years (Eastwood et al., 2006). However, because these immunohistochemical methods detect global (i.e., the average of 1,000s of gene loci) changes, we cannot infer specific functional changes with respect to any particular gene.

The VZ and SVZ, which collectively form the germinal matrix, in simplest terms give rise to glutamatergic and GABAergic interneurons, respectively (Adle-Biassette et al., 2018; ten Donkelaar, 2000). The SVZ also gives rise to precursors of astrocytes and oligodendrocytes. The size and proliferative activity within the SVZ peak between 20 and 26 weeks of gestation (Del Bigio, 2011), followed by rapid involution to 30 to 32 weeks and more gradual disappearance thereafter (Arshad et al., 2016). The proliferation peak in the temporal lobe is earlier (M. R. Del Bigio; unpublished findings). Our graphs of epigenetic PTMs suggest global increases in SVZ cell expression of H3K4me3, H3K9ac, and H4K5ac (which are all associated with active gene transcription) around the time of involution prior to 34 weeks gestation when the cells are leaving the proliferative stage. In the VZ of midgestation human fetuses studied here, PNAE was associated with reduced H4K12ac. However, in the SVZ no significant changes were observed. Ethanol has profound effects on the on survival and proliferation of NPCs (Boschen and Klintsova, 2017; Resendiz et al., 2014; Smith et al., 2014; Wilhelm and Guizzetti, 2016). This toxicity could account for the microcephaly in FASD (De La Monte and Kril, 2014; Jarmasz et al., 2017).

Among CA1 neurons of the fetal hippocampus, PNAE was associated with reduced immunoreactivity for 5mC, which is typically a gene transcription silencer. Within temporal cortex and hippocampus of young infants, we observed differential expression of several epigenetic marks in association with PNAE. The affected histone marks all play a role in active gene transcription. In experimental animals, most in utero and postnatal alcohol exposures caused a decrease in DNA methylation, a decrease in histone methylation, and an increase in histone acetylation (Chater-Diehl et al., 2017; Laufer et al., 2017; Lussier et al., 2017). These are in partial alignment with our results.

Because rodent brains are relatively immature at birth, many experiments use early postnatal alcohol administration to model late gestation human in utero exposure. Hippocampal and neocortical tissue from mice and rats that received alcohol during postnatal days 1 to 11 had increases in global DNA methylation, H3K4me3, H3K9me2, H3K27me2, and H3K27me3 (Chater-Diehl et al., 2016; Otero et al., 2012; Subbanna et al., 2013, 2014) and decreases in H3K9me2 and H3K27me2 (Subbanna et al., 2013). These results do not coincide with our findings. Discrepancies may be due to brain-specific interspecies differences or the absence of the maternal influences (i.e., maternal and placental metabolism) in the postnatal rodent experiments (Burd et al., 2007). In 1 recent study, mice were injected with ethanol (2.5 g/kg) on postnatal day 7 and euthanized ~8 h later. Global DNA methylation was decreased in the hippocampus and the cortex of ethanol-treated mice when compared to saline-treated mice (Nagre et al., 2015). This correlates with our findings in early fetuses despite the use of different methods. We must point out, however, that we do not know the interval between PNAE and fetal death.

In the absence of overt morphologic abnormalities, we observed several changes in epigenetic marks among the mature ciliated ependymal cells in both human and macaque PNAE. H3K4me3, H3K9ac, and H3K27ac were significantly reduced in humans, while 5fC and H3K36me3 were significantly reduced in macaques. The ependyma serves several functions including provision of a barrier between cerebrospinal fluid (CSF) and brain extracellular space, facilitating movement of signaling molecules in the CSF, and providing a niche for mature brain subventricular zone (stem) cells (Del Bigio, 2010; Ohata and Alvarez-Buylla, 2016). Little is known about epigenetic regulation in the mature ependymal layer. It is worth noting that, although none of the human cases studied here were hydrocephalic, hydrocephalus due to aqueduct stenosis was one of the more frequent malformations encountered in our PNAE/FASD autopsy study (Jarmasz et al., 2017). Integrity of the ependymal lining along the cerebral aqueduct is necessary for maintaining patency (Sival et al., 2011). We must consider the

Table 4. Statistically significant results for human control and PNAE pairings (n = 18 pairs)

Early fetus = 21 to 25 weeks postconception (PC); late fetus = 31 to 40 weeks PC; early infant = 43 to 48.5 weeks PC; infant = 53 to 70.5 weeks PC.
Up and down arrows represent the direction of change; a dash represents no change.
n/a represents comparisons that had low ranked values and too few comparisons to generate a valid p value.
Two-tailed p values are significant at $p < 0.05$ and are in bold; 1-tailed p values significant at $p < 0.05$ showing a trend are italic and underlined.

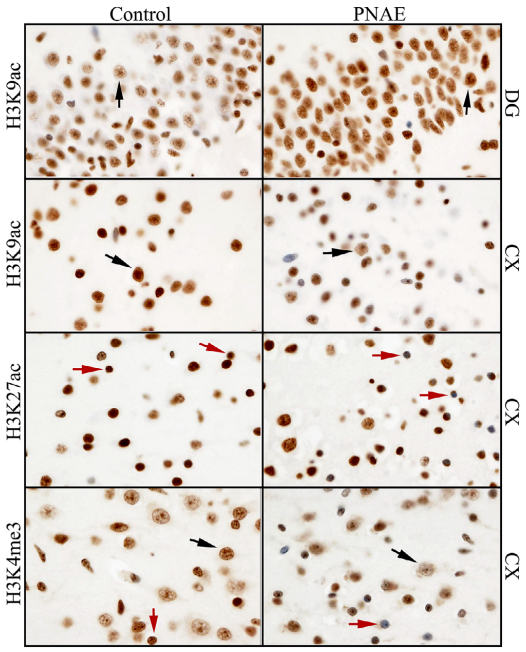

Fig. 9. Photomicrographs showing immunoreactivity for histone acetylation and methylation marks in human control and PNAE dentate gyrus (DG) and temporal neocortex. In the DG of young infants (43 weeks postconception), granular neurons of PNAE cases had greater immunoreactivity for H3K9ac than controls ($p = 0.0352$). In the temporal cortex of young infant PNAE cases, large neurons (black arrows) had less intense immunoreactivity than controls for histone marks H3K9ac ($p = 0.0202$) and H3K27ac ($p = 0.0229$). Reduced immunoreactivity was also apparent in small round nuclei (presumably oligodendrocytes; red arrows). Images were taken at 200× magnification. DAB detection of antibody (brown) with hematoxylin counterstain (blue).

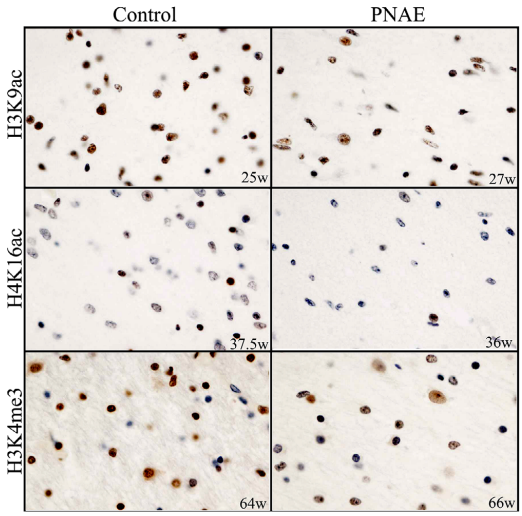

Fig. 10. Photomicrographs showing immunoreactivity for epigenetic marks in human control and PNAE white matter. Compared to controls, H3K9ac was lower in early fetal (21 to 25 weeks) PNAE ($p = 0.0377$). Both H4K16ac and H3K4me3 also tended to be lower ($p = 0.0661$ and $p = 0.0572$, respectively) in the late fetal (31 to 40 weeks) and infant (53 to 70.5 weeks) groups. These global decreases in immunoreactivity did not appear to be cell morphology specific. The postconception age in weeks (w) is indicated for each panel. Images were taken at 200× magnification. DAB detection of antibody (brown) with hematoxylin counterstain (blue).

possibility that PNAE-associated epigenetic changes might adversely affect the function of ependymal cells, which in turn could alter the health of the subjacent NPCs.

Owing to the difficulty obtaining human specimens with documented history of PNAE, there are numerous limitations to our study. (i) Small sample sizes in heterogenous groups are subject to type II errors (i.e., failure to identify real differences). (ii) We calculated numerous nonindependent paired t-tests, which increases the risk for type I error. Hence, these data must be considered exploratory and the reported p values should be viewed with caution. (iii) None of the cases had a comprehensive genetic (i.e., gene mutation) analysis, so we cannot be certain that abnormalities attributed to PNAE are, in fact, related to an unrecognized genetic disorder (Zarrei et al., 2018). We previously described many complex abnormalities and confounding factors in the autopsy cohort of PNAE/FASD cases (Jarmasz et al., 2017). Here, we avoided cases with severe malformations and attempted to restrict the analysis to brains of small size (micrencephaly). (iv) Hypoxic-ischemic stress frequently occurs prior to in utero death of fetuses; oxidative stress due to placental insufficiency could mask epigenetic changes caused by PNAE (Brocardo et al., 2011). In a largely overlapping cohort of human fetal and infant brains with a history of PNAE, we found immunohistochemical evidence for oxidative changes in the DNA and lipids of stillborn fetus brains, but there were no differences between controls and PNAE cases (Appendix S8). (v) We showed in a previous study (Jarmasz et al., 2019) that some histone acetylation marks diminish with increasing PMD. This necessitated the use of PMD time as an additional factor to be controlled, which in turn narrowed options for control cases. (vi) The unavoidably imprecise history of alcohol use (timing and quantity) during the pregnancy (Jarmasz et al., 2017) could explain the lack of consistent changes among epigenetic marks. Precisely timed studies in pregnant mice have shown, for example, that the offspring have different phenotypes when PNAE occurs on gestational day 7 compared with day 8 (Sulik, 2005). Extremely high doses at earlier stages can lead to more severe abnormalities such as neural tube defects (Hunter et al., 1994).

To compensate for the limitations of the human samples, we included a parallel analysis of macaque monkey binge PNAE brain samples. However, even within the controlled experiment, variable phenotypic outcomes were encountered (Clarren et al., 1990; Sheller et al., 1988). There are several possible reasons why our human and macaque results did

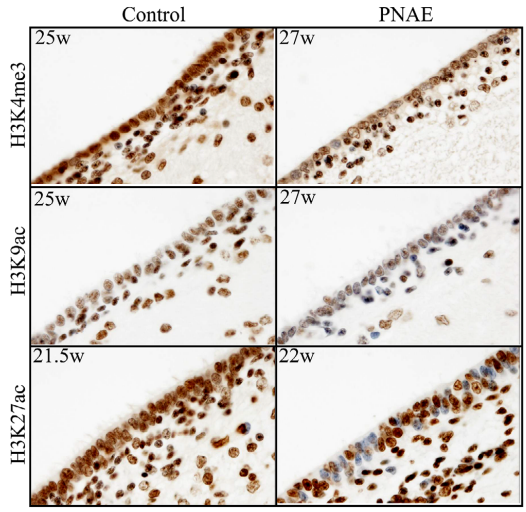

Fig. 11. Photomicrographs showing immunoreactivity for epigenetic marks in ependymal cells lining the temporal horn of human control and PNAE cases. Compared to controls, the intensities of H3K4me3 (p = 0.0234) and H3K9ac (p = 0.0198) were significantly lower in the early fetal age group (21 to 25 weeks). For H3K27ac, the proportion of positive cells was lower (p = 0.0142). The postconception age in weeks (w) is indicated for each panel. Images were taken at 200× magnification. DAB detection of antibody (brown) with hematoxylin counterstain (blue).

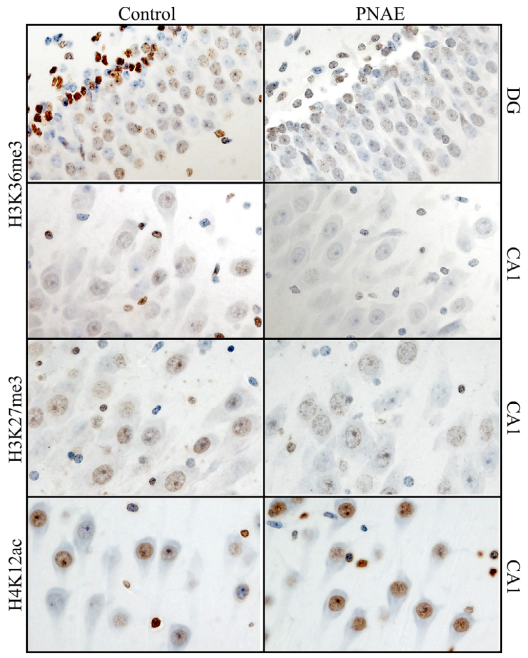

Fig. 12. Photomicrographs showing immunoreactivity for epigenetic marks in ~6-month-old control and PNAE macaque hippocampal neurons. H3K36me3 was significantly lower in the immature cells of the dentate gyrus adjacent to the cornu ammonis CA4 region (p = 0.0054). Among CA1 neurons, the proportions of neurons immunoreactive for H3K9ac (p = 0.0253) and H3K27me3 (p = 0.0146) were reduced in PNAE, while the proportion of H4K12ac-positive cells in PNAE cases was increased (p = 0.0445). Images were taken at 400× magnifications. DAB detection of antibody (brown) with hematoxylin counterstain (blue).

not correspond. The monkey brain sections required slightly different immunohistochemical techniques and often had inconsistent labeling, likely related to prolonged fixation in formalin. The humans died from natural causes, which would often include some degree of hypoxia, and the monkeys died from anesthetic overdoses, which are unlikely to immediately cause changes in epigenetics (Ju et al., 2016; Mori et al., 2014; Pekny et al., 2014). Although the monkeys survived a similar postnatal duration (6 months), in comparative developmental terms, they are approximately equivalent to 2.7- to 3.5-year-old humans (http://translatingtime.org/translate). In addition, a recent study documented transcriptional differences between the brains of humans and rhesus macaques in prenatal, early postnatal, and adult

Table 5. Statistically significant results for macaque control and PNAE pairings

Bolded p values represent statistical significance at $p < 0.05$ after Benjamini–Hochberg correction at a false discovery rate of 0.1. p Values significant at $p < 0.05$ but failed Benjamini–Hochberg correction represent a trend and are italic and underlined.

↓—decreased in PNAE (n = 6) relative to control (n = 5); ↑—increased in PNAE (n = 6) relative to control (n = 5); "–" represents no change in PNAE (n = 6) relative to control (n = 5).

[a]Minimal immunoreactivity.

stages of life. The postconception day 60 macaque specimens were fairly closely aligned with postconception day 102 to 115 human samples, while 2- to 7-year-old macaques aligned with adolescent and adult human samples. This indicates a protracted development of the brain in humans in comparison with rhesus macaques at the level of gene transcription, which is an epigenetically driven process (Zhu et al., 2018).

A major target in FASD research is identification of a DNA methylation pattern sufficiently characteristic to be used as a biomarker for early diagnosis in living children. This usually relies on whole genome methylation analysis of DNA extracted from leukocytes or buccal epithelium cells. In buccal cells from 12 males with FASD (3 to 6 years), 269 differentially methylated cytosine–phosphate–guanines (CpGs) were identified (Laufer et al., 2015). In buccal cells from 110 FASD and 96 control children (5 to 18 years), differentially methylated CpGs were found in 403 genes, many of which are related to neurons and brain diseases (e.g., autism, epilepsy, substance abuse; Portales-Casamar et al., 2016). In a separate validation cohort of 24 FASD and 24 control children (ages 3.5 to 18 years), 82 hypermethylated and 79 hypomethylated genes were detected, some the same as in the previous study (Lussier et al., 2018). The extent to which gene-specific methylation changes in buccal epithelial cells reflects upon global methylation in the nuclei of brain neurons is unknown.

In summary, we showed a variety of global epigenetic changes in brain cell nuclei of human fetuses and infants with a history of PNAE. These partially align with experimental PNAE studies in rodents. However, rapid developmental changes in the expression of specific DNA cytosine modifications and histone PTMs across ages, as well as environmental influences, make it difficult to translate observations in rodents to findings in humans. In general, our exploratory findings support the broad hypothesis that DNA and histone epigenetic changes occur in PNAE. These changes might contribute to the abnormalities in brain development that are associated with FASD. Future work will include detailed cell type analysis (e.g., with double-label immunofluorescence) to confirm specific cell populations affected by PNAE, in particular the heterogenous progenitor cells in the SVZ and the multiple cell types in the cerebral cortex. Eventually, we hope to correlate these global changes with gene-specific modifications in brain and perhaps in accessible nonneural tissues.

ACKNOWLEDGMENTS

We thank Susan Janeczko and Diane Legarta for technical assistance.

FUNDING

This work was funded by a grant from the Canadian Institutes of Health Research (CIHR, grant # TEC—128094) and a grant from Canada Israel International Fetal Alcohol Consortium (CIIFAC). Dr. Del Bigio and Dr. Davie are supported by the Canada Research Chairs program. Ms. Jarmasz was funded by the Graduate Enhancement of Tri-Council Stipends (GETS) through the University of Manitoba, and by a scholarship from the Liquor and Gaming Authority of Manitoba. The original Macaque study was supported by USPHS Grants AA05616, RR00166, and HD02274.

CONFLICT OF INTEREST

The authors declare that they have no conflict of interest.

RESEARCH INVOLVING HUMAN PARTICIPANTS AND/OR ANIMALS

All applicable international, national, and/or institutional guidelines for the care and use of animals were followed. For the human study, ethics approval was obtained from the Research Ethics Board at the University of Manitoba (#HS1311 – H2011:213). The Macaque Project was performed in the Infant Primate Research Laboratory (jointly operated by the University of Washington Regional Primate Research Center and the Child Development and Mental Retardation Center of the University of Washington Center on Human Development & Disability) in compliance with University of Washington Administrative Policy for the humane treatment of animals used in research.

INFORMED CONSENT

The tissues analyzed were selected retrospectively; the Research Ethics Board agreed that the potential for emotional harm to parents contacted about deceased children exceeded the risks of discovery about important unknown pathology.

AUTHORS' CONTRIBUTIONS

JSJ conducted almost all the research, put almost all results together, and wrote the manuscript. HS performed some of the Macaque immunostaining and imaging. DB analyzed oxidative changes in brain tissue and reprocessed the monkey brain tissue. SJA and SKC provided the Macaque brain samples and contributed to the discussion and final review of the manuscript. JRD provided guidance over the selection of markers and contributed to the discussion and final review of the manuscript discussion. MRD planned the project, provided financial support, effectuated the statistical analysis, and finalized the manuscript.

Abstract

Background: Risk of fetal alcohol spectrum disorder (FASD) is not based solely on the timing and level of prenatal alcohol exposure (PAE). The effects of teratogens can be modified by genetic differences in fetal susceptibility and resistance. This is best illustrated in twins.

Objective: To compare the prevalence and magnitude of pairwise discordance in FASD diagnoses across monozygotic twins, dizygotic twins, full-siblings, and half-siblings sharing a common birth mother.

Methods: Data from the Fetal Alcohol Syndrome Diagnostic & Prevention Network clinical database was used. Sibling pairs were matched on age and PAE, raised together, and diagnosed by the same University of Washington interdisciplinary team using the FASD 4-Digit Code. This design sought to assess and isolate the role of genetics on fetal vulnerability/resistance to the

teratogenic effects of PAE by eliminating or minimizing pairwise discordance in PAE and other prenatal/postnatal risk factors.

Results: As genetic relatedness between siblings decreased from 100% to 50% to 50% to 25% across the four groups (9 monozygotic, 39 dizygotic, 27 full-sibling and 9 half-sibling pairs, respectively), the prevalence of pairwise discordance in FASD diagnoses increased from 0% to 44% to 59% to 78%. Despite virtually identical PAE, 4 pairs of dizygotic twins had FASD diagnoses at opposite ends of the fetal alcohol spectrum—Partial Fetal Alcohol Syndrome versus Neurobehavioral Disorder/Alcohol-Exposed.

Conclusion: Despite virtually identical PAE, fetuses can experience vastly different FASD outcomes. Thus, to protect all fetuses, especially the most genetically vulnerable, the only safe amount to drink is none at all.

Keywords

fetal alcohol spectrum disorder; twins; genetics; prenatal alcohol exposure

Introduction

The effects of teratogens can be modified by genetic differences in fetal susceptibility and resistance [1]. Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of the teratogen alcohol during pregnancy. FAS is characterized by growth deficiency, a unique cluster of minor facial anomalies and central nervous system (CNS) structural and/or functional abnormalities. Not all fetuses exposed to and damaged by prenatal alcohol exposure (PAE) have FAS. The physical, cognitive, and behavioral deficits observed among individuals with PAE are not dichotomous, that is either normal or clearly abnormal. Rather, the outcomes all range along separate continua from normal to clearly abnormal [2]. This full range of outcomes caused by PAE is called Fetal Alcohol Spectrum Disorders (FASD). Diagnoses like FAS, Partial FAS (PFAS), Static Encephalopathy/Alcohol Exposed (SE/AE) and Neurobehavioral Disorder/Alcohol Exposed (ND/AE) fall broadly under the umbrella of FASD [2,3].

Fetal risk of damage from PAE is not just dependent on the timing, frequency, and quantity of exposure. Fetal alcohol spectrum disorders (FASD) are caused by a complex interaction of genes and environment, and are regulated by both parental and fetal genes [4]. Fetal genetics influences a fetus' vulnerability to the teratogenic effects of PAE [5]. In a 1993 study of 16 monozygotic and dizygotic twin pairs, Streissguth and Dehaene [6] reported 100% pairwise concordance in FASD diagnoses among monozygotic twin pairs, while dizygotic twins were only 64% concordant. The outcomes of that study strongly suggested that genetic loci regulate susceptibility to, or resistance against FASD. This 1993 study was conducted prior to the creation of rigorous FASD diagnostic systems. Patients were diagnosed as FAS or Fetal Alcohol Effects. If two fetuses exposed to identical levels of alcohol can experience vastly different FASD outcomes, this would have important implications for public health messaging and the setting of exposure thresholds in FASD diagnostic guidelines.

The purpose of this study was to compare the prevalence and magnitude of pairwise discordance in FASD diagnoses across four groups of sibling pairs: monozygotic twins, dizygotic twins, full-siblings, and half-siblings sharing a common birth mother. All sibling pairs had virtually identical or reportedly similar levels of PAE, were raised together, were diagnosed by the same interdisciplinary team using the 4-Digit Diagnostic Code and were identical or similar in age at the time of diagnosis. This sibling-pair design sought to more fully assess and isolate the role of genetics on fetal vulnerability to the teratogenic effects of PAE by eliminating or minimizing pairwise discordance in age, PAE and other prenatal and postnatal risk factors.

Specific Aims:

1. To determine if the prevalence of FASD diagnostic discordance was higher among dizygotic twin pairs than among monozygotic twin pairs.
2. To determine if the prevalence of FASD diagnostic discordance increases as the proportion of genome shared between sibling-pairs decreases across the four study groups: monozygotic twins, dizygotic twins, full-siblings, and half-siblings sharing a common birth mother.
3. To document the greatest magnitude of FASD diagnostic discordance observed between twin pairs with virtually identical PAE. Can twins with virtually identical PAE present at opposite ends of the fetal alcohol spectrum?
4. To estimate the proportion of phenotypic variance in FASD diagnoses due to genetic factors (heritability).

Methods

A retrospective study was conducted using data collected from twin and sibling pairs that received a FASD diagnostic evaluation at the University of Washington Fetal Alcohol Syndrome Diagnostic & Prevention Network (FASDPN).

FASD Diagnostic Method:

FASD diagnoses were rendered using the FASD 4-Digit Diagnostic Code. It is described in full by Astley [2, 7, 8]. Briefly, the 4 digits of the FASD 4-Digit Code reflect the magnitude of expression of the 4 key diagnostic features of FASD, in the following order: 1) growth deficiency, 2) FAS facial phenotype, 3) CNS structural/functional abnormalities, and 4) PAE (Figure 1). The magnitude of expression of each feature is ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong “classic” presence of the FASD feature. Each Likert rank is specifically case defined. There are a total of 102 4-Digit Codes that fall broadly under the umbrella of FASD. These codes cluster under four clinically meaningful FASD diagnoses: fetal alcohol syndrome (FAS) (4-Digit Code Diagnostic Categories A, B): Partial FAS (PFAS) (Diagnostic Category C); Static Encephalopathy/Alcohol-Exposed (SE/AE) (Diagnostic Categories E, F); and Neurobehavioral Disorder/Alcohol-Exposed (ND/AE) (Diagnostic Categories G, H) (Figure 1). Individuals that did not meet criteria for one of these FASD diagnostic classifications were identified in this study as Not FASD/Alcohol-Exposed (Diagnostic Categories I, J).

Study Groups:

The sibling pairs were partitioned into four study groups: 1. monozygotic twins, 2. dizygotic twins, 3. full-siblings, and 4. half-siblings sharing a common birth mother. Monozygotic twin pairs share virtually 100% of their genome. Dizygotic and full-sibling pairs share, on average, 50% of their genome. Half-sibling pairs with a common birth mother share, on average, 25% of their genome [9].

Data from all twin and sibling pairs that met the following inclusion criteria were used in this study:

- Sibling pairs were monozygotic twins, dizygotic twins, full-siblings, or half-siblings sharing the same birth mother.
- Both siblings received an FASD diagnostic evaluation at an FASDPN clinic by the same interdisciplinary team using the 2004 FASD 4-Digit Diagnostic Code.
- Siblings did not present with another genetic syndrome.
- Age at diagnosis could range from newborn to adult. Effort was made to select pairs that both fit into one of three age ranges at the time of diagnosis (0–3 years, 4–8 years, 9 or more years). This minimized the chance that FASD diagnostic contrasts between pairs may be due to one sibling being too young to fully assess or comparably assess brain function.
- All siblings had confirmed PAE. Twin pairs, by definition, had virtually identical PAE. Full sibling pairs and half-sibling pairs had to have concordant Alcohol Ranks (e.g., both siblings had to have Rank 3 alcohol exposure or both had to have Rank 4 alcohol exposure).
- Effort was made to select siblings raised together who experienced identical or similar other prenatal and postnatal risk factors.
- Siblings could be of any gender or race.

Data Set:

All data collected during an FASD diagnostic evaluation at the FASDPN are entered into the FASDPN database with patient consent and University of Washington Human Subjects Division approval. Approximately 3,000 patients have been evaluated in the clinic to date. The data document patient demographics, PAE, all other reported prenatal and postnatal adverse exposures and events and measures of growth, facial features, and structural and/or functional brain abnormalities used to derive the FASD 4-Digit Code. These data are recorded on three standardized diagnostic forms: the New Patient Information Form, FASD Diagnostic Form, and FAS Facial Photographic Analysis Report posted on the FASDPN website www.FASDPN.org [2, 8].

Key data used in this study included the patient's FASD 4-Digit Code, FASD diagnostic category (FAS, PFAS, SE/AE, ND/AE and Not FASD/AE), and their Growth, Face, CNS and Alcohol Ranks (Figure 1). The CNS Rank in the 4-Digit Code serves two purposes: 1) Ranks 1 through 4 document the probability of underlying CNS structural abnormality

(Rank 1: unlikely; Rank 2: possible; Rank 3: probable; and Rank 4: definite). 2) Ranks 1 through 3 also document the magnitude of CNS dysfunction as measured using standardized neuropsychological tools (Rank 1: no dysfunction; Rank 2: moderate dysfunction; and Rank 3 severe dysfunction). The CNS functional Ranks 1–3 introduced by the 4-Digit Code were case-defined to predict increasing likelihood of structural CNS abnormality—a predictive correlation that was subsequently confirmed through magnetic resonance imaging [7]. To distinguish these two CNS measures in the current study, they are labeled CNS1–4 and CNS1–3. PAE is ranked by the 4-Digit Code on a 4-point Likert scale (Figure 1A). Only subjects with Rank 3 or Rank 4 PAE were enrolled in this study. An Alcohol Rank 4 is assigned when PAE is confirmed and reported to be high risk (generally high peak blood alcohol concentrations delivered at least weekly in early pregnancy). An Alcohol Rank 3 is assigned when PAE is confirmed, but the amount reported is low to moderate risk (designated as PAE Rank 3b in this study) or the details on the amount and timing are unknown (designated as PAE Rank 3a in this study). The information used to generate the Alcohol Rank is presented on page 8 of the 4-Digit Code FASD Diagnostic Form [2]. In preparation for a FASD diagnostic evaluation, efforts are made to document the quantity, frequency and timing of maternal alcohol use before and during the index pregnancy. Although 99.5% of patients evaluated at the FASDPN clinic have confirmed PAE, only 30 to 40% have quantity, frequency and/or timing of exposure detailed in their records [10]. Recall error and reporting bias likely impact the accuracy of this more detailed information, therefore the more global measure of PAE “Alcohol Rank” was used as the primary measure of PAE risk in this study. In addition to the risk posed by PAE, measures of other prenatal and postnatal risks were also used in this study. Other prenatal risk factors documented in the FASDPN clinical database include poor prenatal care, pregnancy complications, presence of other syndromes/genetic abnormalities, and prenatal exposure to other substances (e.g., medications, tobacco, illicit drugs, and/or other teratogens). The 4-Digit Code ranks the magnitude of these other prenatal risks in a single composite measure labeled “Other Prenatal Risks Rank”. Rank 1 equals no risk; Rank 2 equals unknown risk; Rank 3 equals some risk; and Rank 4 equals high risk. Rank 4 is assigned when there is exposure to another teratogen (e.g., Dilantin) or when another syndrome or genetic condition is present (e.g., down syndrome, Fragile X, etc.). Rank 3 is assigned to all other prenatal risks. Postnatal risk factors documented in the FASDPN database include perinatal complications, number of home placements, physical and/or sexual abuse, neglect, and trauma. The 4-Digit Code ranks the magnitude of these other postnatal risks in a single composite measure labeled “Other Postnatal Risks Rank”. Rank 1 equals no risk; Rank 2 equals unknown risk; Rank 3 equals some risk; and Rank 4 equals high risk. Rank 4 is used to note severe postnatal circumstances that have been shown to have a significant adverse effect on development in most instances. Examples include physical/sexual abuse, multiple home placements, trauma, and severe neglect) [2]. Rank 3 is used to note conditions akin to those in Rank 4, but the circumstances are less severe.

Statistical Analyses:

The primary focus of the study was to compare the prevalence of discordant FASD diagnoses between sibling pairs across the 4 study groups. Descriptive statistics (means, SD, and proportions expressed as valid percentages (e.g., subjects with missing data are not

included in the denominator)) were used to profile the demographic and clinical outcomes of the 4 study groups. The chi-square test with tests for linear trend was used to compare proportions between the study groups. One-way ANOVA was used to compare outcomes measured on a continuous scale between the study groups. Two-tailed p-values < 0.05 were interpreted as statistically significant.

Heritability is formally defined as the proportion of phenotypic variation that is caused by genotypic variation in a population. FASD is not a genetic disorder, but fetal genetics appears to modify the teratogenic effects of PAE [5, 6]. Heritability has historically been estimated from studies of twins. Monozygotic twin pairs share essentially 100% of their genome. Dizygotic twin pairs share, on average, 50% of their genome. If a trait appears to be more similar in monozygotic twins than in dizygotic twins (when the twin pairs were raised together in the same environment), genetic factors likely play an important role in determining (or modifying) that trait. By comparing a trait in monozygotic twins versus dizygotic twins, one can calculate an estimate of its heritability. Heritability estimates range from 0% to 100%. A heritability close to 0% indicates that almost all of the variability in a trait is due to environmental factors (e.g., PAE and other prenatal and postnatal risk factors), with very little influence from genetic differences. A heritability estimate close to 100% indicates that almost all of the variability in a trait comes from genetic differences, with very little contribution from variability in environmental factors. When a phenotype is determined by a combination of genetic and environmental factors, heritability will be somewhere between 0% and 100%. Comparing discordance for monozygotic versus dizygotic twins allows an indirect estimate of the importance of genetic factors in producing the phenotype. Heritability estimates based on twin discordance studies can be simplistically viewed as: percent heritability = ((dizygotic discordance minus monozygotic discordance)/dizygotic discordance)*100 [9, 11]. It is important to understand that heritability does not indicate what proportion of a trait is determined by genes and what proportion is determined by environment. A heritability of 80% does not mean that a trait is 80% caused by genetic factors; it means that 80% of the variability in the trait in a population is due to genetic differences. Heritability measures the fraction of variation between individuals in a population that is due to their genotypes.

Results

Demographic and Clinical Profiles of the Four Study Groups

The study selection criteria generated 84 sibling pairs broken into four study groups (monozygotic twins, dizygotic twins, full siblings and half sibling sharing the same birth mother) with key factors that defined and differentiated the groups (Table 1).

The demographic and FASD diagnostic profiles of the study sample (Table 2) were highly representative of the entire FASDPN clinic population (n = 3,000) from which it was selected [10]. The gender and age distributions were comparable between the 4 study groups. Race was 100% concordant across all 84 twin/sibling pairs. The number of full and half sibling pairs included in the study may appear smaller than one would expect from a patient population of 3,000. A number of factors inherent in the FASDPN clinical dataset limited the number of full and half sibling pairs available for inclusion in the study. In

general, 85% of the patients evaluated by the FASDPN are in foster/adoptive care—no longer living with their birth parents. Confirmation of full or half sibling status requires knowledge of both birth parents' names. This is typically available on only half of the FASDPN patient population. Of the 54% (n = 1,617) with birth parent names available, 8% (n = 129) were siblings (full or half). Seventy-two of the 129 full and half siblings met the inclusion criteria for the study. The primary reason siblings failed to meet the study's inclusion criteria were they were too different in age (e.g., infant vs adolescent) at the time of their FASD evaluation to draw valid conclusions regarding the concordance/discordance of their diagnoses.

The matching criteria used to select twin and sibling pairs effectively minimized pairwise discordance in PAE and other prenatal and postnatal risk factors (Table 3). By definition, PAE was 100% concordant (virtually identical) between the monozygotic and dizygotic twin pairs. The Other Prenatal Risk Rank was 100% concordant between the monozygotic, dizygotic and full-sibling pairs, and 87.5% concordant between the half-sibling pairs. The Postnatal Risk Rank was highly concordant across all 4 groups (monozygotic: 100%; dizygotic: 87.2%; full-sibling: 91.3% and half-sibling: 75.0%), but did decrease linearly as the proportion of genome shared between siblings decreased.

Specific Aims 1 and 2: Pairwise concordance/discordance of FASD diagnostic outcomes

FASD diagnoses (FAS, PFAS, SE/AE, ND/AE, Not FASD/AE) were 100% concordant between monozygotic twin pairs, but only 56.4% concordant among dizygotic twin pairs (Table 4). This closely mirrored the proportion of the genome shared between twin pairs (monozygotic 100%; dizygotic 56%).

The prevalence of pairwise concordance in FASD diagnoses decreased significantly and linearly as the proportion of genome shared between siblings decreased across the 4 study groups (100% among 9 monozygotic twin pairs sharing 100% of their genome; 56.4% among 39 dizygotic twin pairs sharing 50% of their genome; 41.7% among 27 pairs of full-siblings sharing 50% of their genome; and 22.2% among 9 pairs of half-siblings sharing 25% of their genome) (Chi^2 linear trend = 1.7, p = 0.001) (Table 4, Figure 2).

When looking at the sub components that define FASD (growth deficiency, FAS facial phenotype, and CNS structural and/or functional abnormalities), the prevalence of pairwise discordance in the 4-Digit Rank for each of these components increased across the 4 groups as the proportion of genome shared between siblings decreased (Table 4, Figure 2). It is interesting to note that the prevalence of pairwise discordance in the Face Rank was the only component that increased significantly and linearly as the proportion of genome shared between siblings across the four groups decreased. The Rank 4 FAS facial phenotype, as defined by the 4-Digit Code, is the only component of FASD that is confirmed to be specific to (caused only by) PAE [7]. Other prenatal and postnatal risks can impact growth and brain development, but only PAE can cause the FAS facial phenotype. Thus, even though the prevalence of pairwise discordance in the Postnatal Risk Rank increased significantly across the 4 groups (monozygotic: 0%, dizygotic: 12.8%, full-sibling: 16.7%, and half-sibling: 25.0%) (Table 3, Figure 2), discordance in postnatal risk factors cannot influence the pairwise discordance observed in Face Ranks. It is also interesting to note that the

proportion of twin and sibling pairs within each study group that have the same (concordant) Face Ranks closely matches the proportion of the genome shared between the twin and sibling pairs within each study group (Figure 2).

There was no evidence in this study population that gender influenced the severity or pairwise discordance of FASD diagnostic outcomes. The severity of the FASD diagnosis was comparable between males and females across the entire study sample (n = 168) (Chi^2 = 5.4, p = 0.14).

Among the 19 dizygotic twins with discordant genders:

- The female had a more severe FASD outcome than the male in 31.6% of the pairs (6/19)
- The male had a more severe FASD outcome than the female in 26.3% of the pairs (5/19)
- The male and female had the same FASD outcome in 42.1% of the pairs (8/19)

Specific Aim 3: Magnitude of FASD diagnostic discordance between twin pairs

FASD Diagnostic Discordance: Since there was 100% diagnostic concordance between monozygotic twin pairs, this analysis focused on the 39 dizygotic twin pairs. Despite virtually identical PAE, 4 of the 39 dizygotic twin pairs had FASD diagnostic contrasts as large as PFAS vs ND/AE (Table 4). The sibling in each sibling pair with PFAS experienced severe CNS functional and/or structural abnormalities (i.e., the 3rd digit in their 4-Digit Code was Rank 3 or 4) while their co-twin experienced low to moderate CNS dysfunction (i.e., the 3rd digit in their 4-Digit Code was Rank 2). Two of these large contrasts occurred among same-sex dizygotic twins, (4334 vs 4324, 1434 vs 1224) and two occurred among mixed-gender dizygotic twins (4344 vs 2324, 1343 vs 1123). The four twin pairs had virtually identical PAE, were raised together, and had reportedly comparable prenatal and postnatal experiences (e.g., prenatal tobacco exposure, prenatal exposure to illicit drugs, multiple home placements, neglect, and/or physical/sexual abuse). In other words, their contrasts in FASD outcomes would appear to better-explained by their discordant genetic vulnerability to PAE, than their discordant environmental influences.

Four full-sibling pairs and one half-sibling pair also experienced large contrasts in FASD diagnoses (FAS vs ND/AE: 4-Digit Codes: 3443 vs 1223 and 3343 vs 1123) and PFAS vs ND/AE: 4-Digit Codes: 2434 vs 2324; 1443 vs 1323 and 2324 vs 4344) (Table 4). And like the dizygotic twins described above, these five sibling pairs had the same Prenatal Alcohol Ranks, were raised together, and had reportedly comparable prenatal and postnatal experiences (e.g., prenatal tobacco exposure, prenatal exposure to illicit drugs, multiple home placements, neglect, and/or physical/sexual abuse). Once again, their contrasts in FASD outcomes would appear to better-explained by their discordant genetic vulnerability to PAE, than their discordant environmental influences.

FAS Facial Phenotype Discordance: The 4-Digit Code ranks the magnitude of expression of the FAS facial phenotype on a 4-point Likert scale (Rank 1: absent; Rank 2:

mild; Rank 3: moderate; Rank 4: severe) (Figure 1A). As the proportion of genome shared between siblings decreased from 100% to 50% to 50% to 25% across the four groups (9 monozygotic, 39 dizygotic, 27 full-sibling and 9 half-sibling pairs, respectively), the prevalence of pairwise discordance in the FAS Facial Rank increased from 0.0% to 25.6% to 29.6% to 55.6% (Table 4). The prevalence of concordance in Facial Rank across the four groups closely followed the proportion of genome shared between siblings across the four groups (Figure 2).

Since the Rank 4 FAS facial phenotype, as defined by the 4-Digit Code, is the only FASD physical feature confirmed to be highly specific to (caused only by) PAE [7] it is interesting to document the prevalence of pairwise discordance (if any) involving the Rank 4 FAS facial phenotype (Table 4).

Two of the nine monozygotic twin pairs presented with the Rank 4 FAS facial phenotype. Both twins in each pair presented with concordant Rank 4 faces. Three of the 39 dizygotic twin pairs presented with the Rank 4 FAS facial phenotype; two pairs presented with concordant Rank 4 facial phenotypes and one pair presented with discordant Face Ranks (Rank 4 vs Rank 2). One twin in the discordant dizygotic twin pair presented with PFAS and a Rank 4 FAS facial phenotype. All three facial features of FAS were present—short PFLs, smooth philtrum and thin upper lip (mean PFL z-score −3.5, philtrum smoothness Rank 5, upper lip thinness Rank 4). In contrast, the co-twin presented with ND/AE and a Rank 2 Facial Phenotype. Only one of the three FAS facial features was present—a thin upper lip (mean PFL z-score −1.8, philtrum smoothness Rank 3, upper lip thinness Rank 4).

The Rank 4 facial phenotype was also observed among full-siblings and half-siblings (Table 4). Three of the 27 full-sibling pairs presented with the Rank 4 facial phenotype—all three pairs were discordant (Face Ranks 2 vs 4 and Face Ranks 3 vs 4). The Rank 4 facial phenotype was also observed in two of the 9 half-sibling pairs—both pairs had discordant Face Ranks (Face Ranks 2 vs 4). Even though the Alcohol Ranks were concordant for each of these five full-sibling and half-sibling pairs, this does not ensure that the day-to-day level of PAE was identical between each sibling pair.

Specific Aim 4: Heritability

Comparing pairwise discordance in FASD outcomes for monozygotic versus dizygotic twins allows an indirect estimate of the importance of genetic factors in modifying the teratogenic effects of PAE in this study sample. Percent heritability (((dizygotic discordance minus monozygotic discordance)/dizygotic discordance)*100) for different FASD outcomes in the current study were as follows:

- **FASD diagnosis** (FAS, PFAS, SE/AE, ND/AE, Not FASD/AE)

  ((0.436 – 0.00) / 0.436)*100 = **100%**
- **FAS Facial Rank**:

  ((0.256 – 0.0) / 0.256)*100 = **100%**
- **Growth Rank**

((0.436 – 0.111)/0.436)*100 = **74.5%**

- **CNS 1–4 Rank**

  ((0.436 – 0.111)/0.436)*100 = **74.5%**

Monozygotic twin pairs in this study had virtually identical genomes and virtually identical PAE. Under those genetic-environmental conditions, their FASD diagnoses and FAS facial phenotype Ranks were identical (0% discordant). In contrast, the dizygotic twin pairs in this study had virtually identical PAE, but shared only 50% of their genomes. Under those genetic-environmental conditions, 43.6% of the twin pairs had discordant FASD diagnoses and 25.6% had discordant FAS Facial phenotype Ranks. Based on these discordance rates for the monozygotic and dizygotic twin pairs, heritability estimates for the FASD diagnosis and the FAS Facial Rank were both 100%. In other words, essentially all of the discordance observed between twin pairs for these two outcomes appears to be due to differences in their genotypes, not differences in their environmental risk factors.

Heritability estimates for the Growth Rank and the CNS 1–4 Rank were both 74.5%, signifying that the Growth and CNS Ranks were determined by a combination of genetic and environmental factors. Although the prenatal environmental factor PAE was virtually identical between the twin pairs, PAE was not the only environmental risk factor in this study that could adversely impact growth and CNS development. Other prenatal risk factors like prenatal exposure to tobacco and other illicit drugs can impact growth and CNS development, but they, like PAE were virtually identical between the twin pairs. Thus, it is unlikely that these other prenatal risk factors explain the discordance in growth and CNS development observed between the twin pairs. On the other hand, postnatal environmental risk factors like neglect, abuse, and multiple home placements can adversely impact a child's growth and CNS development and did vary slightly between the dizygotic twin pairs—5 of the 39 dizygotic pairs had discordant Postnatal Risk Ranks (Table 3). But a much higher number of dizygotic pairs had discordant Growth Ranks (n = 17) and discordant CNS 1–4 Ranks (N = 17) (Table 4). More specifically, not all 5 dizygotic pairs with discordant Postnatal Risk Ranks had discordant Growth or CNS 1–4 Ranks. Only 2 of the 5 pairs had discordant Growth Ranks and only 3 of the 5 pairs had discordant CNS 1–4 Ranks. Stated another way, only 2 (12%) of the 17 dizygotic pairs with discordant Growth Ranks had discordant Postnatal Ranks, and only 3 (18%) of the 17 dizygotic pairs with discordant CNS1–4 Ranks had discordant Postnatal Ranks. Thus, as the heritability estimates suggest, variations in the Growth and CNS 1–4 Ranks appeared to be influenced by both genetic and environmental factors. Overall, the heritability estimates generated for the growth (74.5%), FAS face (100%) and CNS (74.5%) components of FASD are reflective of the fact that growth and CNS development are susceptible to a multitude of prenatal and postnatal environmental risk factors, whereas the FAS facial phenotype is highly specific to early prenatal exposure to alcohol.

If fetal genotype is modifying the teratogenic impact of PAE, the prevalence of pairwise concordance across FASD outcomes would more closely reflect the percent of genome shared between sibling pairs than the pairwise concordance of PAE and other prenatal and postnatal risk factors. This is illustrated graphically In Figure 2 (and Table 4). Monozygotic

twins, dizygotic twins, full siblings and half siblings share on average 100%, 50%, 50% and 25% of their genome respectively as depicted by the first set of bars. The pattern of pairwise concordance reflected in the bars for each FASD outcome more closely resemble the pattern of bars for Genome Shared than the patterns of bars reflecting pairwise concordance in Alcohol Rank, other Prenatal Risks, or Postnatal Risks. Since the FAS facial phenotype, as defined by the 4-Digit Code, is so highly specific to (caused only by) PAE, the most compelling evidence supporting the role genetics plays in modifying the teratogenic impact of PAE is illustrated in how highly correlated the bar patterns are between Genome Shared and Face Rank-and how poorly correlated the bar patterns are between Face Rank and Alcohol Rank (especially between monozygotic and dizygotic twin pairs with virtually identical PAE).

Discussion

Fetal genotype modifies the teratogenic effects of PAE:

The outcomes of this study provide conclusive evidence that fetal genotype can modify the teratogenic effects of PAE. When twin pairs with virtually identical PAE were genetically identical, their FASD diagnoses were identical. When twin pairs with virtually identical PAE were genetically different, their FASD diagnoses were often different (44% presented with discordant FASD diagnoses). And when their diagnoses were discordant, the magnitude of discordance was extreme 10% of the time. For example, four of the 39 pairs of dizygotic twins were born at opposite ends of the fetal alcohol spectrum (PFAS and ND/AE), despite virtually identical PAE. Finally, as the proportion of genome shared between siblings decreased from 100% to 50% to 50% to 25% across the four study groups (monozygotic, dizygotic, full-sibling and half-sibling pairs respectively), the prevalence of pairwise discordance in FASD diagnoses increased linearly from 0% to 44% to 59% to 78%.

The prevalence of pairwise concordance in FASD diagnoses observed in our 48 twin pairs (monozygotic 100%, dizygotic 56%) was comparable to the prevalence of concordance observed in 16 twin pairs (monozygotic 100%, dizygotic 64%) reported by Streissguth and DeHaene [6] back in 1993—the only other FASD twin group study published to date. The 16 twin pairs (5 monozygotic and 11 dizygotic) were born to alcohol-abusing mothers from two countries (the United States and France). The study population included 11 Caucasian and 5 Native American twin pairs ranging in age from 1.5 to 30 years. The study was conducted prior to the creation of rigorous, case-defined FASD diagnostic systems. Patients were diagnosed as FAS or Fetal Alcohol Effects (FAE) in accordance with gestalt approach to diagnosis published by Clarren and Smith in 1978 [12]. Thirty-nine percent had FAS, 19% had FAE and 42% were alcohol exposed but unaffected. The higher concordance observed in their dizygotic twin pairs will be due in part to the fact that concordance in a study using only two FASD diagnoses (FAS and FAE) will always be higher than concordance in a study using 4 FASD diagnoses (FAS, PFAS, SE/AE, and ND/AE). Over the years, the outcomes of ten additional twin pairs with PAE have been published as single-case studies [13–20]. Formal FASD diagnostic evaluations were rarely conducted, but the clinical descriptions of the twin pairs were consistent with monozygotic twin pairs having more concordant outcomes than dizygotic twin pairs.

Similar to humans, evidence of genetic modification of FASD outcomes also come from animal studies. For example, a study by Debelak and Smith [21] examined 11 genetic strains of chick embryos following ethanol exposure during early neurulation and found that the strains could be classified into very sensitive, moderately sensitive, or insensitive to ethanol-induced apoptosis of cranial neural crest cells, which give rise to facial structures. Comprehensive reviews on the genetics of FASD are presented by Mead and Sarkar [4] and Eberhart and Parnell [5].

Discordance in the FAS facial phenotype:

It is interesting to note the rather high prevalence of pairwise discordance (43.6%) in FASD diagnoses among dizygotic twins in this study, despite virtually identical PAE. It is clear that discordance in PAE does not explain their discordant FASD diagnoses, but are there factors other than PAE that may explain the discordance? FASD is characterized by growth deficiency, a specific cluster of minor facial anomalies, and abnormal CNS structure and/or function. Only the Rank 4 FAS facial phenotype, as defined by the 4-Digit Code, is confirmed to be specific to (caused only by) PAE [7]. The FAS facial phenotype is not caused by other prenatal and postnatal risk factors. In contrast, growth deficiency and CNS structural/functional abnormalities can be caused by a multitude of other prenatal and postnatal risk factors. Despite efforts to minimize postnatal contrasts between the twin pairs in this study (Table 3, Figure 1), some of the pairwise discordance in growth and CNS outcomes used to generate the FASD diagnoses is likely explained, in part, by discordant postnatal risk factors.

Documenting the prevalence of discordance (if any) for the Rank 4 FAS facial phenotype is of particular interest because the Rank 4 FAS facial phenotype is so highly specific to PAE [7]. If identical PAE can result in discordant Rank 4 facial phenotypes between twin pairs, this would further strengthen the evidence that genes are modifying the teratogenic impact of PAE. Since the FAS facial phenotype requires PAE in a very narrow window of time (during the gastrulation period of fetal development) [22, 23], the only pairwise discordance in Rank 4 facial phenotypes that would be meaningful (that could be validly interpreted) would be among monozygotic and dizygotic twin pairs—the only two groups where the timing of PAE can be confirmed to be virtually identical on a day-to-day basis between twin pairs.

Two of the nine monozygotic twin pairs presented with Rank 4 FAS facial phenotypes. Both twins in each pair presented with concordant Rank 4 faces. Three of the 39 dizygotic twin pairs presented with Rank 4 FAS facial phenotypes; two pairs presented with concordant Rank 4 faces and one pair presented with discordant Face Ranks (Rank 4 vs Rank 2). The twin pair with discordant Face Ranks presented as follows: Twin 1: PFAS, Face Rank 4, all three of the FAS facial features (mean PFL z-score −3.5, philtrum smoothness Rank 5, upper lip thinness Rank 4). Twin 2: ND/AE, Face Rank 2, only 1 of the 3 FAS facial features—a thin upper lip (mean PFL z-score −1.8, philtrum smoothness Rank 3, upper lip thinness Rank 4). The work by Das et al., [24], presented below, provides a compelling genetic explanation for why Face Ranks were always concordant among monozygotic twins, but occasionally discordant among dizygotic twins.

Das et al., [24] reported a significant gene-environment interaction explaining variation in facial morphology associated with ethanol use in pregnancy. Genetic diversity in ethanol metabolizing enzymes occurs in the general population. Ethanol is metabolized to acetaldehyde by two enzyme systems: the microsomal ethanol oxidizing system and alcohol dehydrogenase (ADH) [25, 26]. The presence of the ADH1B*3 allele has been found to be protective for offspring neurodevelopmental and growth outcome after maternal ethanol consumption in pregnancy [27]. In 2004, Das et al [24] demonstrated that among African American women and their offspring, the presence of an ADH1B*3 allele was protective for the effects of maternal ethanol ingestion during pregnancy on infant facial formation. The protective effect demonstrated was present with the allele present in only the mother, only the infant, or both the mother and the infant. Exposure to ethanol and absence of the ADH1B*3 allele in both the mother and infant resulted in significant reductions in three facial measurements obtained from infant facial photographs-palpebral fissure length, inner canthal distance and the distance from the bridge of the nose to the bottom of the upper lip. Based on the findings of Das et al., [24] one could speculate that discordant FAS Face Ranks could occur in dizygotic twins (as observed in our study) if the ADH1B*3 allele was absent in the mother and one twin, but present in the other twin. Based on the same line of reasoning, one would expect monozygotic twins to always present with concordant Face Ranks (as was observed in our study). Replication of the Das et al., study using a study population of monozygotic and dizygotic twins with PAE would greatly advance our understanding how the ADH1B*3 allele modifies the teratogenic impact of PAE.

Implications for public health messaging and setting FASD diagnostic exposure thresholds:

Despite virtually identical PAE, 4/39 (10%) dizygotic twin pairs had FASD diagnostic contrasts as large as PFAS vs ND/AE. The four twin pairs had virtually identical PAE, were raised together, and had reportedly identical prenatal and postnatal experiences (e.g., prenatal tobacco, illicit drug exposure, home placements, physical/sexual abuse). In other words, their contrasts in FASD outcomes would appear to better-explained by their discordant genetic vulnerability to PAE, than their discordant environmental influences. These 4 twin pairs provide powerful evidence that what may be construed in public health messaging (and some FASD diagnostic guidelines [28–30] as a safe level of exposure for one fetus, may very well place another fetus at significant risk. Not only can the same level of PAE cause strikingly different outcomes in two fetuses, but PAE reportedly below the threshold of exposure required by some FASD diagnostic guidelines can result in full FAS (See Figure 9 in Astley, et al., [31]). Thus, as stated by the U.S. Centers for Disease Control and Prevention [32] “*There is no guaranteed safe level of alcohol use at any time during pregnancy. Fetal alcohol spectrum disorders are completely preventable if a woman does not drink during pregnancy.”*

Potential Limitations

Zygosity Classification:

Twins were classified as monozygotic or dizygotic for this study based on clinical and social service records shared with the FASDPN clinic at the time of their FASD evaluation. It is

unknown how many twin pairs had zygosity confirmed through DNA genotyping. While there remains a small chance that one or more twin pairs in this study have their zygosity misclassified, a study of 578 twin pairs conducted by the National Academy of Sciences found parent report of zygosity was confirmed accurate by DNA genotyping over 95% of the time [33]. When misclassification occurred, it was most likely to occur among monozygotic twins who were not strikingly similar in appearance and thus incorrectly classified as dizygotic. This direction of error would lead to more conservative estimates of heritability. In the current study, all monozygotic twins looked identical and all dizygotic twins were easily distinguished from one another.

Do twins share identical prenatal environments?

Not necessarily. It is for that reason the prenatal environments and PAE shared between our 48 twin pairs is described throughout this study as virtually identical. How twins experience the prenatal environment depends, in part, on chorionicity, i.e., whether twins share a single chorion (monochorionic) or have separate chorions (dichorionic). Monozygotic twins can be mono- or dichorionic, whereas dizygotic twins are dichorionic [34]. The chorionicity of the 9 monozygotic twin pairs in the current study was unknown. The chorion is the outer-most fetal membrane that contains the amnion/amniotic sac. The amnion is the thin inner-most fetal membrane that protects the embryo/fetus and contains amniotic fluid. The chorion connects the amnion, amniotic sac, and the fetus to the placenta and contributes to placental development. Thus, if twins share a chorion (e.g., are monochorionic) they will share a single placenta, whereas twins with separate chorions (e.g., dichorionic) develop individual placentas. Dizygotic twins are dichorionic, since they form from two separately fertilized eggs. Among Caucasian populations, total twinning rates were estimated at 15–16 per 1,000 in 2003 [35]. In Caucasian populations, monozygotic twins comprise ~26% of all twins. For Caucasian populations about 17% of all twin pairs are monozygotic-monochorionic, ~9% are monozygotic-dichorionic and ~74% are dizygotic-dichorionic. All twins can be expected to have many kinds of in-utero differences, such as placental flow in monozygotic twins and the amount of microchimerism in dizygotic twins [36]. The greatest risk associated with monochorionic placentation is related to the structure of blood vessels. One twin typically has better placement and therefore receives more of the nutrients [34]. The placenta also functions as a barrier, allowing small molecules (e.g., gases, nutrients, waste material, antibodies) to pass between mother and child through passive transport [37, 38]. Other small molecules that can impact fetal development (e.g., some maternal hormones like cortisol; bacteria; teratogens such as alcohol) can also be diffused through the placenta [37, 39]. Unequal placental sharing is a major cause of fetal growth discordance in monozygotic twins [40]. It is interesting to note that one of the few occurrences of discordant outcomes between monozygotic twins in the current study was discordant growth in one twin pair (Growth Rank 3 versus Growth Rank 1). Both twins had concordant weight percentiles (ranging from the 20th to 40th percentiles) at birth and 2 years of age. Height percentiles, however, were significantly discordant. One twin was significantly shorter (1st and 10th percentiles at birth and 2 years of age) than the other (20th and 60th percentiles at birth and 2 years of age). All in all, while prenatal environments, including level of PAE, are not necessarily 100% identical between twin pairs, the near perfect match between percent of genome shared and FASD diagnostic concordance (monozygotic twins: 100% genome

shared and 100% FASD concordance; dizygotic twins: 50% genome shared, 56% FASD concordance) suggests the prenatal -environments and PAE levels in our 48 twin pairs were virtually identical.

Conclusions

Not all fetuses are equally vulnerable to the adverse effects of prenatal alcohol exposure. Risk is not just dependent on timing and level of exposure. Fetal genetics plays an important role. As demonstrated in this study, despite virtually identical prenatal alcohol exposures, two fetuses can experience vastly different FASD outcomes. So which fetus is genetically vulnerable? We currently have no way of knowing. Thus, to protect all fetuses, especially the most genetically vulnerable, the only safe amount to drink is none at all.

C

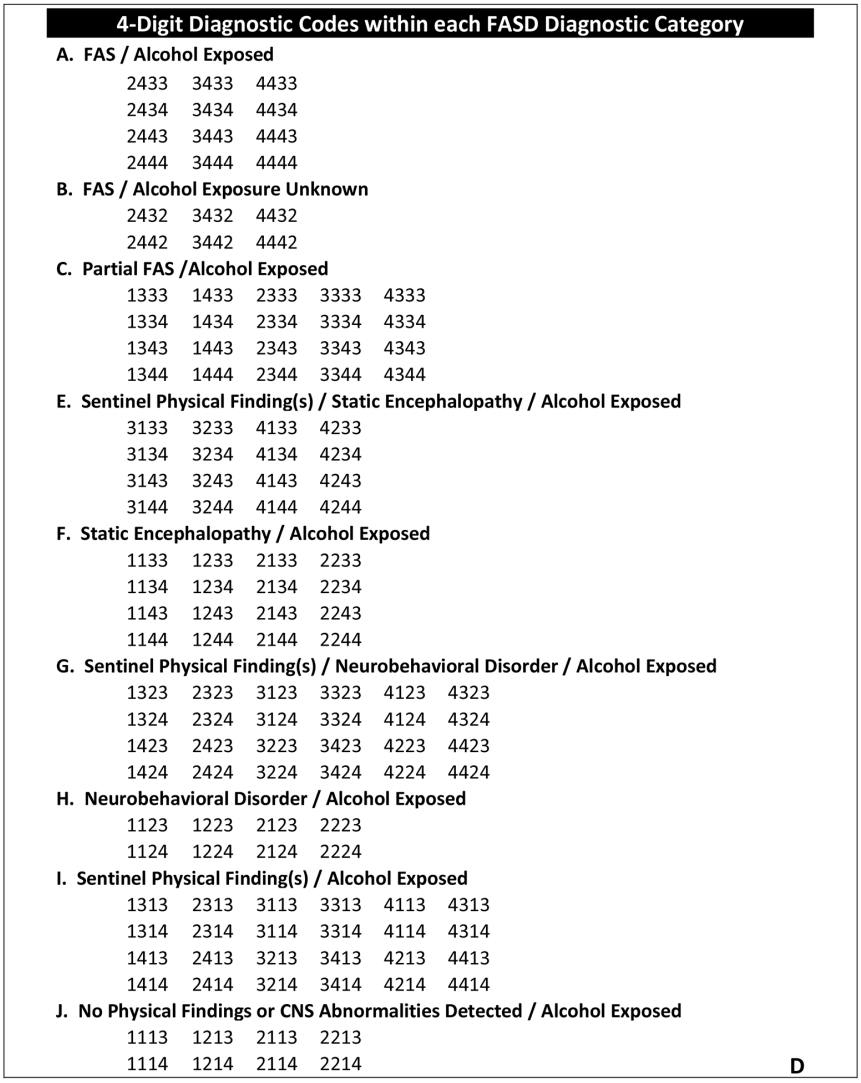

Figure 1. FASD 4-Digit Diagnostic Code.

A) Abbreviated case-definitions for the fetal alcohol spectrum disorder (FASD) 4-Digit Code [2]. The 4-Digit Code 3434 is one of 12 4-Digit Codes that fall under the diagnostic category FAS. **B)** The Rank 4 FAS facial phenotype requires 3 features: 1) palpebral fissure lengths 2 or more standard deviations below the mean; 2) a smooth philtrum (Rank 4 or 5 on the University of Washington Lip-Philtrum Guide); and 3) a thin upper lip (Rank 4 or 5 on the University of Washington Lip-Philtrum Guide). **C and D)** The 4-Digit Code produces four diagnostic subgroups under the umbrella of FASD: FAS (Diagnostic Categories A, B), PFAS (Diagnostic Category C), SE/AE (Diagnostic Categories E, F), and ND/AE (Diagnostic Categories G, H). Abbreviations: CNS: central nervous system; H: height percentile; W: weight percentile.

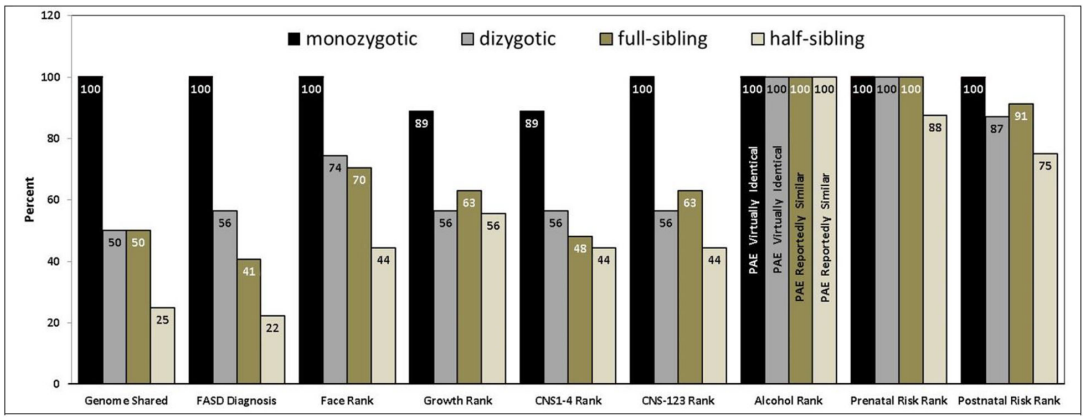

Figure 2. Twin/Sibling Pairwise Concordance in FASD outcomes and prenatal/postnatal risks.

Monozygotic twins, dizygotic twins, full siblings and half siblings share 100%, 50%, 50% and 25% of their genome respectively as depicted by the first set of bars. If fetal genetics is modifying the teratogenic impact of PAE, the pattern of pairwise concordance reflected in the bars for each FASD outcome will more closely resemble the pattern of bars for Genome Shared than the patterns of bars reflecting pairwise concordance in Alcohol Rank, other Prenatal Risks or Postnatal Risks. The bar patterns across all FASD outcomes are far more reflective of the pattern of bars for Genome Shared than the pattern of bars for Alcohol Rank, Prenatal Risk Rank or Postnatal Risk Rank. Although the bar pattern for Postnatal Risk Rank resembles the bar pattern for Face Rank, discordance in postnatal risk factors cannot be contributing to discordance in Face Rank because only prenatal factors can impact facial morphology. Since the FAS facial phenotype, as defined by the 4-Digit Code, is so specific to (caused only by) PAE, the most compelling evidence supporting the role genetics plays in modifying the teratogenic impact of PAE is illustrated in how highly correlated the bar patterns are between Genome Shared and Face Rank and how poorly correlated the bar patterns are between Face Rank and Alcohol Rank (especially between monozygotic and dizygotic twins with virtually identical PAE).

Table 1.

Key factors that defined and differentiated the 4 study groups.

Features shared between sibling pairs	Study Groups			
	1. Monozygotic twins	2. Dizygotic twins	3. Full-siblings	4. Half-siblings with the same birth mother
	9 pairs	39 pairs	27 pairs	9 pairs
Birth mother	identical	identical	identical	identical
Birth father	identical	identical	identical	different
Genome shared	~100%	~50%	~50%	~25%
Prenatal alcohol exposure	virtually identical	virtually identical	100% same Rank	100% same Rank
Other prenatal risks	virtually identical	virtually identical	100% same Rank	88% same Rank
Siblings raised together	100%	100%	96%	100%
Other postnatal risks	100% same Rank	87% same Rank	83% same Rank	75% same Rank
Matched in age within one of 3 age-ranges (0–3; 4–8, 9+ years)	100%	100%	*93%	*89%

* 2 pairs of full-siblings and 1 pair of half-siblings had one sibling that was in a younger age category. In each of these 3 pairs, the younger sibling had the more severe FASD diagnostic outcome.

Comparison of the 4-Digit Code, Canadian 2015, Australian 2016 and Hoyme 2016 fetal alcohol spectrum disorder diagnostic guidelines

ABSTRACT

Background: As clinicians strive to achieve consensus worldwide on how best to diagnose fetal alcohol spectrum disorders (FASD), the most recent FASD diagnostic systems show convergence and divergence. Applying these systems to a single clinical population illustrates the contrasts between them, but validation studies are ultimately required to identify the best system.

Methods: The 4-Digit-Code, Hoyme 2016, Canadian 2015 and Australian 2016 FASD diagnostic systems were applied to 1,392 patient records evaluated for FASD at the University of Washington. The diagnostic criteria and tools, the prevalence and concordance of diagnostic outcomes, and validity measures were compared between the systems.

Results: The proportion diagnosed with fetal alcohol syndrome (FAS) and FASD varied significantly (4-Digit-Code 2.1%, ≤79%; Hoyme 6.4%, 44%, Australian 1.8%, 29%; Canadian 1.8%, 16%). Eighty-two percent were diagnosed FASD by at least one system; only 11% by all four systems. Key factors contributing to discordance include: requiring high alcohol exposure; excluding growth deficiency; relaxing the facial criteria; requiring brain criteria that prevent diagnosis of infants/toddlers; and excluding moderate dysfunction from the spectrum. Primate research confirms moderate dysfunction (1-2 domains ≤-2 standard deviations) is the most prevalent outcome caused by PAE (FAS 5%, severe dysfunction 31%, moderate dysfunction 59%). Only the 4-Digit-Code replicated this diagnostic pattern.

Conclusion: The needs of individuals with FASD are best met when diagnostic systems provide accurate, validated diagnoses across the lifespan, the full spectrum of outcome, the full continuum of alcohol exposure; and utilize diagnostic nomenclature that accurately reflects the association between outcome and alcohol exposure.

INTRODUCTION

Alcohol is a well-recognized teratogen and both human and animal research indicates that the impact of prenatal alcohol exposure (PAE) manifests as a spectrum of developmental variations in severity and type of dysfunction across individuals [1-3]. These outcomes vary significantly based on timing and dosage of exposure as well as the presence of other risk factors and are typically characterized as including physical impacts (i.e., growth deficiency, facial dysmorphology and structural brain abnormalities) as well as functional impairment of the central nervous system (CNS). This spectrum of outcome was found in early primate studies on the impact of prenatal alcohol exposure. For example Clarren et al. [4] document the distribution of developmental outcomes when the only risk factor present was PAE. In that study, the primates had been exposed weekly to binge exposures equivalent to a six-pack of beer for the first 3, 6 or entire 24 weeks of gestation (mean maternal peak plasma ethanol concentrations ranged from 176 to 271 mg/dl). The primate model confirmed that PAE causes a spectrum of outcomes; the most common outcome of PAE was moderate CNS dysfunction (the 4-Digit Code equivalent of Neurobehavioral Disorder/Alcohol Exposed ND/AE) (59% of primates) followed

Citation: Hemingway SJA, Bledsoe JM, Brooks A, Davies JK, Jirikowic T, Olson E, et al. (2019) Comparison of the 4-Digit Code, Canadian 2015, Australian 2016 and Hoyme 2016 Fetal Alcohol Spectrum Disorder Diagnostic Guidelines. Adv Pediatr Res 6:31. doi: 10.35248/2385-4529.19.6.31

by more severe CNS impairment (the 4-Digit Code equivalent of Static Encephalopathy/Alcohol Exposed SE/AE) (31%); notably sentinel physical impacts (the 4-Digit Code equivalent of FAS/PFAS) were found in only 5% of primates under these controlled conditions, and a similar number of primates exhibited little to no impacts of PAE (5%).

These facts present a challenge to public health systems seeking ways to best capture this spectrum of outcomes in order to appropriately diagnose and serve individuals that may have been impacted by PAE. As the field of fetal alcohol spectrum disorders (FASD) strives to achieve consensus worldwide on how best to meet this diagnostic challenge, the most recent versions of published guidelines (4-Digit Code, 2004 [5]) Canadian, 2015 [6], Hoyme, 2016 [7], and Australian, 2016 [8] show both convergence and divergence in their approach. For example, the new Canadian and Australian diagnostic systems have many features in common with one another and have adopted the facial criteria of the 4-Digit Code, but diverge substantially from the 4-Digit Code and Hoyme systems by removing growth deficiency from their diagnostic criteria [9] and adopting a nomenclature (FASD with the face, and FASD without the face) that reflects a dichotomy rather than a spectrum of outcomes. The 4-Digit Code [5] and Hoyme [7] criteria continue to generate a spectrum of diagnoses under the umbrella of FASD (fetal alcohol syndrome (FAS), partial FAS (PFAS), Alcohol Related Neurodevelopmental Disorder (ARND), Static Encephalopathy/ Alcohol Exposed (SE/AE), Neurobehavioral Disorder/Alcohol Exposed (ND/AE), and Alcohol Related Birth Defects (ARBD)) and maintain the 3 original core diagnostic criteria (growth deficiency, facial anomalies, and CNS abnormalities). The 4-Digit Code and Hoyme systems differ significantly in their diagnostic nomenclature, diagnostic tools, and the specific criteria used to generate each diagnosis. The Canadian [6] and Hoyme systems require high PAE; the 4-Digit Code and Australian systems require confirmed PAE at any reported level. The Canadian and Australian [8] systems do not include moderate dysfunction under the umbrella of FASD; the 4-Digit Code and Hoyme systems do. The contrasts in these systems create confusion for clinicians faced with diagnosing FASD. Applying these systems to a single clinical population illustrates the contrasts between them, but validation studies are ultimately required to identify the best system.

The objectives of this study were to:

1. Compare the tools, nomenclature and criteria used by the four diagnostic systems.
2. Administer each system to the records of 1,392 patients to:
   a. Compare the prevalence of FASD diagnoses produced by each system.
   b. Assess diagnostic discordance/concordance between the four systems.
   c. Assess and compare the diagnostic performance (validity) of each system.

A comprehensive comparison of the 4-Digit Code and Hoyme 2016 systems was conducted in 2017 [10]. This study expands the comparison to include all four diagnostic systems using the same clinical population of 1,392 patients. Key findings from the published comparison of the 4-Digit Code and Hoyme systems are included in this report, but the Reader is referred to the previous publication [10] for more detail. Since contrasts in the diagnostic tools and criteria used by each system impact our application of each system to our study population, the methods and results for Objective 1 are presented first, followed by the methods and results for Objective 2.

OBJECTIVE 1. COMPARISON OF THE TOOLS, NOMENCLATURE AND CRITERIA USED BY THE FOUR SYSTEMS

Methods

The following tools, nomenclature and criteria used by the four diagnostic systems were compared.

Lip-philtrum guides

The 4-Digit Code introduced two guides: Lip-Philtrum Guide 1 for Caucasians and all races with thinner upper lips like Caucasians, and Lip-Philtrum Guide 2 for African Americans and all races with thicker upper lips like African Americans (Figures 1A and 1B). These Lip-Philtrum Guides were adopted for use by the Canadian and Australian systems. Hoyme 2016 introduced two different lip/philtrum guides: the North American Lip/Philtrum Guide [7] produced from a U.S. white population and the South African Mixed Race Lip/Philtrum Guide [5] produced from a Cape Coloured (mixed race) population in the Western Cape Province (Figures 1C and 1D).

The Rank 1-5 lips depicted on the 4-Digit Code Caucasian and Hoyme et al. [7] North American guides were compared using the objective, quantitative measure of lip thinness called lip circularity (perimeter^2/area) generated by the FAS Facial Photographic Analysis Software [12]. Circularity is computed by outlining the vermilion border of the upper lip with the computer mouse (Figure 2C); the thinner the lip, the bigger the circularity.

PFL normal growth charts

The 4-Digit Code uses the Stromland Scandinavian PFL normal growth charts for all races except African American [13]. The Stromland PFL norms cover the full lifespan (birth to adult). These same charts were used for the Hoyme system. The Canadian and Australian systems use the Stromland charts for patients <6 years of age and the Clarren Canadian PFL [14] charts for patients 6 years of age and older.

Facial analysis software

The 4-Digit Code advises measuring the facial features from 2D digital photos using the FAS Facial Photographic Analysis Software [12]. The Canadian and Australian systems also encourage the use of the FAS Facial Photographic Analysis Software. The authors of the Hoyme system "feel direct examinations of facial features are more practical in an office setting". Since empirical studies have already confirmed the superior accuracy of the photo versus direct method of facial measurement [13,15], a formal assessment of photo versus direct measurement of facial features was not repeated in this study.

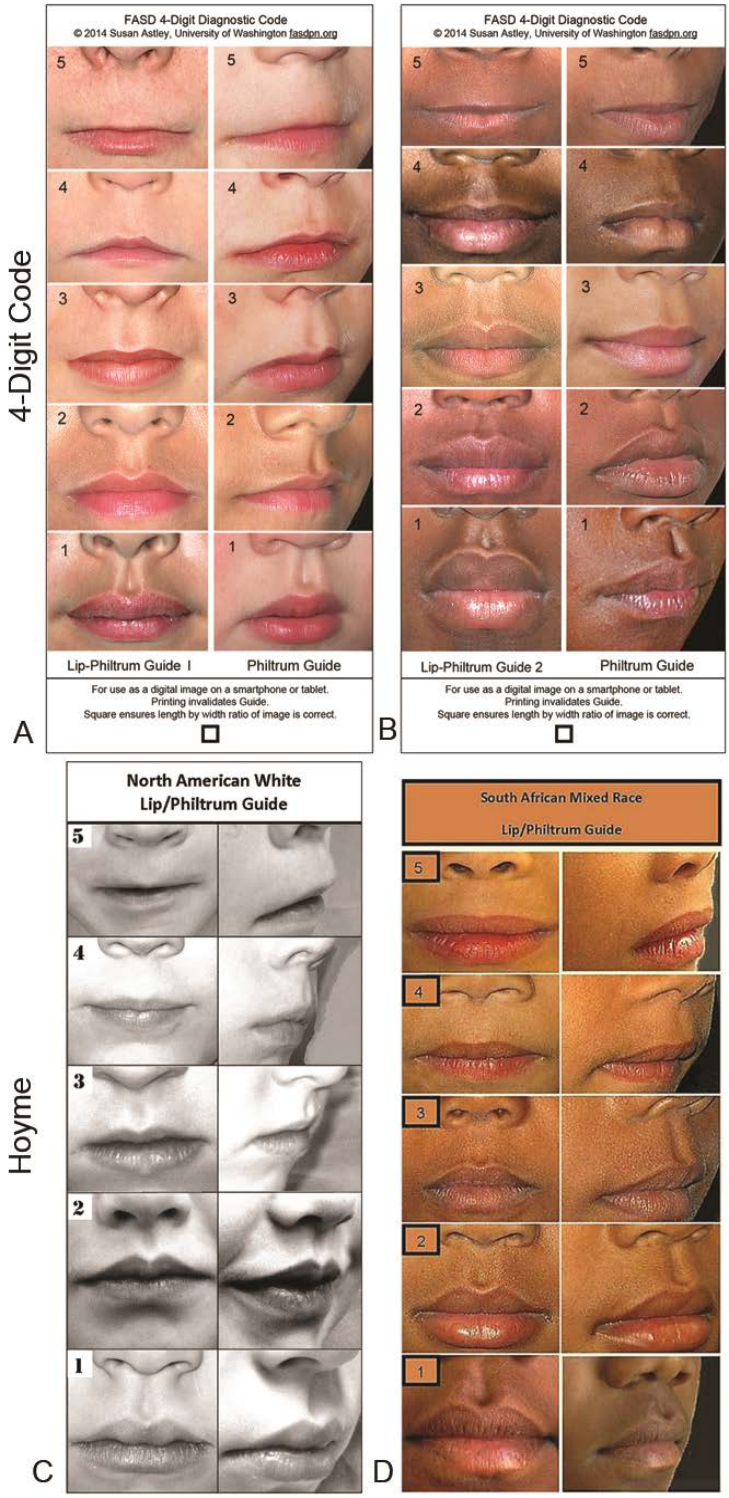

Figure 1. Lip/Philtrum Guides.
The 4-Digit Code [5] introduced two guides in 1999: A) Lip-Philtrum Guide 1 for Caucasians and all races with thinner upper lips like Caucasians, and B) Lip-Philtrum Guide 2 for African Americans and all races with thicker upper lips like African Americans. Hoyme introduced two different lip/philtrum guides: C) the North American Lip/Philtrum Guide in 2016 [7] produced from a U.S. white population (reproduced with permission from Pediatrics [7] copyright 2019 by the AAP) and D) the South African Mixed Race Lip/Philtrum Guide in 2015 [11] produced from a Cape Coloured (mixed race) population in the Western Cape Province (reproduced with permission from AJMG [11] copyright 2019 by John Wiley & Sons).

Diagnostic nomenclature and criteria

Tables were created to illustrate the key contrasts between the diagnoses generated by each system, the nomenclature assigned to each diagnosis, and the diagnostic criteria.

Results

Contrasts in lip-philtrum guides

Astley et al. [10] confirmed the Hoyme lip philtrum guides differ significantly from the 4-Digit Code Lip-Philtrum Guides resulting in substantially relaxed FAS facial features relative to the 4-Digit Code.

The Hoyme 2016 North American White Lip/Philtrum Guide does not match the "Caucasian" 4-Digit Code Lip-Philtrum Guide 1 (Figure 2A).

> **Philtrum:** The Rank 1 through 5 philtrums depicted on both the 4-Digit and Hoyme guides appeared broadly equivalent by visual inspection.
>
> **Upper Lip:** Lip thinness is measured using the objective measure of upper lip thinness (circularity=perimeter^2/area). Circularity confirmed the Hoyme Rank 1, 2, 3, and 4 lips were equivalent to the 4-Digit Ranks 2, 2, 3, and 2 respectively (Figure 2A). The image depicting the vermilion portion of the Hoyme Rank 5 upper lip is not sufficiently clear to judge its level of equivalency with the 4-Digit Code Rank 5 lip. Circularity, as demonstrated in a video link (Figure 2C) confirms the Hoyme Rank 4 lip is substantially thicker than the 4-Digit Code Rank 4 lip (e.g., it is equivalent to the 4-Digit Code Rank 2 lip (Figure 2A). Unlike the 4-Digit Code Lip-Philtrum Guide, the lips pictured on the Hoyme Guide do not become progressively thinner with increasing Rank and no lip on the Hoyme Guide is equivalent to the 4-Digit Ranks 1 or 4. Despite the contrasts between the two lip/philtrum guides, both are intended for use on North American Caucasian populations and thus were used to address Objective 2 below

The Hoyme et al. South African Mixed Race Lip/Philtrum Guide (Figure 1D) does not match the "African American" 4-Digit Code Lip-Philtrum Guide 2 in Figure 1B.

> **Philtrum:** The Rank 1 through 5 philtrums depicted on both guides appeared broadly equivalent by visual inspection.
>
> **Upper Lip:** The objective measure of upper lip thinness (circularity=perimeter^2/area) confirmed the Hoyme Rank 1, 2, 3, 4 and 5 lips were equivalent to the 4-Digit Ranks 2, 3, 3, 3 and 3 respectively (Figure 1 in Astley et al. [10]). Unlike the 4-Digit Code Lip-Philtrum Guide, the lips pictured on the Hoyme Guide do not become progressively thinner with increasing Rank. There are no lip images on the Hoyme Guide that correspond to the 4-Digit Ranks 1, 4 or 5. The Hoyme Rank 5 lip is thicker (circularity 40.1) than the Hoyme Rank 4 lip (circularity 46.0). Most importantly, the Hoyme Rank 4 lip (the clinical cut-off for FAS) is thicker than the 4-Digit Rank 4 lip. The Hoyme Rank 4 lip is equivalent to the 4-Digit Rank 3 lip. The Hoyme Rank 5 lip (circularity 40.1) is substantially thicker than the 4-Digit Rank 5 lip (circularity 80).
>
> Based on our findings here and the findings of Hoyme et al. [11], the South African Mixed Race Lip/Philtrum Guide is not appropriate for use on an African American population and thus was not used to address Study Objective 2. The study population for Objective 2 was adjusted accordingly (as described below) to accommodate this finding

Contrasts in Diagnostic Categories and Nomenclature

The key contrasts in the diagnostic categories and nomenclature used by each system are highlighted in Table 1.

Contrasts in diagnostic criteria

Key contrasts in diagnostic criteria are highlighted in red font in Table 2.

Discussion

Growth deficiency

The Hoyme criteria use the same cut-off (prenatal or postnatal height and/or weight ≤10th percentile) to define growth deficiency as the 4-Digit Code, but the Hoyme criteria classify growth deficiency on a dichotomous scale (present/absent), whereas the 4-Digit Code ranks growth deficiency on a 4-point ordinal scale with emphasis on short stature. The 4-Digit Code method for ranking growth deficiency is confirmed to be highly predictive of CNS dysfunction among individuals with PAE and appears to differentiate growth deficiency (postnatal short stature) significantly associated with PAE from growth deficiency (low birth weight) significantly associated with prenatal tobacco exposure [9]. Rank 3 and Rank 4 growth deficiency was confirmed to be as highly correlated with, and predictive of, severe brain dysfunction as the 4-Digit Code Rank 4 FAS facial phenotype. Individuals with Rank 3 or 4 growth deficiency had a two to three-fold increased risk for severe brain dysfunction. Sixty percent of patients with Rank 4 growth deficiency had severe brain dysfunction. Growth deficiency is so highly predictive of severe CNS dysfunction among infants/toddlers with PAE, it becomes a vital clinical tool for identifying and qualifying infants/toddlers for early intervention. The Canadian and Australian systems removed growth deficiency from their FASD diagnostic guidelines.

Facial phenotype

When compared to the 4-Digit Code Rank 4 FAS facial phenotype (used by the 4-Digit Code, Canadian and Australian systems), the Hoyme FAS facial phenotype is substantially relaxed. This is best illustrated using the 4-Digit Code Facial ABC-Score printed on the backside of the 4-Digit Code "Caucasian" Lip-Philtrum Guide 1 in Figure 3A. The 4-Digit Code Rank 4 FAS facial phenotype is defined by a single ABC-Score (Facial ABC-Score CCC, Face Rank 4) (Figure 3A). The three letters "CCC" reflect the magnitude of expression of the short PFL, smooth philtrum, and thin upper lip in that order. C reflects severe expression in the FAS range, B reflects moderate expression, and A reflects normal expression. The Hoyme FAS facial criteria are relaxed relative to the 4-Digit Code in three ways:

1. Only 2 of 3 cardinal features are required.
2. The PFL is relaxed from the 3rd percentile to the 10th percentile.

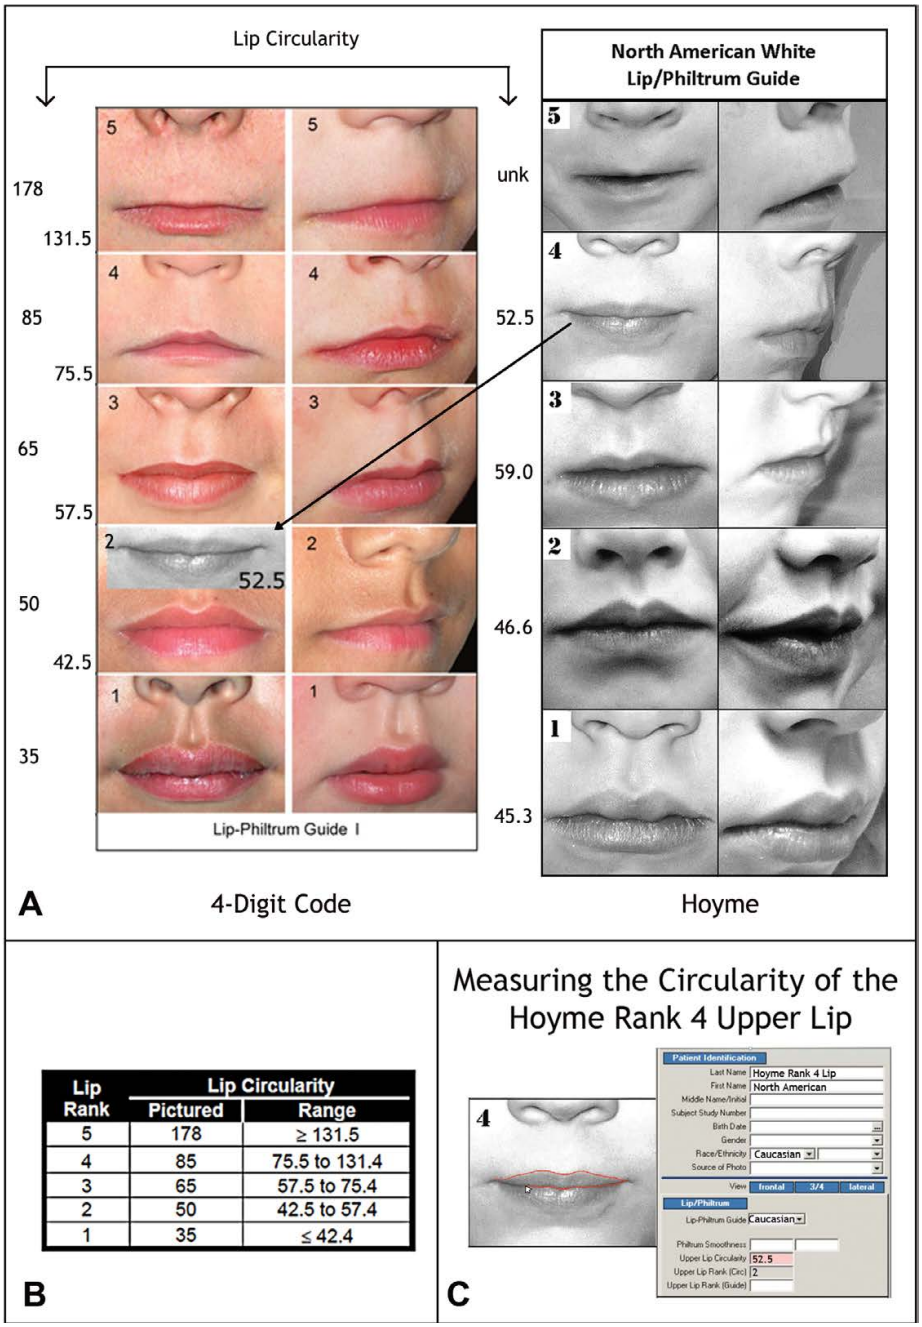

Figure 2. The Hoyme North-American White Lip/Philtrum Guide differs from the 4-Digit Code "Caucasian" Lip-Philtrum Guide 1. The Ranks 1 through 5 philtrums depicted on both Guides appears broadly equivalent, but the upper lips are substantially different. A) Lip circularity (perimeter^2/area) is printed to the left of each guide. B) The range of circularities that define each 4-Digit Code Lip Rank are presented in the Lip Circularity table printed on the backside of the 4-Digit Code Lip-Philtrum Guide. C) The FAS Facial Photographic Analysis Software [12] computes circularity when the User outlines the vermilion border of the upper lip (click on video link for demonstration http://depts.washington.edu/fasdpn/movie/Fig2Cvideo.mp4. Lip circularity confirms the Hoyme Rank 1, 2, 3, and 4 lips are equivalent to the 4-Digit Ranks 2, 2, 3, and 2 respectively. The vermilion portion of the Hoyme Rank 5 upper lip is not sufficiently clear to judge its level of equivalency with the 4-Digit Code Rank 5 lip. There is no lip image on the Hoyme Guide that reflects the 4-Digit Rank 1 or Rank 4 lips. The lips on the 4- Digit Guide become progressively thinner (circularity becomes progressively larger) with increasing Rank. This is not true for the Hoyme Guide. The circularity of the Hoyme Rank 4 lip (the clinical cut-off for FAS) is 52.5, confirming it falls within the circularity range (42.5 to 57.5) of the 4-Digit Code Rank 2 lip. The black and white overlay (A) of the Hoyme Rank 4 lip on the 4-Digit Code Guide 1 demonstrates both visually and numerically that the Hoyme Rank 4 lip is substantially thicker than the 4-Digit Code Rank 4 lip. This analysis confirms the Hoyme North American White Lip/Philtrum Guide is not a valid tool for use with the FASD 4-Digit Diagnostic Code. (North American White Lip/Philtrum Guide used with permission from the American Academy of Pediatrics).

Table 1. Diagnostic categories and overlap of nomenclature used by 4 FASD diagnostic systems.

4-Digit Code 2004 [5]	Hoyme et al., 2016 [7]	Canadian 2015 [6]	Australian 2016 [8]
FAS Alcohol Exposed or Unknown	**FAS** Alcohol Exposed or Unknown	**FASD with the Face** Alcohol Exposed or Unknown	**FASD with the Face** Alcohol Exposed or Unknown
pFAS Alcohol Exposed	**pFAS** Alcohol Exposed or Unknown	**FASD without the Face** High Alcohol Exposure	**FASD without the Face** Alcohol Exposed
SE/AE Static Encephalopathy Alcohol Exposed	**ARND** High Alcohol Exposure Must be ≥ 3 years old		
ND/AE Neurobehavioral Disorder Alcohol Exposed			
	ARBD High Alcohol Exposure		

Table 2. Key contrasts in diagnostic criteria between the four systems.

Criteria	4-Digit Code 2004 [5]	Hoyme et al., 2016 [7]	Canadian 2015 [6]	Australian 2016 [8]
Growth	≤ 10th percentile. Growth: normal, mild, moderate, severe. Emphasis on short stature	≤ 10th percentile Growth: normal/ abnormal	Excluded	Excluded
FAS Face	All 3 features PFL ≤ 3rd percentile. Lip & Philtrum Rank 4 or 5 on 4-Digit Code Lip-Philtrum Guides. Face: normal, mild, mod, severe. Specificity: ~95%. Photo Software confirmed more accurate than direct exam.	2 of 3 features. PFL≤10th percentile. Lip & Philtrum Rank 4 or 5 on Hoyme Lip/Philtrum Guides. Face: normal, abnormal. Specificity: ~71%. "We feel that direct exams are more practical in an office setting"	All 3 features. PFL ≤ 3rd percentile. Lip & Philtrum Rank 4 or 5 on 4-Digit Code Lip-Philtrum Guides. Face: normal, abnormal. Specificity: ~95%. Photo Software recommended.	All 3 features. PFL ≤ 3rd percentile. Lip & Philtrum Rank 4 or 5 on 4-Digit Code Lip-Philtrum Guides. Face: normal, abnormal. Specificity: ~95%. Photo Software recommended.
Alcohol Related Birth defects (ARBD)	Excluded	Cardiac: atrial septal defects, aberrant great vessels, ventricular septal defects, conotruncal heart defects; Skeletal: radioulnar synostosis, vertebral segmentation defects, large joint contractures, scoliosis; Renal: aplastic/ hypoplastic/dysplastic kidneys, "horseshoe" kidneys/ureteral duplications; Eyes: strabismus, ptosis, retinal vascular anomalies, optic nerve hypoplasia; Ears: conductive hearing loss, neurosensory hearing loss	Excluded	Excluded
Brain structure	Structural/neurological abnormalities. OFC ≤ 3rd percentile. Structure alone meets CNS criteria.	Structural/neurological abnormalities. OFC ≤ 10th percentile. Structure alone does not meet CNS criteria.	Structural/neurological abnormalities. OFC ≤ 3rd percentile. Structure alone does not meet CNS criteria. Serves as 1 of 3 brain domains.	Structural/neurological abnormalities. OFC ≤ 3 rd percentile Structure alone does not meet CNS criteria. Serves as 1 of 3 brain domains.
Brain Function	Severe: 3 or more domains ≤ - 2 SDs. Moderate: 1-2 domains ≤ -2 SDs and/or 1 or more domains ≤ 1.5 SDs. Function: normal, moderate, severe.	Moderate to Severe 1 or more domains ≤ -1.5 SDs. Function: normal, abnormal.	Severe: 3 or more domains ≤ -2 SDs. Function: normal, abnormal.	Severe: 3 or more domains ≤ -2 SDs. Function: normal, abnormal.
Alcohol	Confirmed Exposure (at any reported level) or Unknown Exposure (if 4-Digit Rank 4 FAS face present).	Confirmed High Exposure (≥ 6 drinks/wk for (≥ 2 weeks) or ((≥ 3 drinks/occasion, (≥ 2 occasions) or Unknown Exposure (if Hoyme FAS face present).	Confirmed High Exposure (≥ 7 drinks/week) or (≥ 4 drinks/occasion, ≥ 2 occasions) or Unknown Exposure (if 4-Digit Rank 4 FAS face present).	Confirmed Exposure (at any reported level) or Unknown Exposure (if 4-Digit Rank 4 FAS face present).
Children	Diagnostic criteria do not vary with age.	Children ≤ 3 yrs, brain criteria for FAS and PFAS relaxed to developmental delay ≤ -1.5 SDs. Not eligible for a diagnosis of ARND.	Children ≤ 6 yrs: FASD with Face=3 facial features and microcephaly.	Children ≤ 6 yrs: FASD with Face=3 facial features and microcephaly with confirmed or unknown PAE.

At Risk	5.2.1: Prenatal alcohol exposure, with the estimated dose at a level known to be associated with neurodevelopmental effects; Central nervous system criteria from FASD with or without the Face are not met; and there is some indication of neurodevelopmental disorder in combination with a plausible explanation as to why the neurodevelopmental assessment results failed to meet the criteria for substantial impairment (e.g., patient was too young; incomplete assessment). 5.22: All 3 facial features present but do not yet have documentation or evidence of the requisite 3 or more neurodevelopmental domain criteria or true microcephaly. 7.3: Infants and young children with prenatal alcohol exposure but who do not meet the criteria for FASD should be designated as "At risk for neurodevelopmental disorder and FASD, associated with prenatal alcohol exposure."	Individuals who, despite assessment, fail to meet criteria for FASD at the current time, but may nevertheless potentially have FASD. Example include: Neurodevelopmental assessment is incomplete or inconclusive. Despite confirmed PAE, neurodevelopmental impairment is present in fewer than 3 domains. Neurodevelopmental impairment is present in 3 or more domains, but impairment is not sufficiently severe to meet criteria. Comprehensive, age-appropriate neurodevelopmental assessment is impossible or unavailable e.g., in infants and young children. These individuals may be considered 'at risk of FASD' and require follow-up and reassessment. Confirmed or unknown PAE,<6 yrs, all 3 facial features, do not meet neurodevelopmental criteria and do not have microcephaly.

Readers are referred to the published guidelines for each system for how these criteria are used to generate diagnoses under the umbrella of FASD. Key contrasts are in red font.

3. A Rank 4 or 5 thin upper lip is required, but as illustrated in our analysis above, the Rank 4 lip on the Hoyme North American Lip/Philtrum Guide is equivalent to the Rank 2 lip on the 4-Digit Lip-Philtrum Guide 1.

This results in almost every 4-Digit Code Facial ABC-Score meeting the relaxed Hoyme facial criteria (Figure 3B) including 13 of the 15 ABC-Scores that depict the 4-Digit Code Rank 2 (mild) facial phenotype and 3 of the 8 ABC-Scores that depict the complete absence of all three FAS facial features (Rank 1). Clinically, the 4-Digit Code classifies Rank 1 and 2 facial phenotypes as being within the normal range. The practical clinical impact of this relaxation is illustrated in Figure 3C in which an adolescent with high function (e.g., FSIQ 123) and confirmed absence of PAE met the Hoyme criteria for the full FAS facial phenotype.

In addition to the contrasts in facial criteria, the scales of measurement used to clinically classify the facial phenotype also differ. The 4-Digit Code documents the full continuum of expression of the FAS facial phenotype (Face Ranks 1 through 4); a continuum confirmed to be highly predictive of CNS dysfunction [9,16]. Patients with the Rank 3 facial phenotype have a 2-fold increased risk of severe brain dysfunction, whereas patients with the full Rank 4 FAS facial phenotype have a 5-fold increased risk of severe brain dysfunction. In contrast, the Hoyme system documents the facial phenotype as present (equivalent to 4-Digit Face Ranks 2, 3 and 4 and half of Rank 1) and absent (equivalent to the other half of Rank 1) (Figure 3B). The Canadian and Australian systems adopted the 4-Digit Code Rank 4 FAS facial phenotype using the 4-Digit Code Lip-Philtrum Guides, but like the Hoyme et al. system, documents the phenotype as present (4-Digit Code Face Rank 4) or absent (4-Digit Code Face Ranks 1-3). The clinical and research impact of dichotomizing the FAS facial phenotype is illustrated below in Objective 2C.

CNS abnormalities

CNS Functional Abnormalities: The Hoyme criteria that define neurobehavioral impairment appear broadly equivalent to the 4-Digit Code criteria for moderate to severe CNS dysfunction (CNS Ranks 2 and 3). The Canadian and Australian systems adopted the criteria introduced by the 4-Digit Code for severe CNS dysfunction (CNS Rank 3: 3 or more domains of function, 2 or more SDs below the mean). The Canadian and Australian systems exclude moderate dysfunction (the 4-Digit Code equivalent of ND/AE) from under the umbrella of FASD. CNS Structural Abnormalities: The Hoyme criteria for deficient brain growth, abnormal morphogenesis, or abnormal neurophysiology were equivalent to the 4-Digit Code criteria for CNS structural and neurological abnormalities (CNS Rank 4) with the exception of the cut-off used to define microcephaly (Hoyme criteria: ≤10th percentile; 4-Digit Code: ≤3rd percentile). The Canadian and Australian systems adopted the 4-Digit Code criteria for CNS structural abnormalities, but unlike the 4-Digit Code, do not allow structural abnormalities alone to meet the CNS criteria for FASD. Rather, CNS structural abnormalities must be accompanied by at least two domains of function 2 or more SDs below the mean to meet the Canadian and Australian CNS criteria for FASD.

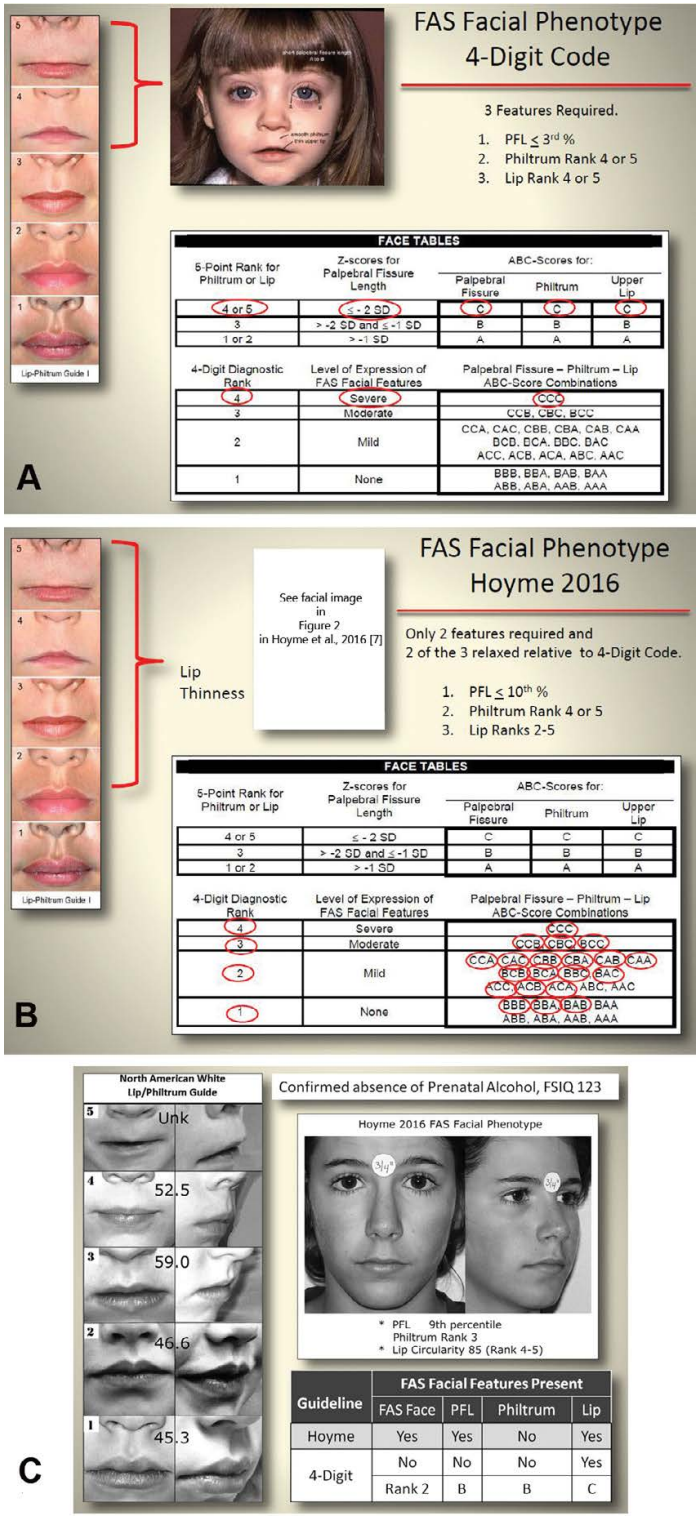

Figure 3. The Hoyme FAS facial phenotype is substantially relaxed relative to the 4-Digit Code.
(A) The 4-Digit Code FAS facial phenotype is defined by the Facial ABC-Score "CCC" as depicted in the Face Table on the backside of Lip-Philtrum Guide 1. (B) The relaxed criteria for the Hoyme FAS facial phenotype results in almost every 4-Digit Code Facial ABC-Score meeting the relaxed Hoyme facial criteria [10]. The prevalence of the FAS facial phenotype was 10-fold higher using the Hoyme criteria (n=552; 40%) compared to the 4-Digit Code (n=54; 4%). (C) The practical clinical impact of this relaxation is illustrated in which an adolescent with high function (e.g., FSIQ 123) and confirmed absence of PAE met the Hoyme criteria for the full FAS facial phenotype. Copyright Susan Astley Hemingway, University of Washington.

Alcohol exposure

The Hoyme 2016 criteria for documented PAE are more stringent than the 4-Digit Code and include thresholds (≥6 drinks/week for ≥2 weeks during pregnancy or ≥3 drinks per occasion on ≥2 occasions during pregnancy). The 4-Digit Code requires a confirmed exposure, but does not set thresholds because: 1) recall and reporting of quantity, frequency, and timing of exposure have been confirmed highly unreliable in a clinical setting (especially in populations like the FASDPN clinic where 85% of patients are not in their birth mother's care at the time of the evaluation); 2) details on quantity, frequency and timing are often unavailable; 3) exposure below a designated threshold has not been confirmed safe for all fetuses [17]; and 4) a recent twin study confirmed risk is not just determined by amount of exposure-fetal genetics modifies risk [18]. The Hoyme system allows FAS and PFAS to be diagnosed when exposure is unknown because the Hoyme FAS facial phenotype is required to be present. The Hoyme FAS facial phenotype, however, is only 71% [19] specific to PAE. The 4-Digit Code allows FAS to be diagnosed when exposure is unknown because FAS requires the presence of the Rank 4 FAS facial phenotype and the Rank 4 face is confirmed to be highly specific (95% specificity) to PAE [20]. The Australian system adopted the alcohol exposure criteria used by the 4-Digit Code. The Canadian system, in contrast, requires high exposure (≥ 7 drinks/week or ≥4 drinks per occasion on ≥2 occasions) when the Rank 4 FAS facial phenotype is absent. In the current study population, of the 1,177 with confirmed PAE, only 46% met the Hoyme or Canadian threshold for high exposure.

OBJECTIVE 2. COMPARISON OF DIAGNOSTIC OUTCOMES ACROSS THE FOUR SYSTEMS

Methods

Study population

The records of 1,392 patients were drawn from 1,522 consecutive patients that received an FASD diagnostic evaluation at the University of Washington Fetal Alcohol Syndrome Diagnostic & Prevention Network (FASDPN). The diagnostic evaluations were performed by interdisciplinary teams between 1993 and 2012 using the FASD 4-Digit Code [5]. The interdisciplinary teams included a medical doctor, psychologist, occupational therapist, speech language pathologist, social worker, family advocate, and public health professional [17,21]. All patients with one or both birth parents African American (130 of the 1,522) were excluded from the study because it was unclear which PFL normal growth chart to use for African Americans when applying the Hoyme system [22] and our findings in Astley et al. [10] and those reported by Hoyme [11] confirm the South African Mixed Race Lip/Philtrum Guide is inappropriate for use on an African American population.

Historically, all records resulting from each patient's FASD diagnostic evaluation have been entered into a research database since 1992 with University of Washington Human Subjects approval and patient consent. Over 95% of patients provide consent for their clinical data to be used for research purposes. Patients' records include the following standardized 4-Digit Code data forms: the New Patient Information Form, the FASD Diagnostic Form, digital facial photos, and the FAS Facial Photographic Analysis Report [5,12]. These data are entered into a research database shortly after the patient's FASD diagnostic evaluation reflecting the tools and growth norms available at that time. Over the decades the 4-Digit Code has evolved (1st edition 1997, 3rd edition 2004) [5,23-25], new tools have been developed like the FAS Facial Photographic Analysis Software (Version 1.0 in 2004, Version 2.1 in 2016) [12], and new more accurate growth norms have been adopted (CDC [26] and WHO [27] growth charts and Stromland Scandinavian PFL charts [28].

For the purposes of research, all patients' clinical 4-Digit Codes are updated to "research" 4-Digit Codes to reflect the most current tools and norms available at the time of the research study. For this study, all 4-Digit Codes were updated to reflect the most current 2004, 3rd edition of the 4-Digit Code [5].

Application of the diagnostic tools and norms

The following tools and norms were used to update the 4-Digit Code FASD diagnoses and generate the Hoyme [7], Canadian [6] and Australian [8] FASD diagnoses

Growth

The Hoyme criteria use the same cut-off (prenatal or postnatal height and/or weight ≤10th percentile) to define growth deficiency as the 4-Digit Code, thus all patients with 4-Digit Code Growth Ranks 2,3 or 4 were classified as meeting the Hoyme growth deficiency criteria.

Height and weight normal growth charts: Height and weight percentiles were generated from the Hall [29] birth weight and length growth charts by gestational age; the World Health Organization (WHO) [27] height and weight growth charts for children 0-2 years of age, and the Centers for Disease Control (CDC) 2000 [26] height and weight growth charts for patients 2 years of age and older. The height percentile was adjusted for mid-parental height [30] when both parents' heights were reported. The Canadian and Australian systems excluded growth deficiency as a criterion for FASD.

Facial features

At the time of each patient's FASD diagnostic evaluation, three standardized, digital facial photographs (Figure 4) were taken and measured using the FAS Facial Photographic Analysis Software [12]. As a result, each patient's research record included the following facial measures: PFLs in millimeters, philtrum smoothness (Rank 1 to 5 on the 4-Digit Code Lip-Philtrum Guide1) and upper lip circularity (perimeter^2/area) and corresponding Lip Rank (Rank 1 to 5 on the 4-Digit Code Lip-Philtrum Guide 1).

Palpebral fissure length: For the 4-Digit Code and Hoyme systems, PFL z-scores were updated to reflect the Stromland Scandinavian PFL growth charts [28]. The Stromland charts are confirmed valid for use on a North American population [13] and address the full age span (birth through adult) represented in our study population. In addition, the Stromland PFL growth charts were generated from digital images, thus meeting the recommendation by Hoyme [7] that PFLs measured from photos should be compared to PFL normal growth charts generated from photos. The Hoyme system cites the Canadian PFL charts [14] as one of several published norms obtained from 2-dimensional photography that one may use, but

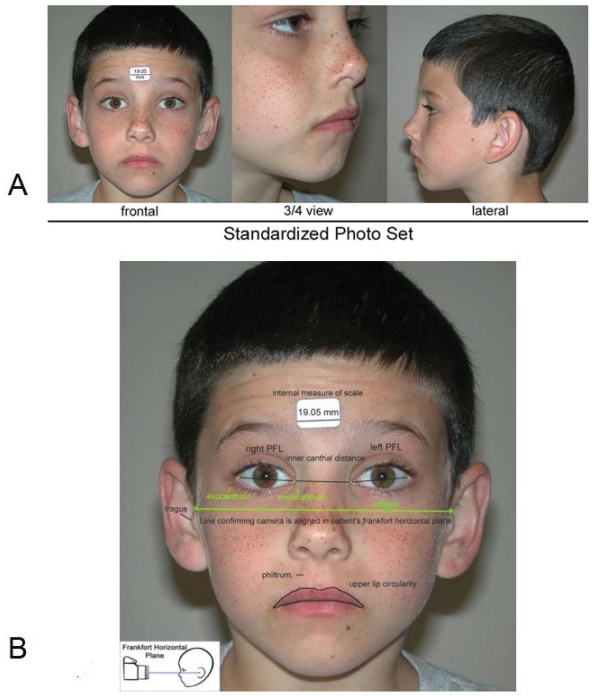

Figure 4. The FAS Facial Photographic Analysis Software [12] was Used to Measure the 3 FAS Facial Features.
A) The palpebral fissure length (PFL), philtrum smoothness, and upper lip thinness are measured from three standardized, digital photographs. B) Standardization includes proper rotation, exposure, focus, and facial expression. An internal measure of scale (a 3/4 inch (19.05 mm) paper sticker) is placed on the forehead to measure the PFLs in millimeters. A video demonstration of the software can be viewed at this link: http://depts.washington.edu/fasdpn/movie/software1024-768cd2.mp4. Copyright Susan Astley Hemingway, University of Washington.

the Canadian norms start at 6 years of age. As demonstrated in Astley et al. [13] transition from the Stromland PFL norms to the Canadian PFL norms at 6 years of age results in an abrupt, artificial decrease in the prevalence of short PFLs due to the discrepancy between the two norms. To avoid this artifact, the Stromland PFL charts that span the entire lifespan were used for the Hoyme system. In accordance with the Canadian and Australian systems, the Canadian PFL growth charts [14] were used for patients 6 years of age and older. The Stromland growth charts [28] were used for patients less than 6 years of age.

Philtrum smoothness and upper lip thinness: The 4-Digit Code "Caucasian" Lip-Philtrum Guide 1 (Figure 1A) was used to Rank philtrum smoothness and upper lip thinness for the 4-Digit Code, Canadian and Australian systems. The Hoyme North American Lip/Philtrum Guide (Figure 1C) was used to rank philtrum smoothness and lip thinness for the Hoyme et al. system. Since the images depicting the Rank 1 through 5 philtrums on the 4-Digit Code and Hoyme guides appeared broadly equivalent (per Objective 1), the philtrum rank assigned at the time of diagnosis using the 4-Digit Code guide was the same philtrum rank assigned to the patient using the Hoyme guide (Figure 1C) (e.g., if the patient had a Rank 4 philtrum using the 4-Digit Code guide, they received a Rank 4 philtrum using the Hoyme guide). In contrast, the analyses in Objective 1 [10] confirmed the Rank 1 through 5 images depicting upper lip thinness did not match between the 4-Digit Guide 1 and the Hoyme North American Guide (Figure 2A). The 4-Digit Code uses the full range of Lip Ranks 1-5 to classify the FAS facial phenotype on a 4-point Likert scale from normal (Face Rank 1) to severe FAS (Face Rank 4). In contrast, the Hoyme FAS/PFAS facial criteria measure lip thinness on a dichotomous scale (thin: ≥ Rank 4, not thin: <Rank 4 on the Hoyme North American Lip/Philtrum Guide (Figure 1C) to classify the FAS/PFAS facial phenotype on a dichotomous scale (present, absent). To accurately and objectively identify which patients met the Hoyme diagnostic criteria for a thin upper lip (≥Rank 4), the Rank 4 upper lip on the Hoyme North American Lip/Philtrum Guide was outlined using the facial software's circularity tool. The video clip in Figure 2C demonstrates this procedure. The circularity of the Hoyme Rank 4 lip was 52.5; equivalent to the 4-Digit Rank 2 lip (defined by the circularity range 42.5 to 57.4). Thus all patients with an upper lip circularity of 52.5 or greater met the Hoyme criteria for a thin upper lip (Rank 4 or 5 on the Hoyme North American Lip/Philtrum Guide).

CNS dysfunction

Based on our findings in Objective 1, all patients with 4-Digit Code CNS Ranks of 2 or 3 (moderate or severe CNS dysfunction) were classified as broadly equivalent to the Hoyme criteria for neurobehavioral impairment (at least 1 domain 1.5 SDs below the mean). All patients with 4-Digit Code CNS Rank 3 (severe dysfunction) were classified as meeting the Canadian and Australian criteria for severe dysfunction (3 or more domains of function, 2 SDs below the mean). All patients with 2 domains of severe dysfunction and microcephaly (OFC≤3rd percentile) also met the Canadian and Australian criteria for severe dysfunction.

CNS structural abnormalities

Based on our findings in Objective 1, all patients with a 4-Digit Code CNS Rank4 (structural/neurological abnormalities) were classified as meeting the Hoyme criteria for deficient brain growth, abnormal morphogenesis, or abnormal neurophysiology. In addition, all patients with an OFC ≤10th percentile were classified as meeting the Hoyme CNS structural criteria. All patients with a 4-Digit Code CNS Rank 4 (structural/neurological abnormalities) were classified as meeting the Canadian criteria for impairment in neuroanatomy or neurophysiology and the Australian criteria for abnormal brain structure/neurology. In contrast to the Hoyme et al. system, the 4-Digit Code, Canadian and Australian systems use a cut-off of ≤3rd percentile for microcephaly. The WHO [27] OFC charts for children 0-5 years of age and the Nellhaus [31] OFC growth charts for children 5-18 years of age were used for all four systems

Statistical analyses

Descriptive statistics (valid percentages) were used to profile the study population. Chi-square tests were used to compare groups and linear trends across groups for outcomes measured on nominal or ordinal scales. One-way analysis of variance (ANOVA) was used to compare means and detect linear trends across three or more groups when outcomes were measured on a continuous scale. T-tests were used to compare means between two independent groups.

Various measures of performance (validity) were administered

to each system to address Objective 2C. Validity is the degree to which a tool (or diagnostic system) is measuring what it purports to measure. Validity is not determined by a single statistic, but by a body of research that demonstrates the relationship between the diagnostic system and the condition it is intended to measure. There are three overarching forms of validity: content validity, criterion validity, and construct validity. Content Validity is a measure of how well the items in the diagnostic system represent the entire range of possible items the diagnostic system should cover. Criterion validity is a measure of a diagnostic tool's accuracy relative to a gold standard. Construct validity refers to the degree to which a test measures what it claims, or purports, to be measuring. It refers to the ability of a measurement tool to measure the physiological concept being assessed. Convergent and discriminant validity are two subtypes of construct validity. Convergent validity refers to the degree to which two measures of constructs that theoretically should be related are in fact related. In contrast, discriminant validity tests whether concepts or measurements that are supposed to be unrelated are in fact unrelated. An important aspect of clinical research is the inference that an association represents a cause-effect relationship. Features of associations that support causation include: the strength of the association; the consistency of observed evidence; specificity of the relationship; temporality of the relationship; the biological gradient of dose-response, biological plausibility; and experimental confirmation. Predictive validity refers to a tool's ability to predict something it should theoretically be able to predict. Statistical measures used to assess these constructs include linear correlation coefficients and tests for trends. Fundamental measures of diagnostic accuracy include sensitivity and specificity. The sensitivity of a test is the proportion of people with the condition who test positive for it (the true positive rate). The specificity of a test is the proportion of people who do not have the condition who test negative for it (the true-negative rate).

Results

Study population

The clinical and socio-demographic profile of the study population (N=1,392) is presented in Table 3. The population spanned the entire age range from newborn to adult with 57% Caucasian and 44% female. Eighty-five percent had confirmed PAE; 15% had unknown PAE. Patients with unknown PAE were included because all four diagnostic systems allow a diagnosis of FAS when PAE is unknown. Since the publication of the 2017 study comparing the 4-Digit Code to the Hoyme system [10], updated information became available on 2 of the 1,392 patients, impacting the distribution of diagnoses generated by the two systems by a fraction of a percent in this study relative to the 2017 study.

Objective 2a: Compare the prevalence of FASD diagnostic outcomes generated by the four systems

The distribution of diagnoses varied substantially across the 4 systems as illustrated in Table 4 and Figures 5A and 5B.

The proportion of patients diagnosed with FAS and FASD varied significantly across the systems (4-Digit 2.1% and ≤79%; Australian 1.8% and 29%; Canadian 1.8% and 16%; and Hoyme 6.4% and 44% (Figure 5A). Even though the proportion of patients diagnosed with FAS (1.8%-2.1%) by the 4-Digit, Canadian and Australian systems was comparable, the patients that made up the 2% within each system were different (see Objective 2b). The distribution of diagnoses also varied substantially across the four systems among the subset of patients <6 years of age at the time of diagnosis (Figure 5B). Key factors contributing to the diagnostic variability include:

1) The Canadian and Australian systems exclude moderate dysfunction as an outcome caused by PAE. This resulted in the greatest magnitude of diagnostic variability between the 4 systems. Exclusion of moderate dysfunction prevented a Canadian diagnosis of FASD in 666 patients with moderate dysfunction and confirmed PAE (48% of whom had confirmed high PAE). 76% had 1 or 2 (but not 3) domains of severe dysfunction and all had multiple domains of moderate dysfunction. Exclusion of moderate dysfunction prevented an Australian diagnosis of FASD in 642 patients with moderate dysfunction and confirmed PAE (50% of whom had confirmed high PAE). 74% had 1 or 2 (but not 3) domains of severe dysfunction and all had multiple domains of moderate dysfunction. Primate research confirms moderate dysfunction (ND/AE) is the most prevalent outcome caused by PAE (5% FAS/PFAS, 31% SE/AE; 59% ND/AE, 5% not FASD) (Figure 6). Only the 4-Digit Code replicated this distribution of diagnoses observed in the primate model of FASD as discussed more fully below. Fifty-three percent of the 1,177 patients with confirmed PAE received a diagnosis of ND/AE using the 4-Digit Code (65% were over 6 years of age).
2) The Canadian and Hoyme systems require confirmed high exposure to alcohol in the absence of the FAS facial phenotype. This prevented 47% of 1,155 patients with confirmed PAE, but without the FAS facial phenotype from receiving a FASD diagnosis using the Canadian system. Forty-three percent of these 548 patients had 1 to 2 domains of severe dysfunction; 34% had 3 or more domains of severe dysfunction. The requirement for high PAE also prevented 59% of 664 patients with confirmed PAE, but without the Hoyme FAS facial phenotype, from receiving a FASD diagnosis using the Hoyme system. Forty-two percent of these 389 patients had 1 to 2 domains of severe dysfunction; 33% had 3 or more domains of severe dysfunction. For reference, the proportion of patients with confirmed high PAE (Alcohol Rank 4) within each FASD diagnosis rendered by the 4-Digit Code is marked by yellow lines (Figures 5A and 5B).
3) The Australian and Canadian systems excluded growth deficiency as a criterion for FASD. This prevented the early identification of 70% of children <8 years old with confirmed PAE and growth deficiency as especially high risk for severe brain dysfunction (3 or more domains of function 2 or more SDs below the mean) later in childhood [9]. More specifically, of the 770 patients classified as Not FASD by the Australian system, 559 had confirmed PAE. Of the 559 with confirmed PAE, 221 were under 8 years of age and 69 presented with Growth Rank 2, 3 or 4 (height and/or weight at or below the 10th percentile). Seventy-percent of these children with confirmed PAE and growth deficiency will present with severe CNS dysfunction later

Table 3. Sociodemographic and 4-Digit Code clinical profile of the study population (n=1,392).

in childhood when they are old enough to participate in a comprehensive neuropsychological assessment. None were identified as "At Risk" by the Australian system. Of the 822 children classified as Not FASD by the Canadian system, 611 had confirmed PAE. Of the 611 with confirmed PAE, 176 were under 8 years of age and 48 presented with Growth Rank 2, 3 or 4. Seventy-one percent of these children with confirmed PAE and growth deficiency will present with severe CNS dysfunction after the age of 8 years. None were identified as "At Risk" by the Canadian system.

4) Relaxation of the FAS facial criteria by the Hoyme system (Figure 3), resulted in ten times more patients presenting with the "Hoyme FAS facial phenotype" (552, 40%) than the Rank 4 FAS facial phenotype (54, 4%) used by the 4-Digit Code, Canadian and Australian systems [10]. Seventy-one percent of the 552 patients with the Hoyme FAS facial phenotype had 4-Digit Code Face Ranks 1 and 2. The relaxed Hoyme criteria also resulted in a clinically significant reduction in facial specificity (71% to 75%) [19,32] to alcohol relative to the Rank 4 FAS facial phenotype (>95% specificity) [10]. Of the 552 patients with the Hoyme FAS facial phenotype, almost half (43%) did not receive a diagnosis under the umbrella of FASD using the Hoyme system. In contrast, all 54 patients with the 4-Digit Code Rank 4 FAS face met criteria for a diagnosis under the umbrella of FASD using the 4-Digit Code. More details on these outcomes are presented in Astley et al. [10].

5) Switching from the Stromland PFL growth charts to the Clarren PFL growth charts at 6 years of age, as recommended by the Canadian and Australian systems, can result in the FAS facial phenotype appearing to "disappear" at age 6 years. Although the Stromland PFL growth charts [28] span the entire age range from birth to adult, the Canadian and Australian systems recommend use of the Clarren PFL normal growth charts [14] that start at age 6 years and the Stromland PFL charts for children under 6 years of age. This results in an artificial decrease in the prevalence of short PFLs and the FAS facial phenotype in children >6 years of age because the mean PFL for age in the Clarren charts is roughly half a SD larger than the PFL in the Stromland charts in Figure 2 in [13]. A PFL of 23 mm in a 6 year old boy is -2.1 SDs on the Stromland charts, but -1.6 SDs on the Clarren charts. To illustrate the impact this has on diagnostic outcomes, of the 30 patients >6 years of age with the Rank 4 FAS facial phenotype using the Stromland PFL charts, only 21 met the Rank 4 FAS facial phenotype criteria using the Clarren PFL charts. This is a 30% reduction in prevalence of the FAS facial phenotype. The discrepancy between the two charts will also result in the FAS facial phenotype appearing to "disappear" with age. If a child presents with the FAS facial phenotype using the Stromland charts at age 5 years, the child will appear to lose the FAS facial phenotype upon re-evaluation at 6 years of age as a result of switching to the Clarren PFL charts. The 4-Digit Code recommends use of the Stromland PFL

Table 4. Prevalence and concordance of FASD diagnoses across the four diagnostic systems.

Variables	Diagnoses generated by the four systems and the various names applied to each													
	FAS, FASD/with Face		PFAS		SE/AE, ARND-severe*, FASD/no Face		ND/AE, ARND-moderate**		ARBD		"FASD" FASD		Not FASD (includes At-Risk)

Number diagnosed by all 4 systems														
	12	0.9	19	1.4	53	3.8	0	0	0	0	152	10.9	235	16.9

* ARND-severe: patients with 3 or more functional domains -2 SDs below the mean. ** ARND-moderate: patients with 2 or more functional domains -1.5 SDs below the mean, but less than 3 functional domains -2 SDs below the mean. "FASD": 4-Digit Code includes FAS and PFAS under the FASD umbrella, but notes SE/AE and ND/AE are only FASDs if a patient's prenatal alcohol exposure caused their SE or ND.

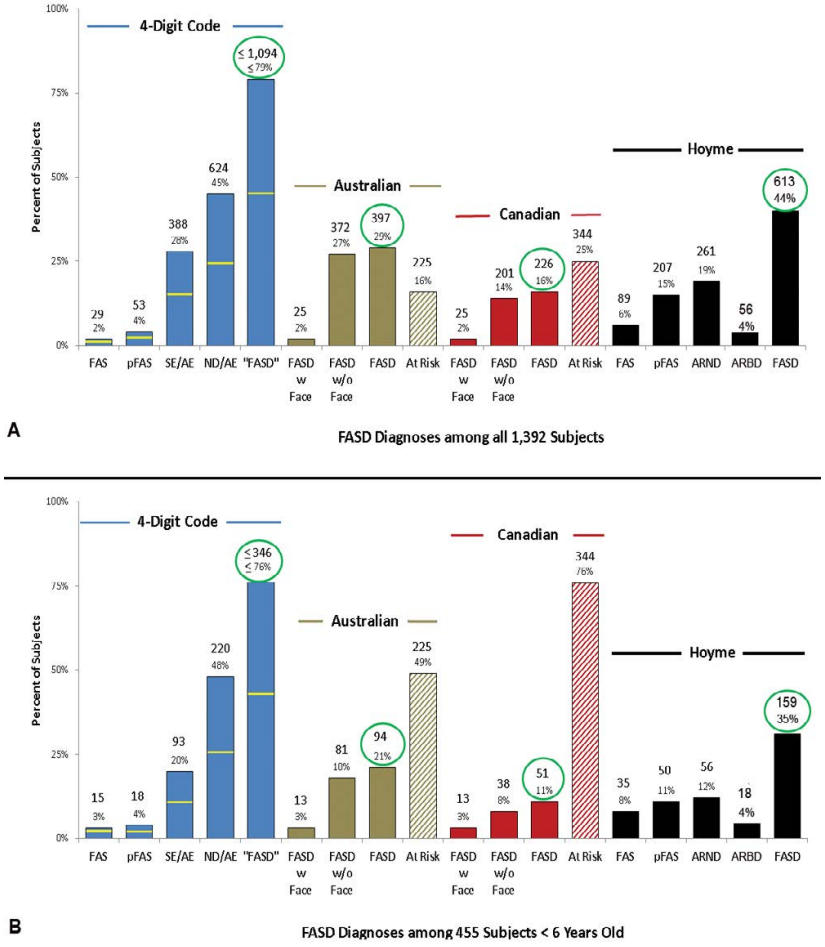

Figure 5. FASD diagnostic outcomes are compared across the four FASD diagnostic systems.
(A) Diagnoses across the entire population (n=1,392). (B) Diagnoses across the subset of 455 patients less than 6 years of age at the time of diagnosis. The yellow lines on the blue bars reflect the proportion of patients with confirmed high PAE (4-Digit Code Alcohol Rank 4). The bars labeled FASD for each system reflect the total number of patients diagnosed under the umbrella of FASD by each system. The term "FASD" is in quotes for the 4-Digit Code to denote that the 4-Digit Code defines FASD as including FAS, PFAS and only those individuals whose SE or ND was caused (at least in part) by their prenatal alcohol exposure.

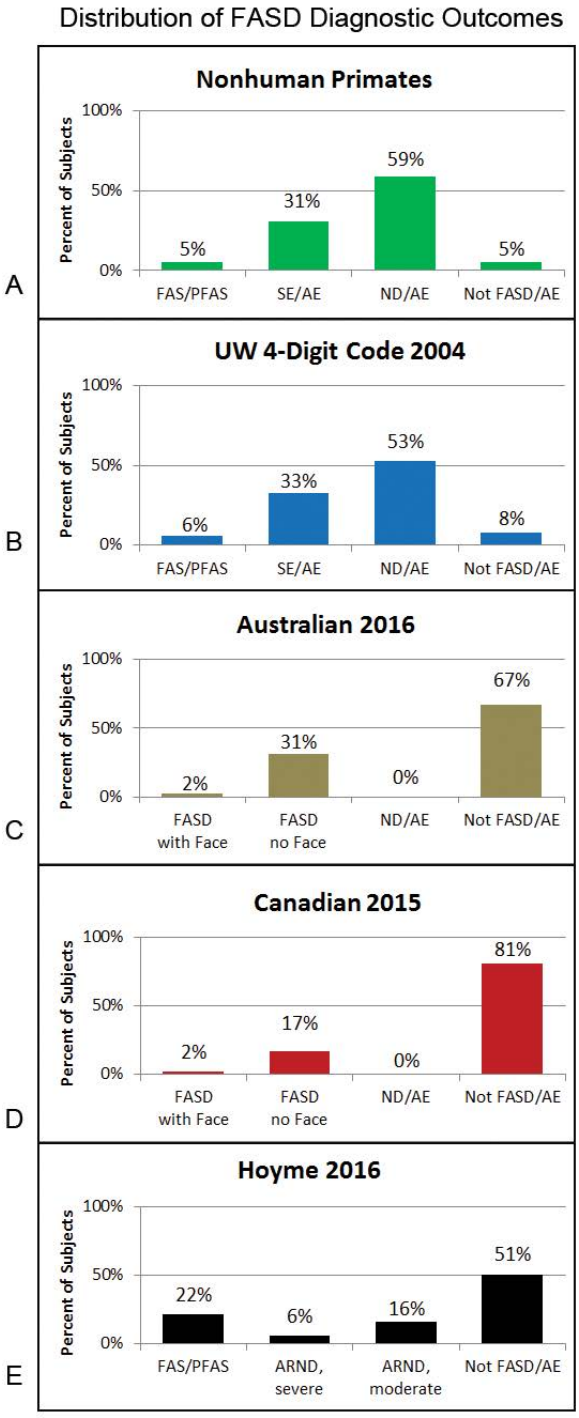

Figure 6. Nonhuman-primate study confirms moderate dysfunction is the most prevalent outcome under the umbrella of FASD.
(A) The 4-Digit Code was applied to the outcomes observed in our highly controlled primate model of FASD [4] where PAE was the only risk factor. Moderate dysfunction (ND/AE) was the most prevalent outcome (59%). (B) The 4-Digit Code was the only diagnostic system that replicated the distribution of diagnoses observed in the primate model. (C-D) The Australian and Canadian systems omit moderate dysfunction from FASD. B-E) The bar charts reflect the distribution of diagnostic outcomes across the 4 systems among the 1,177 patients with confirmed PAE.

Abbreviations: AE: Alcohol Exposed; ARND: Alcohol Related Neurodevelopmental disorder; ND: Neurobehavioral Disorder; SE: Static Encephalopathy. ARND-severe reflect the subset of patients meeting the Hoyme ARND criteria that have 3 or more domains of function≤2 SDs below the mean (rendering it comparable to SE/AE and FASD/no Face. ARND-moderate is the remainder of patients meeting the Hoyme ARND criteria that have less than 3 domains≤2 SDs below the mean.

charts across the full age span [13] to avoid these artifacts in measurement.

6) The Hoyme system includes Alcohol Related Birth Defects (ARBD/AE) under the umbrella of FASD; the other systems do not. Fifty-six individuals met the Hoyme criteria for ARBD/AE (Figure 5A). Of the list of defects that meet the Hoyme criteria for ARBD/AE (Table 2), four types of defects were observed among the 276 patients who met the Hoyme alcohol criteria, but did not meet the Hoyme criteria for FAS, PFAS or ARND. The number of patients presenting with each feature was as follows: strabismus (5), ptosis (36) cardiac anomalies (12) and scoliosis (8). Seven of the 56 patients presented with two of these features. The reported prevalence of these features across the entire study population of 1,392 patients was ptosis (9.0%), cardiac anomalies (3.9%), strabismus (0.5%) and scoliosis (0.4%). Cardiac anomalies were significantly more prevalent among patients receiving a FASD diagnosis (6.5%) using the Hoyme system than among those not receiving a FASD diagnosis (1.9%) (Chi^2 19.2, p=0.000). Ptosis was also significantly more prevalent among patients receiving a FASD diagnosis (14.4%) using the Hoyme system than among those not receiving a FASD diagnosis (4.6%) (Chi^2 38.7, p=0.000). Cardiac anomalies and ptosis were also significantly more prevalent among patients with FASD than without FASD when the other three systems (4-Digit Code, Australian and Canadian) were used to generate the FASD diagnoses. None of these anomalies were significantly correlated with any measure of PAE available in the FASDPN dataset.

Objective 2b: Assess diagnostic discordance/concordance between the four systems

Very little diagnostic concordance was observed across all four diagnostic systems. Of the 1,392 patients, 1,138 (82%) were diagnosed with FASD by at least one of the four systems (Table 4). In contrast, only 152 (11%) were diagnosed with FASD by all four systems. Of the 107 (8%) diagnosed with FAS by at least one of the 4 systems, only 12 (1%) were diagnosed FAS by all four systems.

The patient-by-patient diagnostic outcomes generated by the 4-Digit Code were compared directly with the diagnoses generated by the Hoyme (Figure 7) Canadian (Figure 8) and Australian (Figure 9) systems. The Canadian system was also compared directly with the Australian system (Figure 10) and the Hoyme system in (Figure 11). Of the 1,392 patients, concordant diagnoses (including those being classified as "Not FASD") were as follows: 4-Digit vs Canadian: 31%; 4-Digit vs Hoyme: (38%); 4-Digit vs Australian: (45%); Canadian vs Hoyme (39%) and Canadian vs Australian: (82%). The higher level of concordance between the Canadian and Australian systems is due to the fact that the Australian system adopted the criteria used by the Canadian system, with one important exception. The Canadian system requires confirmed high PAE. The Australian system requires confirmed PAE at any reported level. The higher

level of concordance between the Canadian and Australian systems was due largely to the high proportion (66%, 918/1,392) of patients classified as not under the umbrella of FASD ("At Risk" and "Not FASD").

The discordance across the systems ranged from subtle differences (e.g., the patient received a diagnosis of FAS by one system and PFAS by another system) to marked contrasts (e.g., the patient received a diagnosis of FAS by one system and no diagnosis under the umbrella of FASD by another system). A few examples of these marked contrasts include the following. Additional contrasts are presented in the legends for Figures 7-11.

1. Of the 21 patients that received a diagnosis of FAS/Alcohol Exposed using the 4-Digit Code, 7 had FASD ruled-out altogether using the Hoyme system (see the 4-Digit Code FAS/AE column in Figure 7). All 7 patients were less than 5 years of age. They presented with CNS structural abnormalities (e.g., microcephaly: OFC≤3rd percentile), but early development was broadly within the normal range. All 7 were too young to engage in the necessary level of testing to accurately rule-out moderate or severe CNS dysfunction. The Hoyme system requires both CNS structural abnormalities (e.g., OFC≤10th percentile) and evidence of moderate to severe CNS dysfunction for a diagnosis of FAS.
2. Among the 207 patients that were classified "Not FASD" by the 4-Digit Code, 15 received a FAS diagnosis and 23 received a PFAS diagnosis using the Hoyme system (Figure 7). The 4-Digit Code does not render a diagnosis under the umbrella of FASD if: 1) alcohol exposure is unknown and 2) the Rank 4 FAS facial phenotype is absent. If an individual does not have a confirmed PAE, the 4-Digit Code Rank 4 FAS face can serve as confirmation of exposure because the phenotype is confirmed to be so highly specific to (caused only by) PAE (> 95% specificity) [17]. The Hoyme system allowed these 38 patients with unknown alcohol exposures to receive a diagnosis of FAS or PFAS because they presented with the Hoyme FAS face. But the Hoyme FAS facial criteria are so relaxed (specificity 71% to 75% [19,32]), the facial phenotype does not provide the necessary level of specificity to alcohol to use the facial phenotype to confirm exposure. Among the 38 individuals with unknown PAE and a Hoyme diagnosis of FAS or PFAS, 18 had relaxed PFLs (4th-10th percentile), 16 had relaxed philtrums (4-Digit Philtrum Ranks 2 and 3), 22 had relaxed lips (4-Digit Lip Ranks 1-3); 4 had no FAS facial features (4-Digit Face Rank 1); and 19 had only 1 FAS facial feature (4-Digit Face Rank 2).
3. Among the 779 patients that were classified "Not FASD" using the Hoyme system, 24 received a FAS/PFAS diagnosis using the 4-Digit Code (Figure 7, red bars in the Hoyme "Not FASD" row). All 24 presented with the Hoyme FAS face, but none met the Hoyme FAS or PFAS diagnostic criteria. The Hoyme FAS criteria require the presence of both CNS structural abnormalities (e.g., OFC≤10th percentile) and neurobehavioral impairment. Fifteen presented with a small head circumference (OFC≤10th percentile), but did not present with neurobehavioral impairment. All 15 were under 6 years of age. Of the 15 infants/toddlers, all were microcephalic (OFC≤3rd percentile), but did not present with developmental delay >1.5 SD below the mean. Nine of the 24 presented with severe CNS dysfunction, but were normocephalic. Of the 22 with confirmed PAE, 7 had levels that were reportedly too low to meet the Hoyme alcohol exposure criteria.
4. Among 82 patients diagnosed FAS/PFAS by the 4-Digit Code, 21 were classified as "Not FASD" by the Canadian system (Figure 8). Of the 4 with FAS/Alcohol unknown, all were > 6 years of age with microcephaly, but 2 with severe CNS dysfunction did not meet the Canadian FAS face criteria (the PFLs were -1.7 SDs on the Clarren PFL charts [14] used by the Canadian system, compared to -2.5 SDs on the Stromland PFL charts [28] used by the 4-Digit Code). The other 2 patients met the Canadian facial criteria, but did not meet the severe CNS criteria, despite their microcephaly. Of the 17 with PFAS/AE, all had Rank 3 facial phenotypes (classified as "normal" by the Canadian system) and 14 had Rank 3 alcohol exposure (not meeting the high PAE required by the Canadian system). The remaining 3 had high PAE and microcephaly, but did not meet the Canadian requirement for severe CNS dysfunction.
5. Among 624 patients diagnosed ND/AE by the 4-Digit Code, 220 received an "At Risk" classification, and 404 received a "Not FASD" classification by both the Australian (Figure 9) and Canadian (Figure 8) diagnostic systems. The 404 patients classified "not FASD" by the two systems were all >6 years of age with confirmed PAE (half with confirmed high PAE). Eighty-seven percent had 1 or 2 (but not 3) domains of severe dysfunction and all had multiple domains of moderate dysfunction. The Australian and Canadian systems do not classify patients with moderate dysfunction under the umbrella of FASD. Primate research documents moderate dysfunction is the most prevalent outcome (59%) caused by prenatal alcohol exposure (Figure 6A).
6. Among the 372 patients diagnosed "FASD without the Face" by the Australian system, only 201 (54%) received the same diagnosis from the Canadian system (Figure 10). The remaining 46% (42+129) had confirmed PAE, but did not receive a FASD diagnosis by the Canadian system because they did not meet the Canadian requirement for high PAE.

Objective 2c: Assess measures of performance (validation)

Validity is the degree to which a tool (or diagnostic system) is measuring what it purports to measure. Space does not permit a comprehensive assessment of performance across all 4 systems. Below are select examples to demonstrate the impact different measurement scales and criteria can have on the clinical and research performance of the diagnostic systems. The Reader is referred to Astley [17] for a comprehensive assessment of validation of the 4-Digit Code.

Correlation between the FAS Facial Phenotype and Prenatal Alcohol Exposure

All four systems allow a diagnosis of FAS to be made in the absence of confirmed PAE because the FAS facial phenotype is so highly specific to (caused only by) PAE, the required presence of the face serves as confirmation of PAE. For this practice to be medically valid, the FAS facial phenotype has to be highly specific to PAE. The

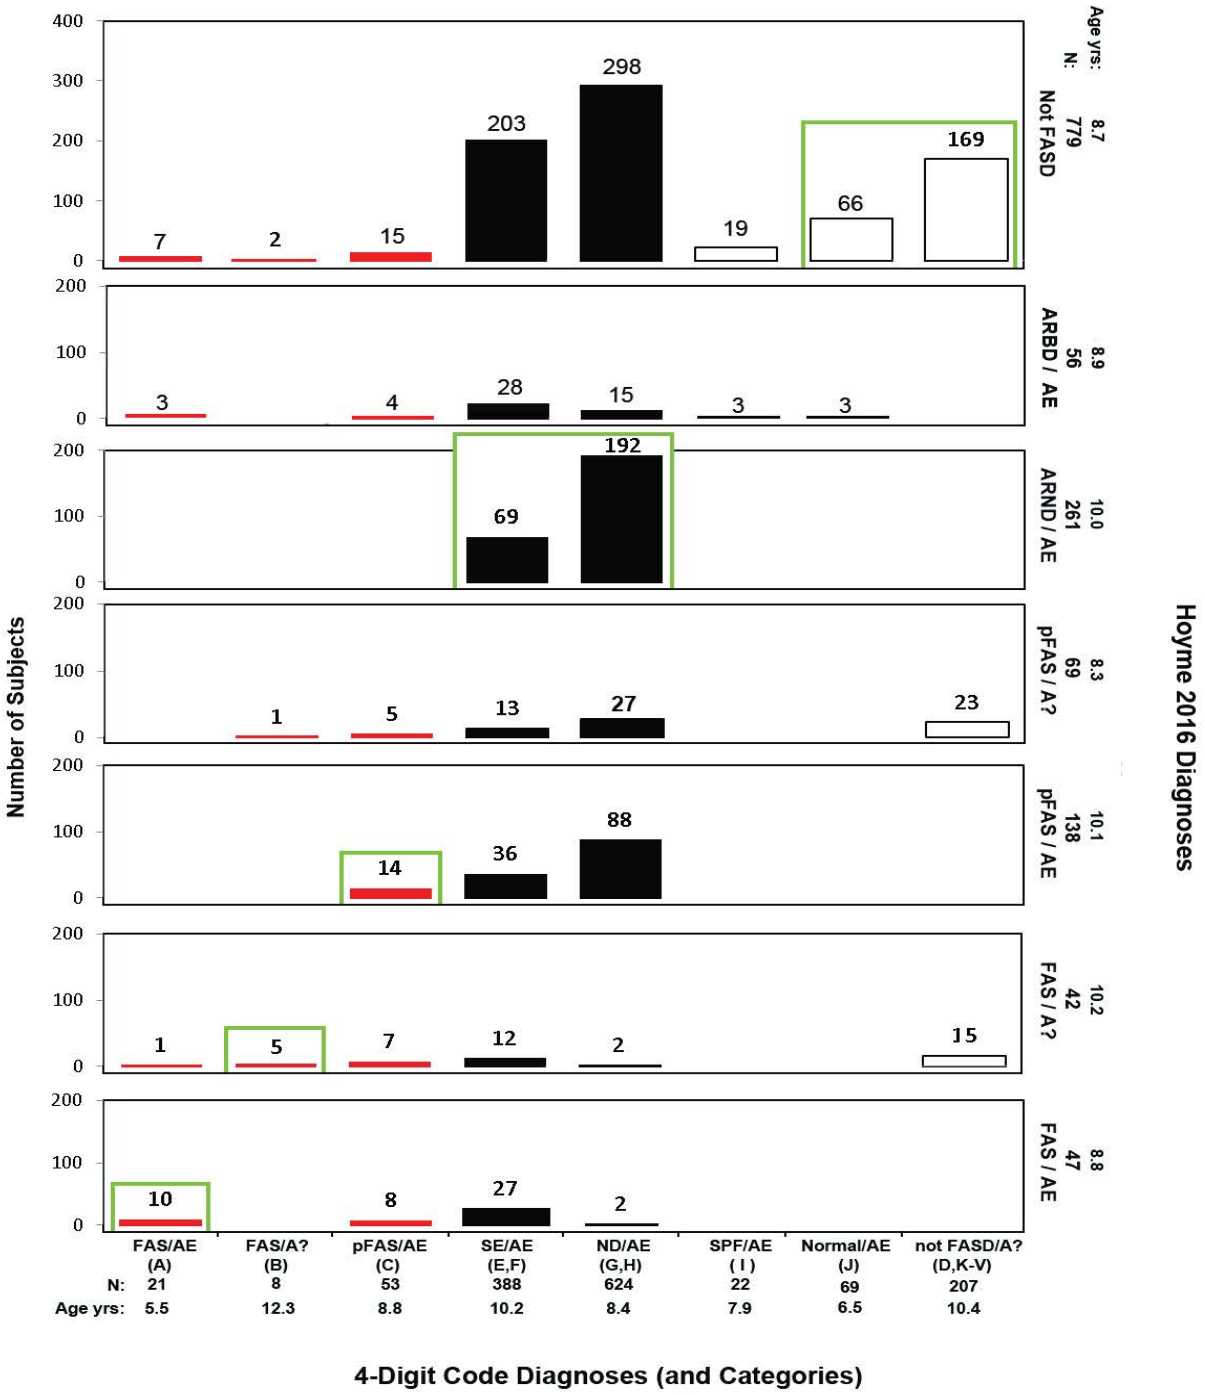

Figure 7. Cross-tabulation of the 4-Digit Code and Hoyme 2016 FASD Diagnostic Outcomes.
Diagnostic concordance (green boxes) between the 4-Digit Code and Hoyme 2016 systems was observed in 38% (528/1,392) of the patients. Red bars reflect FAS and PFAS diagnoses using the 4-Digit Code. Black bars reflect the rest of the FASD spectrum using the 4-Digit Code. As a demonstration for how to interpret this figure; 21 patients received a 4-Digit Code Diagnosis of FAS/AE. Of the 21 patients, 10 received a FAS/AE diagnosis, 1 received a FAS/A? and 10 did not receive a diagnosis under the umbrella using the Hoyme 2016 diagnostic system.
Abbreviations: 4-Digit Code Categories A-V are case-defined in the Diagnostic Guide for FASD [5]. AE: alcohol exposed; A?: alcohol exposure unknown; ND: neurodevelopmental disorder; Not FASD/A?: Individuals who present with or without growth, facial, and/or CNS abnormalities, but are not under the umbrella of FASD because their prenatal alcohol exposure is unknown and they do not meet the criteria for FAS/A?. SE: static encephalopathy; SPF: Sentinel Physical Findings, individuals who present with growth deficiency and/or 1 to 3 FAS facial features, but have normal CNS structure and function; Normal: no evidence of growth, facial, or CNS structural/functional abnormalities. Age yrs; mean age in years at diagnosis.

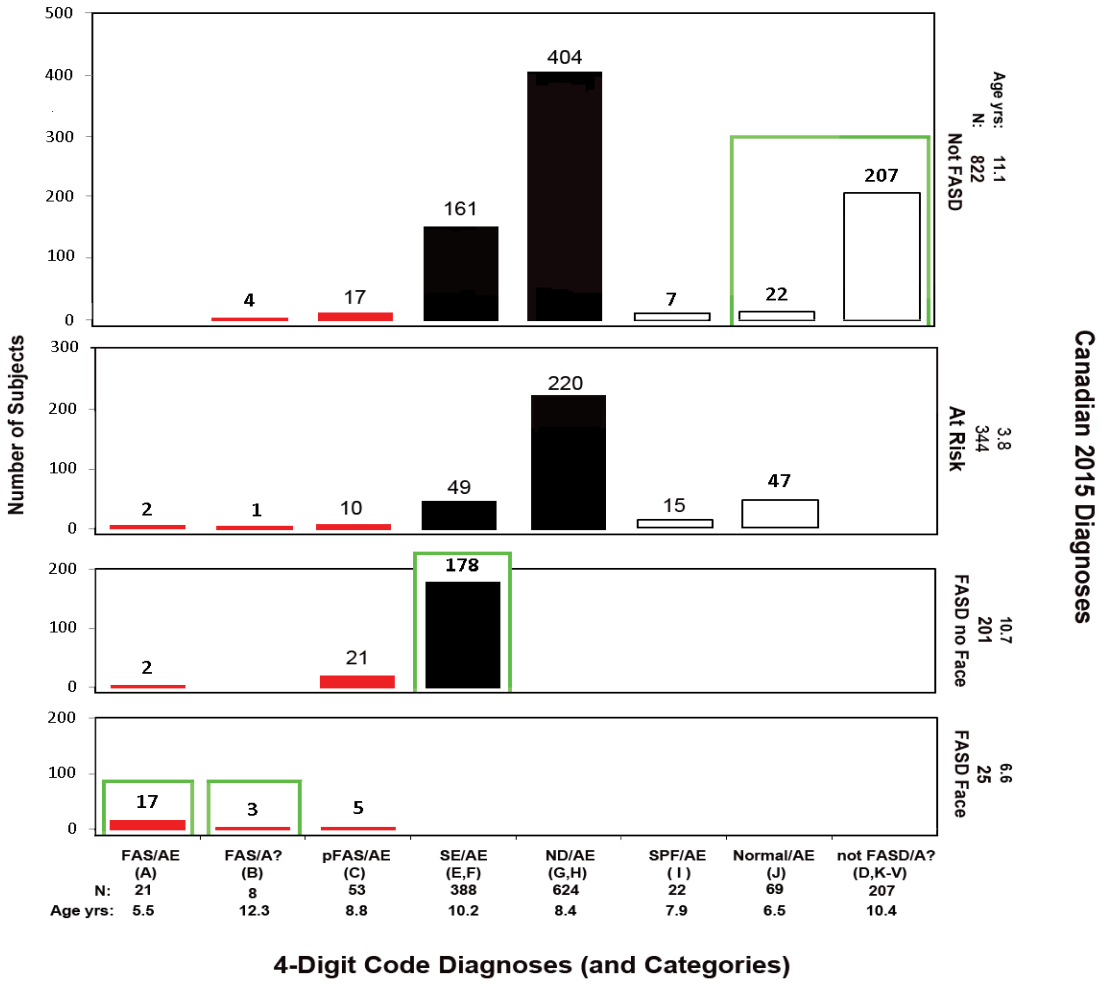

Figure 8. Cross-tabulation of the 4-Digit Code and Canadian 2015 FASD Diagnostic Outcomes.
Diagnostic concordance (green boxes) between the 4-Digit Code and Canadian 2015 systems was observed in 31% (427/1,392) of the patients. Red bars reflect FAS and PFAS diagnoses using the 4-Digit Code. Black bars reflect the rest of the FASD spectrum using the 4-Digit Code. As a demonstration for how to interpret this figure; 388 patients received a 4-Digit Code Diagnosis of SE/AE (severe CNS abnormalities with confirmed PAE). Of the 388 patients, 178 received a "FASD without the Face" diagnosis, 49 received an "At-Risk" classification and 161 received a "Not FASD" classification using the Canadian diagnostic system. All 49 At-Risk are <6 years with confirmed PAE. Over half have severe dysfunction, but do not meet the high PAE criteria for FASD. The remaining has microcephaly, but do not meet the severe dysfunction criteria for FASD. The 161 classified "Not FASD" have the same profile as those classified "At Risk", but all are > 6 years of age, thus will not present with both high PAE and severe dysfunction later in childhood as required for a Canadian FASD diagnosis.
Abbreviations: 4-Digit Code Categories A-V are case-defined in the Diagnostic Guide for FASD [5]. AE: alcohol exposed; A: alcohol exposure unknown; ND: Neurodevelopmental Disorder; Not FASD/A: Individuals who present with or without growth, facial, and/or CNS abnormalities, but are not under the umbrella of FASD because their prenatal alcohol exposure is unknown and they do not meet the criteria for FAS/A?. SE: static encephalopathy; SPF: Sentinel Physical Findings, individuals who present with growth deficiency and/or 1 to 3 FAS facial features, but have normal CNS structure and function; Normal: no evidence of growth, facial, or CNS structural/functional abnormalities. Age yrs; mean age in years at diagnosis.

Rank 4 FAS facial phenotype, introduced by the 4-Digit Code and adopted by the Canadian and Australian systems, has a specificity of >95% [17,20]. The FAS facial phenotype as defined by the Hoyme system is substantially relaxed relative to the 4-Digit Code Rank 4 facial phenotype (Figure 3) and has a substantially reduced specificity (71% to 75%) [19,32]. If the FAS facial phenotype is specific to PAE, validation studies should confirm the FAS facial phenotype is more prevalent among those with higher exposure and does not occur in individuals with confirmed absence of PAE.

One would also expect that the majority of (if not all) individuals presenting with the FAS facial phenotype would meet criteria for a diagnosis under the umbrella of FASD.

No association was observed between the prevalence of the Hoyme FAS facial phenotype and level of alcohol exposure. The Hoyme FAS facial phenotype was equally prevalent and highly prevalent in the Rank 3 (moderate exposure) and Rank 4 (high exposure) groups when alcohol exposure was classified in accordance with the 4-Digit Code (4-Digit Code Alcohol: Chi^2 0.95, p=0.33) (Figure

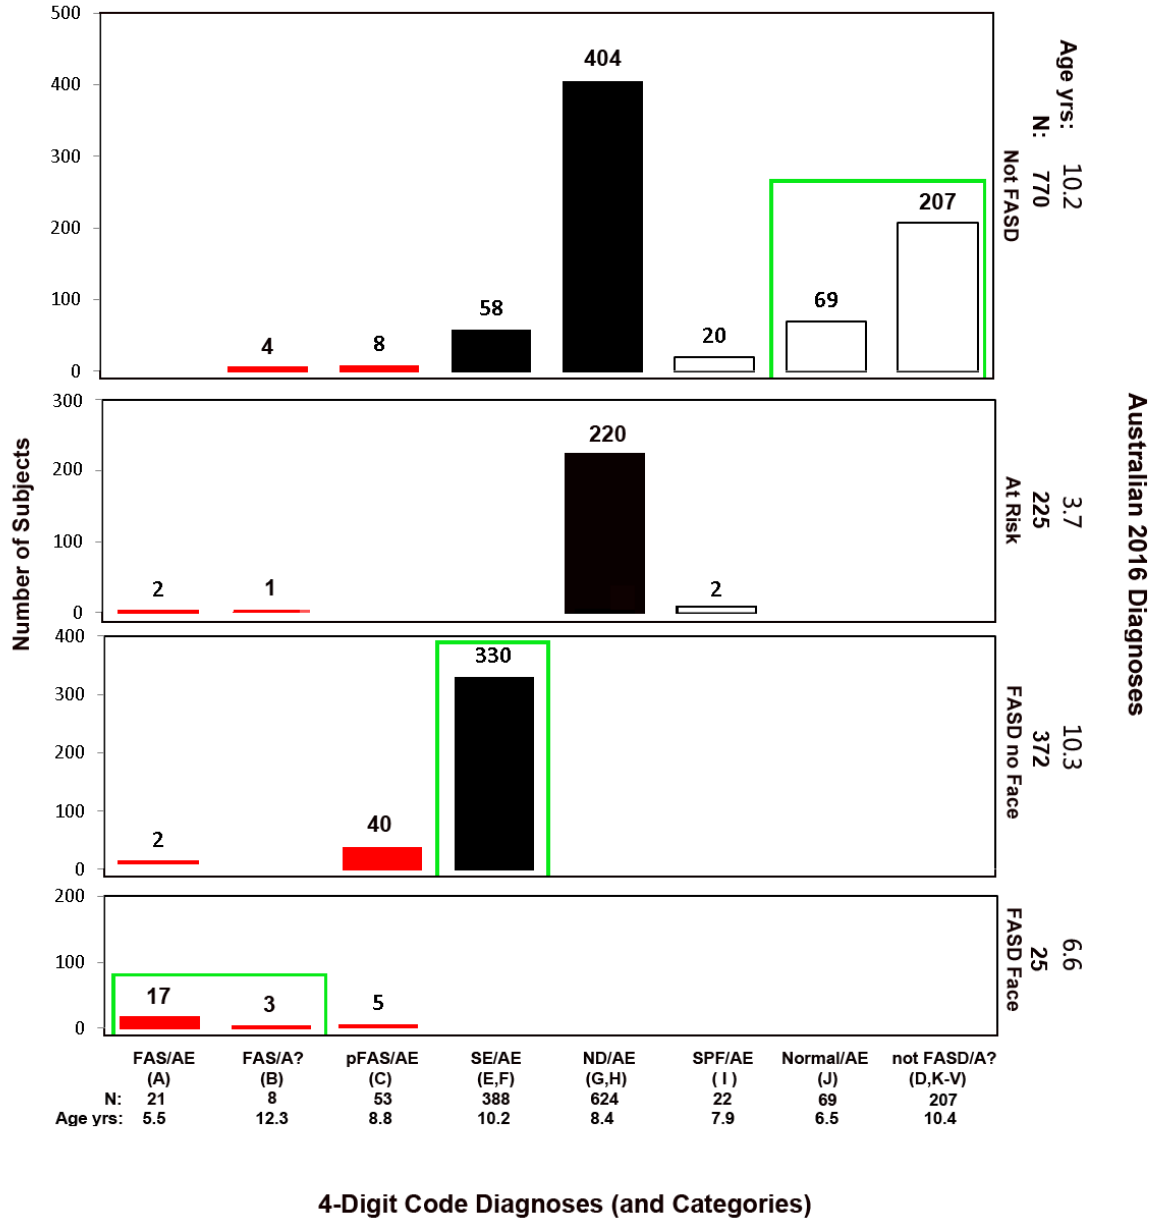

Figure 9. Cross-tabulation of the 4-Digit Code and Australian 2016 FASD Diagnostic Outcomes.
Diagnostic concordance (green boxes) between the 4-Digit Code and Australian 2016 systems was observed in 45% (626/1,392) of the patients. Red bars reflect FAS and PFAS diagnoses using the 4-Digit Code. Black bars reflect the rest of the FASD spectrum using the 4-Digit Code. As a demonstration for how to interpret this figure; 624 patients received a 4-Digit Code Diagnosis of ND/AE. Of the 624 patients, 220 received an "At Risk" classification, and 404 received a "Not FASD" classification using the Australian diagnostic system. The 404 patients classified "not FASD" by the Australian system were all > 6 years of age with confirmed PAE (half with confirmed high PAE). 87% had 1 or 2 (but not 3) domains of severe dysfunction and all had multiple domains of moderate dysfunction. The Australian system does not classify patients with this level dysfunction under the umbrella of FASD. Primate research documents moderate dysfunction is the most prevalent outcome caused by prenatal alcohol exposure (Figure 6). The 220 patients classified as "At Risk" by the Australian system have the same exposure and moderate dysfunction profile, but are all<6 years of age. These 220 are identified as "At Risk" because they are at risk of presenting with severe dysfunction later in childhood, and thus still at risk for FASD.
Abbreviations: 4-Digit Code Categories A-V are case-defined in the Diagnostic Guide for FASD [5]. AE: alcohol exposed; A?: alcohol exposure unknown; ND: neurodevelopmental disorder; Not FASD/A?: Individuals who present with or without growth, facial, and/or CNS abnormalities, but are not under the umbrella of FASD because their prenatal alcohol exposure is unknown and they do not meet the criteria for FAS/A?. SE: static encephalopathy; SPF: Sentinel Physical Findings, individuals who present with growth deficiency and/or 1 to 3 FAS facial features, but have normal CNS structure and function; Normal: no evidence of growth, facial, or CNS structural/functional abnormalities. Age yrs; mean age in years at diagnosis.

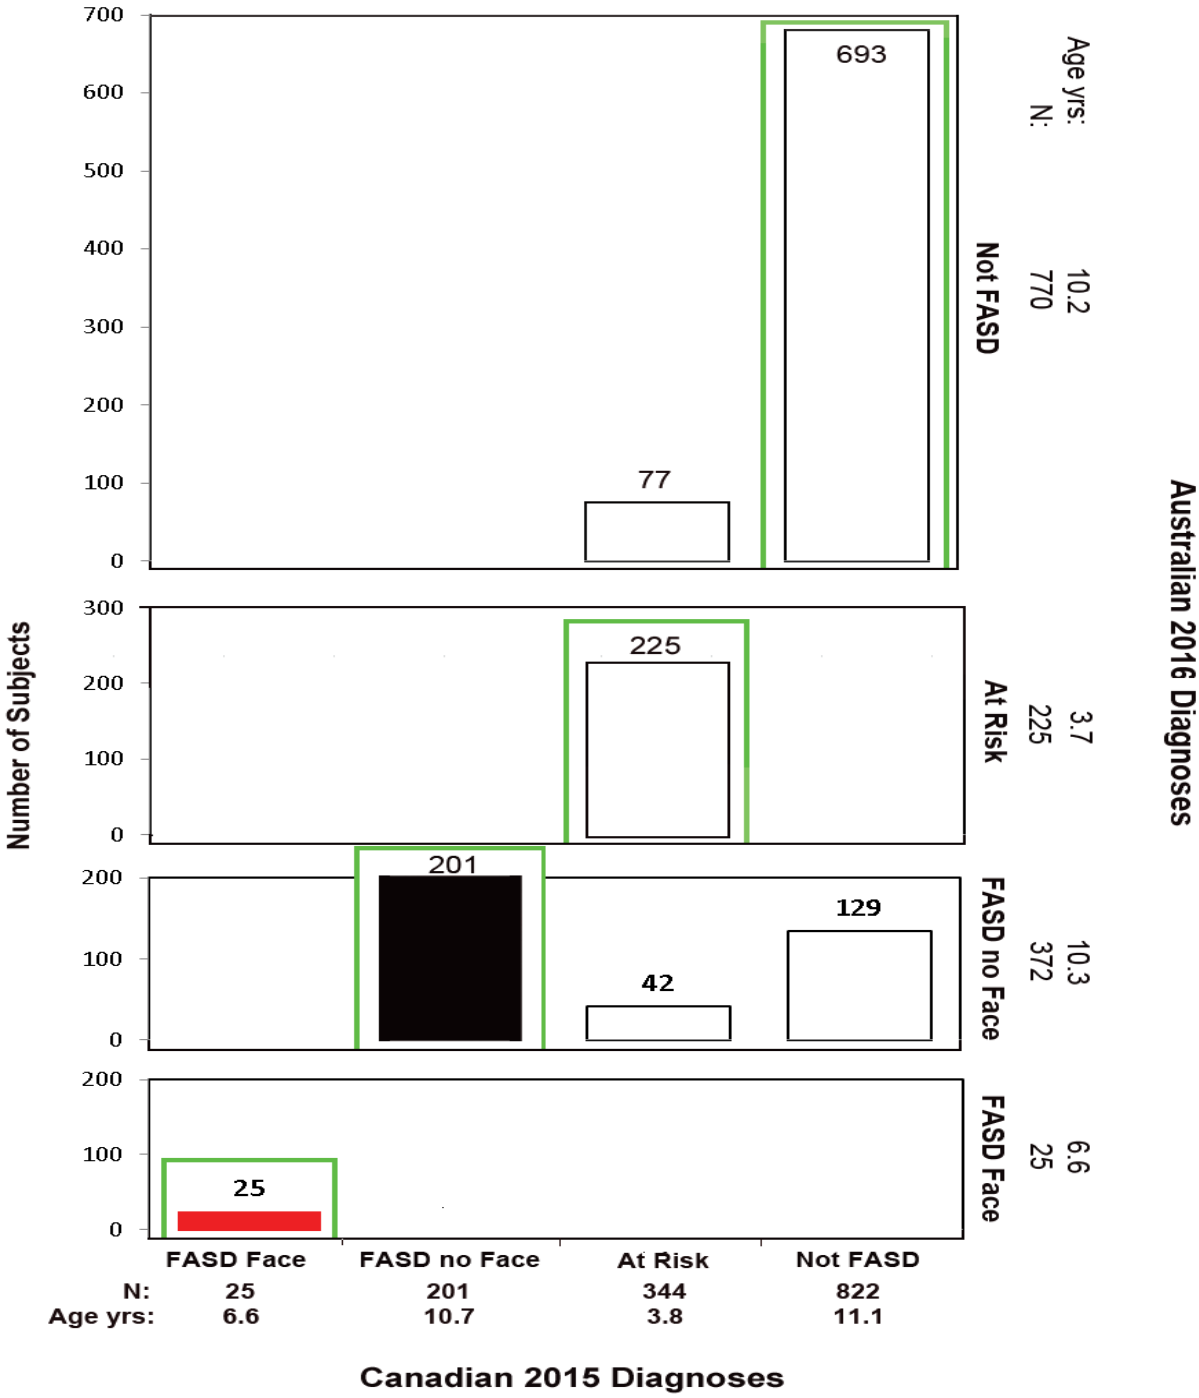

Figure 10. Cross-tabulation of the Canadian 2015 and Australian 2016 FASD Diagnostic Outcomes.
Diagnostic concordance (green boxes) between the Canadian 2015 and Australian 2016 systems was observed in 82% (1,144/1,392) of the patients with the majority of the concordance due to 693 of the patients receiving a "Not FASD" diagnosis by both systems. This higher level of concordance is due to the fact that the Australian system adopted most of the criteria used by the Canadian system, with one important exception. The Canadian system requires confirmed high PAE. The Australian system requires confirmed PAE at any level. Red bars reflect "FASD with and without the Face" diagnoses using the Canadian system. As a demonstration for how to interpret this figure; 822 patients received a Canadian classification of "Not FASD". Of the 822 patients, 129 received an "FASD without the Face" and 693 received a "Not FASD" classification using the Australian diagnostic system. The 129 diagnosed "FASD with no Face" by the Australian system all had confirmed PAE, but the level did not meet the Canadian requirement for high exposure. Red bars reflect "FAS with the Face" diagnoses using the Canadian system. Black bars reflect "FASD without the Face" diagnoses using the Canadian system. Abbreviations: Age yrs; mean age in years at diagnosis.

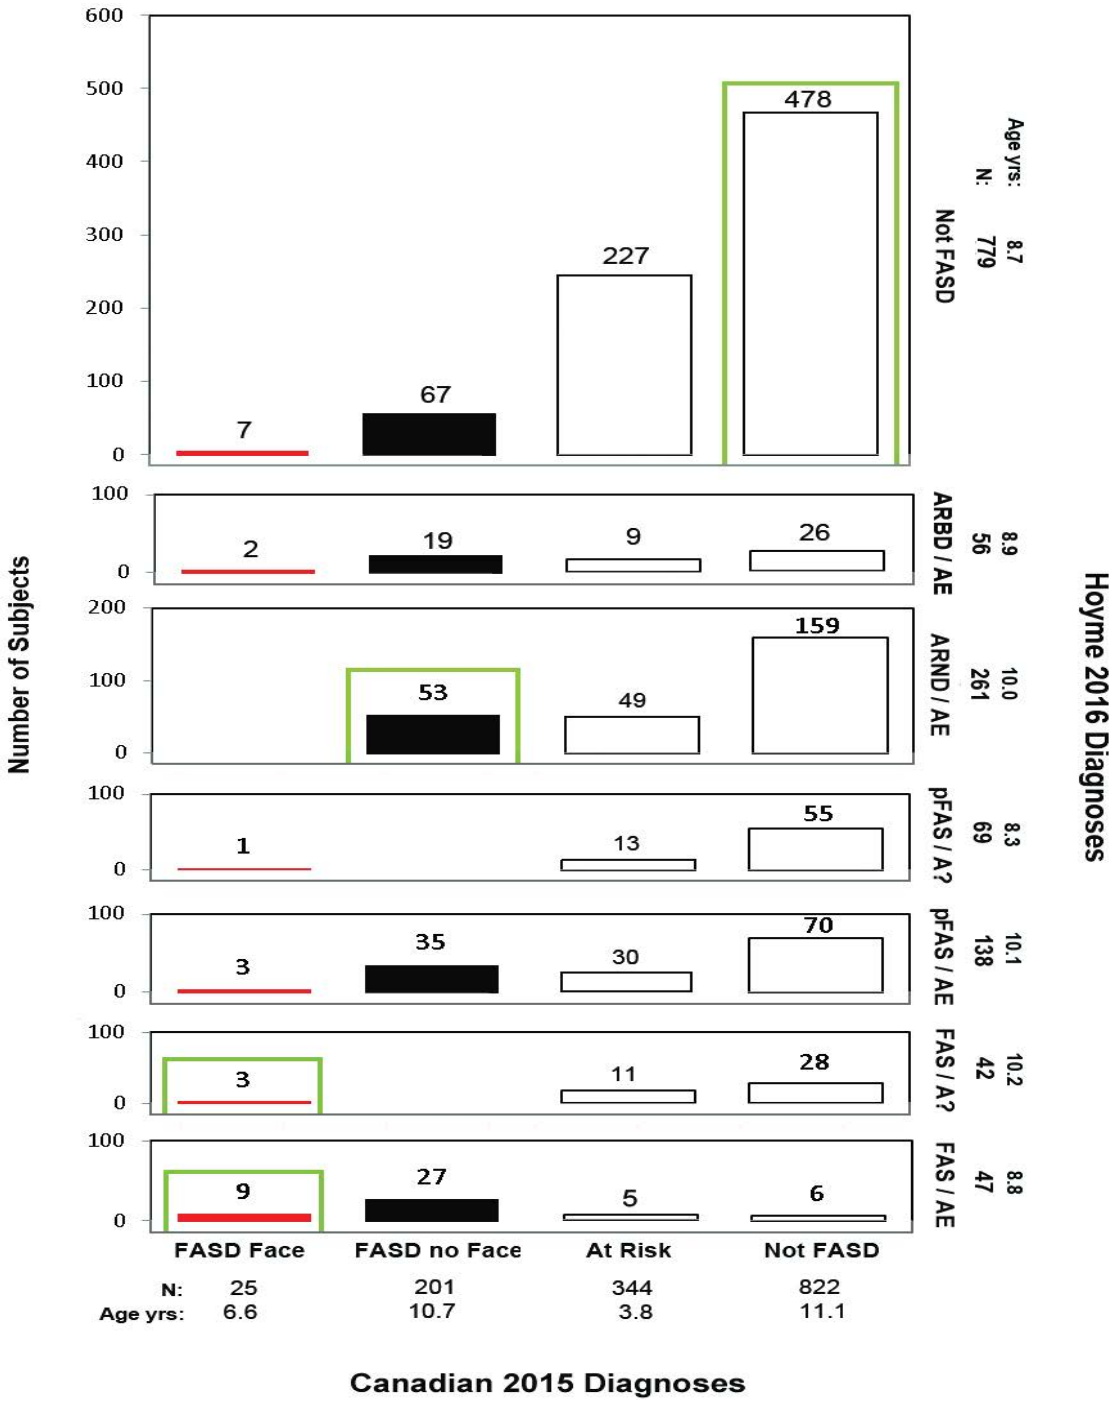

Figure 11. Cross-tabulation of the Canadian 2015 and Hoyme 2016 FASD Diagnostic Outcomes.
Diagnostic concordance (green boxes) between the Canadian 2015 and Hoyme 2016 systems was observed in 41% (569/1,392) of the patients with the majority of the concordance due to 740 of the patients receiving a "Not FASD" diagnosis by both systems. Red bars reflect "FAS with the Face" diagnoses using the Canadian system. Black bars reflect "FASD without the Face" diagnoses using the Canadian system. As a demonstration for how to interpret this figure; 822 patients received a Canadian classification of "Not FASD". Of the 822 patients, 28 received a diagnosis of "FAS/A?, 70 received a diagnosis of pFAS/AE, 55 received a diagnosis of pFAS/A?, 159 received a diagnosis of ARND/AE and 504 received a classification of "Not FASD" using the Hoyme system. Most of the 159 with FAS/PFAS presented with the relaxed Hoyme FAS facial phenotype. Only 8 of the 159 presented with the Canadian FAS face (4-Digit Code Rank 4). The remaining 151 patients with the Hoyme FAS face presented with the following 4-Digit Face Ranks: Rank 1 normal face 15%, Rank 2 mild face 59%, and Rank 3 moderate face 21%. These relaxed FAS facial phenotypes were used by the Hoyme system to overcome the unknown PAE among the 70 patients diagnosed pFAS/A? and the 28 patients diagnosed FAS/A? Abbreviations: Age yrs; mean age in years at diagnosis.

12A). The Hoyme FAS facial phenotype was also equally prevalent and highly prevalent when alcohol exposure was classified in accordance with the Hoyme system (Chi^2 0.01; p=0.92) (Figure 12B). In contrast, the 4-Digit Code Rank 4 FAS face was 5 times more prevalent in the Rank 4 high exposure group than the Rank 3 moderate exposure group (Chi^2 17.5; p=0.000) (Figure 12C). The association between the 4-Digit FAS face and alcohol was weakened substantially when the Hoyme criteria for alcohol exposure were used (Chi^2 6.1, p=0.02). The 4-Digit FAS face was only 2-fold more prevalent in the Hoyme exposed group relative to the Hoyme unknown/too-low exposure group (Figure 12D).

Of the 552 patients with the Hoyme FAS face, 43% did not receive a diagnosis under the umbrella of FASD using the Hoyme system. In contrast, all 54 individuals with the 4-Digit Code Rank 4 FAS face met criteria for a diagnosis under the umbrella of FASD using the 4-Digit Code.

When the Hoyme and 4-Digit Code FAS facial criteria were applied to an adolescent with high function (FSIQ 123) and confirmed absence of PAE (4-Digit Code 1211), she met the Hoyme criteria for the full FAS facial phenotype (Figure 3C). In contrast, her facial phenotype was classified within the normal range by the 4-Digit Code (Face ABC-Score BBC, Face Rank 2).

Should moderate dysfunction be included under the umbrella of FASD? Does PAE cause moderate dysfunction?

All four diagnostic systems include a diagnosis under the umbrella of FASD for individuals that present with severe dysfunction (3 or more domains of function, 2 or more SDs below the mean). Only the 4-Digit Code and Hoyme systems, however, include diagnostic classifications (ND/AE and ARND respectively) for individuals who present with moderate dysfunction (1 or 2 domains of function 2 or more SDs below the mean). Should moderate dysfunction be included under the umbrella of FASD? Does PAE cause moderate dysfunction? To address this question, the 4-Digit Code was applied to our nonhuman-primate model of FASD [4] to document the distribution of diagnostic (FAS/PFAS, SE/AE, ND/AE and Not FASD/AE) outcomes when the only risk factor present was PAE. The primates had been exposed weekly to binge exposures equivalent to a six-pack of beer for the first 3, 6 or entire 24 weeks of gestation (mean maternal peak plasma ethanol concentrations ranged from 176 to 271 mg/dl). The primate model confirmed PAE causes a spectrum of outcome (FAS/PFAS 5%, SE/AE 31%, ND/AE 59%, and Not FASD/AE 5%) with moderate dysfunction (ND/AE) being the most prevalent outcome (Figure 6A). The 4-Digit Code was the only system that produced a near identical distribution of diagnoses across the full spectrum (including 53% ND/AE) illustrated in Figure 6B. The Australian and Canadian outcomes were in greatest contrast with the primate model due to their exclusion of moderate dysfunction from the spectrum. The Australian system produced a good match to the primate model for the severe end of the spectrum (FASD with and without the Face), whereas the Canadian system's requirement for confirmed high PAE results in a poor match between their diagnostic outcomes and the primate model. The Hoyme criteria produce outcomes across the full spectrum, but the distribution did not match the primate model. The relaxed facial criteria placed far more in the FAS/PFAS category and far less in the moderate and severe dysfunction categories. The Australian, Canadian and Hoyme systems placed 51% to 81% of patients with PAE in the "Not FASD" category, in contrast to the 5% observed in the primate model.

Does the pattern and magnitude of dysfunction among patients with moderate dysfunction warrant and qualify them for intervention services?

Of the 402 patients with ND/AE who were 6 years of age or older at the time of their diagnosis, 83% presented with 1-2 domains of severe dysfunction (2 or more SDs below the mean) and 1-6 domains of moderate dysfunction (1 to 1.9 SDs below the mean) (Figure 13). The patterns of moderate dysfunction (1 to 1.9 SDs below the mean) across 9 domains of function (intellect, adaptation, achievement, memory-executive function, language, motor, mental health, behavior and development) is comparable between patients diagnosed with ND/AE, SE/AE and FAS/PFAS using the 4-Digit Code (Figure 14A). The patterns of severe dysfunction (2 or more SDs below the mean) across 9 domains of function is less prevalent among patients with ND/AE than SE/AE and FAS/PFAS (by definition), but present nonetheless (Figure 14B). The magnitude and breadth of dysfunction observed among patients with ND/AE warrant identification and intervention.

The outcomes associated with FASD present along clinically meaningful continuums. Collapsing these continuums to dichotomous (present, absent) scales can hinder clinical practice and research efforts

The following serves as just one of many examples of how collapsing a continuous outcome into a dichotomous (present, absent) scale can adversely impact clinical practice (e.g., the ability to render an accurate diagnosis and predict those at greatest risk) and research efforts (e.g., the power to detect causal associations). The FAS facial phenotype serves two clinically vital functions in the field of FASD. 1) The Rank 4 FAS facial phenotype is so highly specific to PAE it can be used to confirm PAE when a history of PAE is not available for a patient [20,17]. 2) The phenotype presents along a clinically informative continuum that is highly correlated with (and predictive of) the magnitude of CNS damage in a young patient [9,17]. Linear correlations serve as one of the most powerful metrics for identifying causal associations. Identification of causal and predictive associations serves to validate and inform clinical practice. For example, the causal link between the Rank 4 face and alcohol allows the clinician to render a diagnosis of FAS when PAE is unknown. The ability of the Rank 3 face to predict severe CNS dysfunction later in childhood allows the clinician to identify and provide early intervention to infants/toddlers at high risk. When the continuum of expression of the FAS facial phenotype is collapsed into a dichotomous (present, absent) scale, the clinical utility of the phenotype is diminished or even invalidated. For example, as illustrated in Figure 15, a significant linear correlation between the magnitude of expression of the FAS facial phenotype and the prevalence of severe CNS dysfunction (CNS Rank 3) is identified when the facial phenotype is recorded on the 4-point ordinal scale used by the 4-Digit Code (Chi^2 linear trend=10.5, p=0.001) (Figure 15). It is clear from the pattern of association depicted by the blue line (Figure 15) that the prevalence of CNS dysfunction associated with the Rank 1 and 2 facial phenotypes (32% and 36%) are distinctly lower than the prevalence of dysfunction associated with the Rank 3 and 4 facial phenotypes

(50% and 50%). The 4-point scale preserves the clinician's ability to use the Rank 3 and Rank 4 faces to predict which toddlers are at highest risk of severe CNS dysfunction [9]. The 4-point scale also preserves the clinician's ability to use the Rank 4 FAS facial phenotype to serve as confirmation of PAE when a history of PAE is not available. Both these functions are vital in a clinical setting. When the magnitude of expression of the FAS facial phenotype is collapsed into just two categories (present, absent), as introduced by the Hoyme, Canadian and Australian systems, one or both of these clinical functions are lost. For example, the Canadian and Australian systems collapsed the FAS face into (Present: Rank 4; Absent: Ranks 1, 2 and 3). In so doing, the systems preserved the high specificity of the Rank 4 face and thus the important clinical ability to use the Rank 4 face as confirmation of PAE when a history of PAE is unavailable. But, by collapsing the Rank 3 face with the Rank 1 and 2 faces, the Australian and Canadian systems lost the clinical ability to predict which infants/toddlers (those with the Rank 3 face) will present with severe brain dysfunction later in childhood [9]. The significant linear correlation between the FAS facial phenotype and prevalence of severe dysfunction detected by the 4-Digit Code ordinal scale (blue line in Figure 15) was rendered insignificant by the Australian/Canadian dichotomous facial scale (red line in Figure 14, Chi^2=0.5, p=0.46). The Hoyme system also collapsed the FAS face into a dichotomous (present, absent) scale, but used a different cut-point along the 4-Digit Code 4-point Face Rank scale (Present: Ranks 2,3, 4 and half of Rank 1; Absent: the other half of Rank 1) (Figure 3B). By combining Face Ranks 2, 3 and half of Rank 1 with Face Rank 4, the Hoyme system lost the high specificity of the Rank 4 FAS face and thus lost the clinical ability to use the "FAS face" as confirmation of PAE when a history of PAE is unavailable in a patient.

The Hoyme system also lost the clinical ability to predict which infants/toddlers will present with severe brain dysfunction later in childhood because the predictive ability of the Rank 3 and 4 faces are weakened by combining them with the normal Rank 1 and 2 facial phenotypes. The significant linear correlation between the FAS facial phenotype and prevalence of severe dysfunction detected by the 4-Digit Code ordinal scale (blue line in Figure 15) was rendered insignificant (Chi^2=4.7, p=0.10) by the Hoyme dichotomous facial scale (black line in Figure 15).

Discussion

Contrasts in diagnostic outcomes

The four systems produced markedly different outcomes. Eighty-two percent of patients were diagnosed with FASD by at least one of the four systems, but only 11% of patients were diagnosed with FASD by all four systems. Eight percent of patients were diagnosed with FAS by at least one of the 4 systems, but only 1% was diagnosed with FAS by all four systems. The proportion of patients diagnosed with FAS, severe dysfunction, moderate dysfunction, and FASD overall varied significantly across the systems (4-Digit: 2%, 28%, 45%, ≤79%; Hoyme: 6%, 5%, 14% 44%; Australian: 2%, 26%, 0%, 29%; and Canadian: 2%, 14%, 0%, 16%) (Table 4).

Five factors accounted for the greatest contrasts in diagnostic outcomes between the four systems.

1. Extensive evidence supports the inclusion of individuals with moderate dysfunction (ND/AE) under the umbrella of FASD. The pattern and magnitude of dysfunction among patients with moderate dysfunction warrant and qualify them for intervention services. Exclusion of moderate dysfunction by the Canadian and Australian systems prevented 53% of patients with confirmed PAE from receiving a FASD diagnosis with the greatest impact on children less than 6 years of age. Individuals with PAE present with the full spectrum of CNS dysfunction from moderate to severe in Table 3 [1,33,34]. The evidence that supports inclusion of moderate dysfunction (ND/AE or moderate ARND) under the umbrella of FASD is as follows. First, and most importantly, hundreds of laboratory-based studies, including our nonhuman-primate studies in Figure 6A [4,35], confirm prenatal alcohol exposure causes moderate dysfunction. Not only does it cause moderate dysfunction, but moderate dysfunction is the most common outcome. In this study population of 1,177 with PAE and the larger population from which it was drawn (2,550 alcohol-exposed patients evaluated at the WA FASDPN clinics over the past 20 years), 45-53% met the criteria for ND/AE [17]. ND/AE was the most common outcome, exceeding the prevalence of FAS/PFAS (6-10%) and SE/AE (24-33%) combined. It is important to note that alcohol is not the only risk factor contributing to adverse outcomes in the FASDPN patient population (see Figure 21 in Astley [17]). So what would the diagnostic distribution look like if alcohol was the only risk factor? To answer that question, we applied the 4-Digit Code to the outcomes observed in our primate model of FASD [4] (Figure 6A). Remarkably, the distribution of FAS/PFAS (5%), SD/AE (31%) and ND/AE (59%) was near identical to that observed in our FASD clinical population, with ND/AE being the most common outcome. And just like in our primate model, individuals with ND/AE have alcohol exposures as high as those with FAS/PFAS and SE/AE (see Figure 22 in Astley [17]). Are these moderate impairments in brain function associated with underlying CNS structural abnormalities? Again, the answer is yes. Our MRI study confirmed at least 43% of individuals with ND/AE have significant CNS structural abnormalities [36] (see also Figure 15C in Astley [17]). Our extensive experience in the WA FASDPN confirms that it is the children with moderate dysfunction that fair the worst and are often in most need of diagnostic identification and intervention. These are the children that too often slip through the cracks. Their disabilities are often not severe enough in the cognitive domain to qualify them for services (only 3% have an IQ less than 70) [17], but severe enough across many other domains (Figures 13 and 14) (see also Figure 23 in Astley [17]) to adversely impact their ability to fully engage in school and live productive, independent lives. Children with ND/AE received as many intervention recommendations as children with FAS/PFAS and SE/AE in our patient population (see Figure 24 in Astley [17] and Table 4 in Jirikowic et al [37]). And perhaps most importantly, the diagnosis of ND/AE provided caregivers with as much access to services as caregivers of children with FAS/PFAS and SE/AE. Caregivers also reported the interventions worked as well for their children with ND/AE as did caregivers of children with FAS/PFAS and SE/AE (see Figure 31 in Astley [17]).

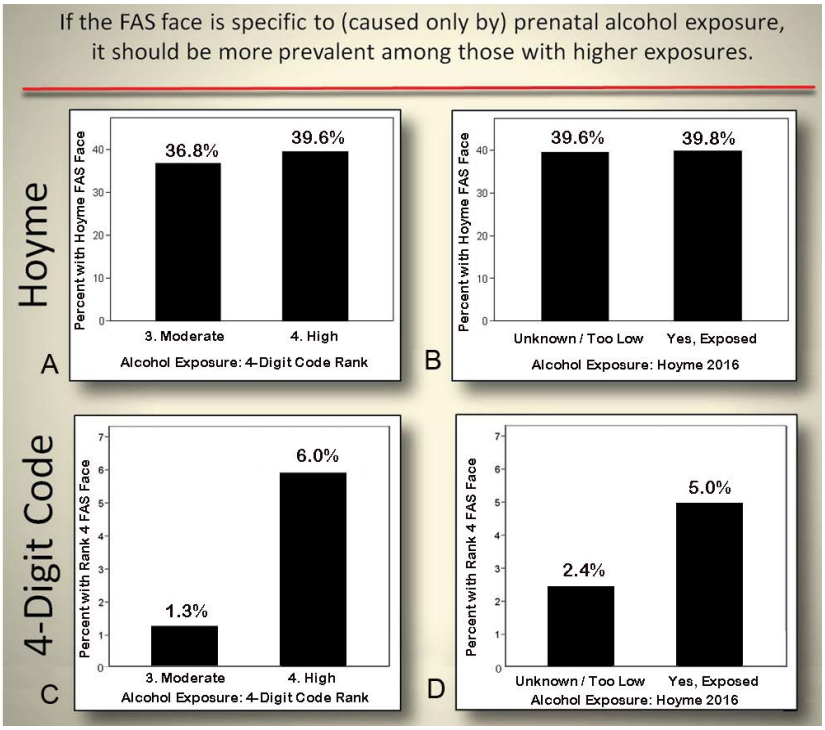

Figure 12. Only the 4-Digit Code FAS Face was Significantly More Prevalent Among Patients with Higher Alcohol Exposure.
The Hoyme 2016 [10] FAS face was equally prevalent and highly prevalent in the moderate (4-Digit Code Alcohol Rank 3) and high (4-Digit Code Alcohol Rank 4) alcohol exposure groups (Chi^2 0.9, p=0.33). B) The Hoyme FAS face was also equally prevalent and highly prevalent between those that did and did not meet the Hoyme alcohol exposure criteria (Chi^2 0.01, p=0.92). In contrast, the 4-Digit Code FAS facial phenotype was highly correlated with measures of prenatal alcohol exposure. C) The 4- Digit Code Rank 4 FAS face was 5 times more prevalent in the high exposure group (4-Digit Code Alcohol Rank 4) than the moderate exposure (Digit Code Alcohol Rank 3) group Chi^2 17.5, p=.000). D) The association between the 4-Digit Code Rank 4 FAS facial phenotype and alcohol was substantially weakened when the Hoyme 2016 criteria for alcohol exposure were applied (Chi^2 6.1, p=0.02). The 4-Digit FAS face was only 2-fold more prevalent in the Hoyme et al. exposed group relative to the Hoyme et al. unknown/too low exposure group.

It is important to clarify that, when we report above that there is extensive evidence to support inclusion of ND/AE under the umbrella of FASD, we are not stating that all individuals who meet the criteria for ND/AE have FASD. By definition all individuals with Fetal Alcohol Spectrum Disorder have a disorder caused, at least in part, by their prenatal alcohol exposure. But not all individuals with ND/AE necessarily have a FASD. Only the subset of individuals whose neurobehavioral disorder was caused, at least in part, by their prenatal alcohol exposure, have a FASD. This is a current inherent weakness in the umbrella term FASD. In the absence of a biomarker that can causally link an individual's alcohol exposure with their neurodevelopmental disorder, there is no way to identify which individuals with ND/AE have FASD. This same argument applies to the diagnostic classifications of SE/AE, ARND and "FASD without the Face". Not all individuals who meet the criteria for SE/AE, ARND and "FASD without the Face" necessarily have FASD. Only the subset of individuals whose CNS abnormalities were caused, at least in part, by their prenatal alcohol exposure has FASD. And once again the field of FASD currently has no way (no biomarker) to identify this subset. Until such a biomarker is identified, if such a biomarker exists, the 4-Digit Code elects to label these categories with terms that do not imply causality.

2. The more stringent Hoyme and Canadian alcohol exposure criteria prevented 47%-59% of patients with confirmed PAE from receiving a diagnosis of FASD. In a clinical setting, one is not in a position to know how accurate the exposure was recalled and reported. Setting a threshold implies the details of all reported exposures are accurate and no fetus can be harmed by exposures below the threshold. Neither of these statements is true and the latter sends a confusing public health message that lower levels are safe. Recognizing this, the 4-Digit Code requires a confirmed exposure, but does not set a threshold. It is interesting to note that Petryk et al., [38] reported similar findings when they retrospectively assessed the impact of applying the 2016 Canadian guidelines to 119 patients with confirmed PAE (4-Digit Code Alcohol Ranks 3 or 4) and severe structural and/or functional CNS abnormalities (4-Digit Code CNS Ranks 3 and/or 4). In the Petryk study, the more stringent Canadian exposure criteria would have prevented 71% of the individuals from receiving a diagnosis under the umbrella of FASD because the reported exposure would not have met the required threshold.
3. Individuals with FASD are born with FASD, but the Hoyme, Canadian and Australian guidelines prevent most children under 3 or 6 years of age with confirmed PAE and structural or functional CNS abnormalities from receiving a diagnosis under the umbrella of FASD.

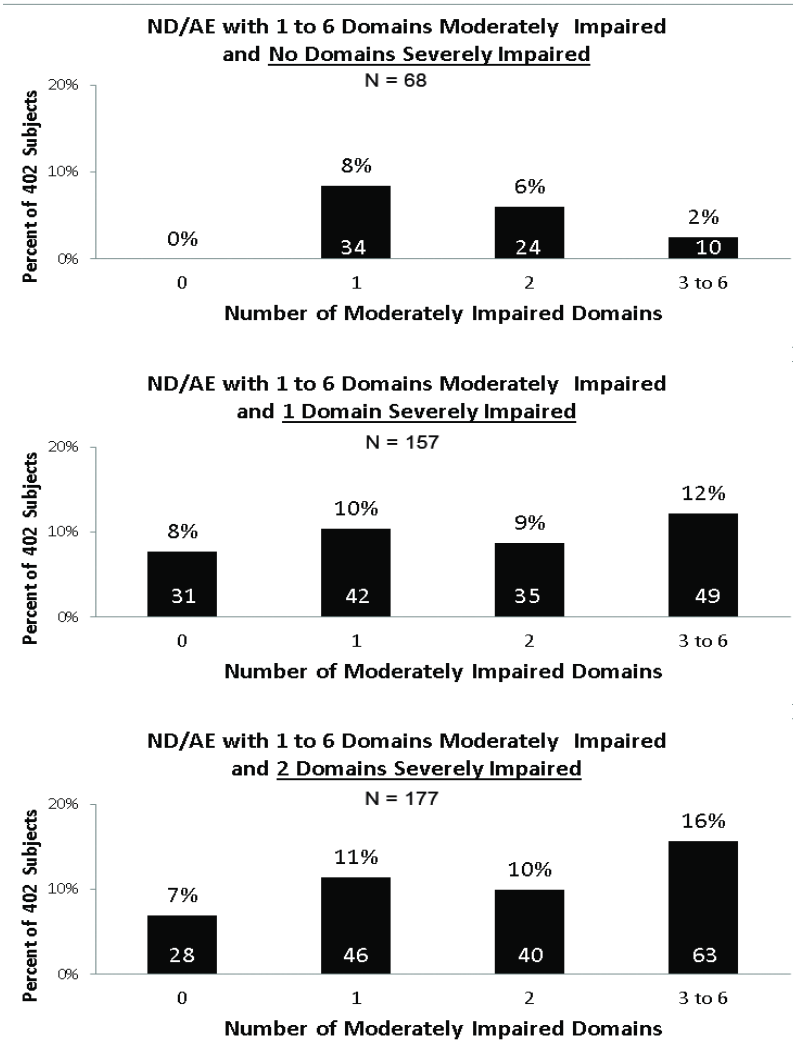

Figure 13. Distribution of Moderate and Severe CNS Dysfunction Among Patients Diagnosed with ND/AE by the 4-Digit Code.
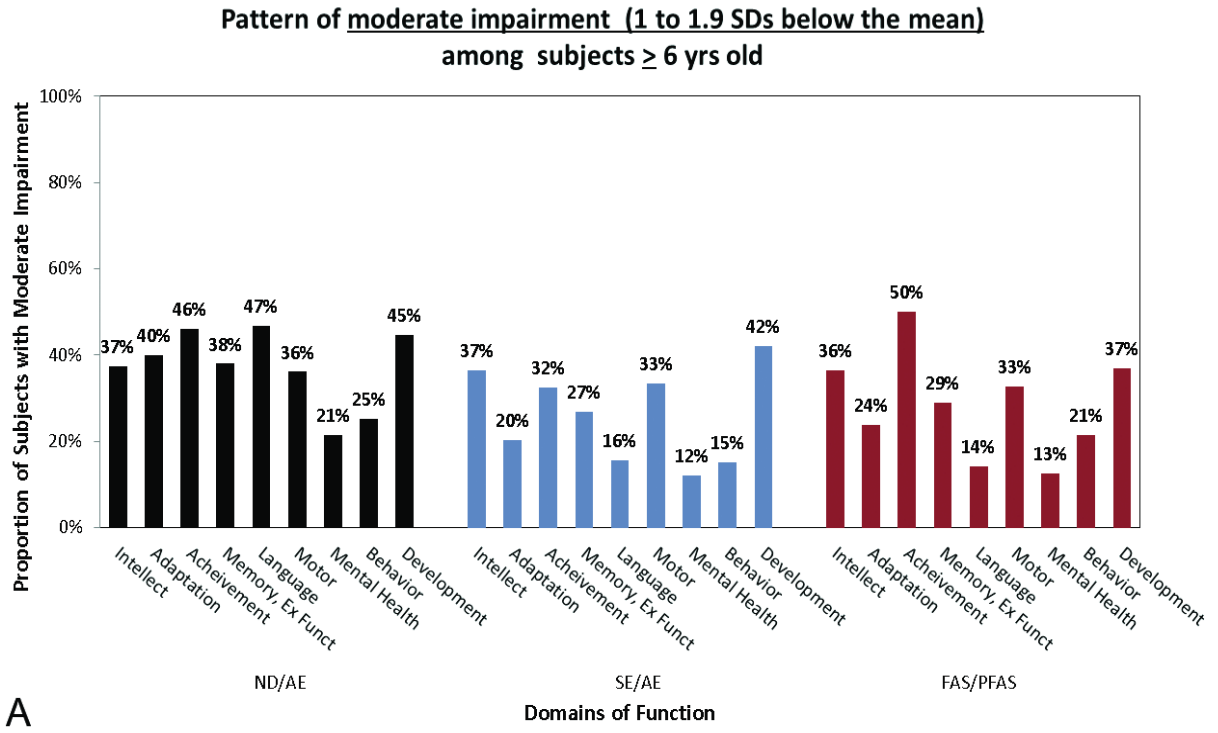
Of the 402 patients diagnosed with ND/AE by the 4-Digit Code who were 6 years of age or older at the time of their diagnosis, 83% (334/402) presented with 1-2 domains of severe dysfunction (2 or more SDs below the mean) and 1-6 domains of moderate dysfunction (1 to 1.9 SDs below the mean). Domains of function included: intellect, adaptation, achievement, memory-executive function, language, motor, mental health, behavior and development, as illustrated in Figure 14. As a demonstration for how to interpret this figure; the bar on the bottom right documents 63 of the 402 patients (16%) presented with 2 domains of severe dysfunction and 3 to 6 additional domains with moderate dysfunction.

The 4-Digit Code allows a diagnosis of FAS/PFAS at birth based solely on physical abnormalities (growth deficiency, FAS face and microcephaly), having confirmed empirically that over 90% of alcohol-exposed infants and toddlers who present with one or more of the sentinel physical features of FAS as defined by the 4-Digit Code (microcephaly ≤3rd percentile, a Rank 4 FAS facial phenotype, or Rank 4 growth deficiency) will present with severe CNS Rank 3 dysfunction later in childhood [9]. In contrast, the Hoyme system requires both reduced head circumference and CNS dysfunction for an FAS/PFAS diagnosis, preventing a diagnosis in infant/toddlers too young to be assessed for CNS dysfunction. In addition, the Hoyme system does not permit a diagnosis of ARND in a child<3 years of age. The Canadian and Australian systems require severe CNS dysfunction for an FASD diagnosis, preventing all children with PAE who present with microcephaly and/or moderate CNS dysfunction from receiving a diagnosis of FASD, with one exception. If the child with PAE presents with microcephaly and the FAS facial phenotype, a diagnosis of "FASD with the Face" can be made in the absence of CNS dysfunction, based on the finding of the 4-Digit Code that microcephaly and the Rank 4 FAS facial phenotype are highly predictive of severe CNS dysfunction later in childhood. Growth deficiency was as strong a predictor of severe brain dysfunction in infants with PAE as the FAS facial phenotype and microcephaly, but the Canadian and Australian systems excluded growth deficiency from their FASD criteria. While this one exception (microcephaly and the FAS facial phenotype) allowed a diagnosis of "FASD with the Face" in a small number of children (n=6)<6 years



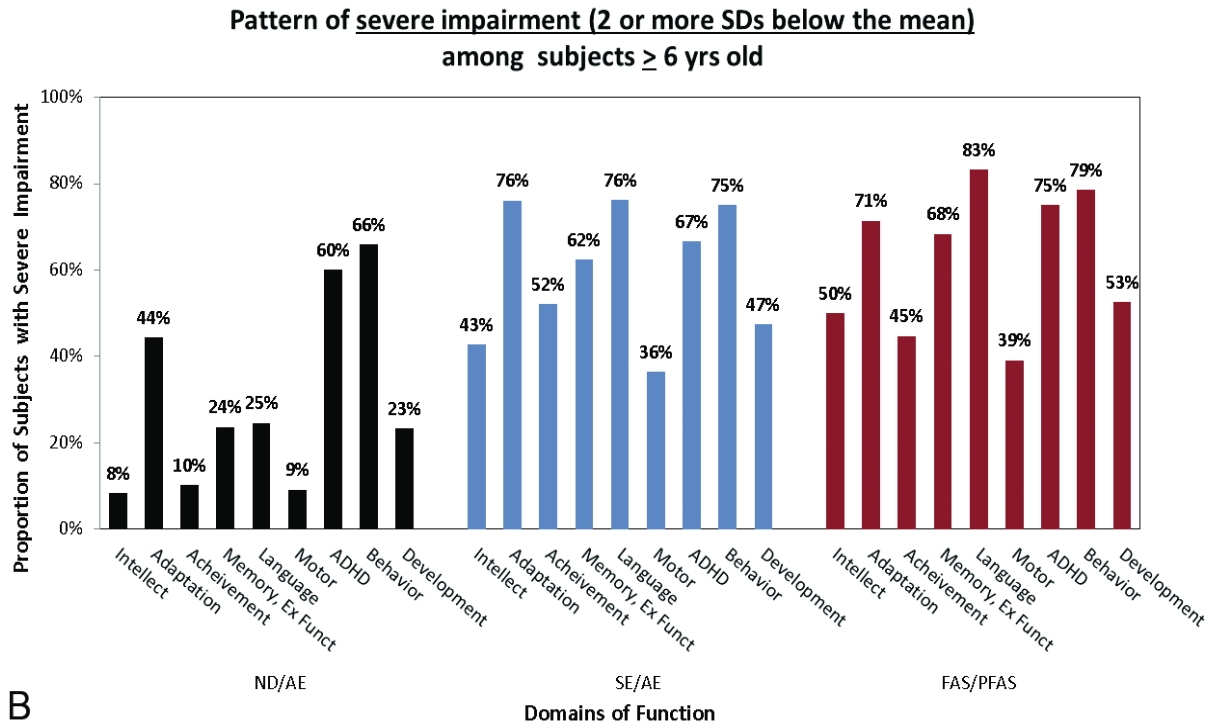


Figure 14. Patterns of Dysfunction Among Patients > 6-years-old with 4-Digit Code Diagnoses ND/AE, SE/AE or FAS/PFAS.
The proportion of patients presenting with moderate dysfunction (1 to 1.9 SDs below the mean) across 9 domains of function (intellect, adaptation, achievement, memory-executive function, language, motor, mental health, behavior and development) is comparable between patients diagnosed with ND/AE, SE/AE and FAS/PFAS using the 4-Digit Code. B) The proportion of patients presenting with severe dysfunction (2 or more SDs below the mean) across 9 domains of function is less prevalent among patients with ND/AE than SE/AE and FAS/PFAS (by definition), but present nonetheless.

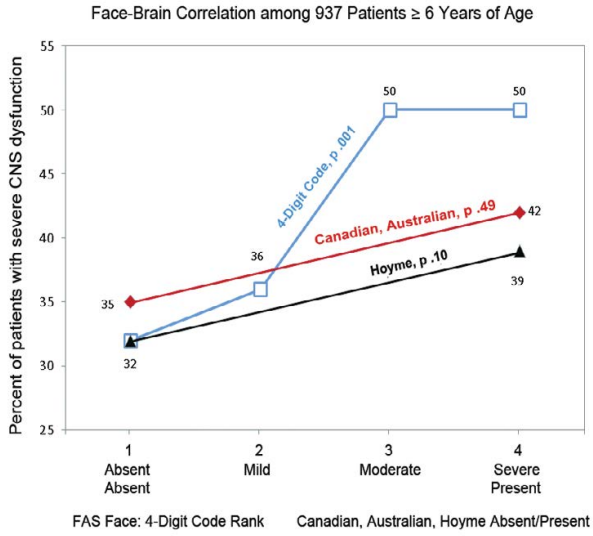

Figure 15. Significant Correlation Between Face and Brain Lost when the Facial Phenotype is Reduced to Present/Absent.

The FAS facial phenotype presents along a clinically meaningful continuum. A significant correlation between the magnitude of expression of the FAS facial phenotype and the prevalence of severe CNS dysfunction (CNS Rank 3) is identified when the facial phenotype is recorded on the 4-point ordinal scale used by the 4-Digit Code (blue line: Chi^2 linear trend=10.5, p=0.001). Linear trends serve as one of the most powerful metrics for identifying causal associations. When the magnitude of expression of the FAS facial phenotype is collapsed into just two categories (present, absent), as introduced by the Hoyme, Canadian and Australian systems, the significant correlation between face and brain is lost. Not only does a dichotomous scale have less statistical power to identify real associations, but where the ordinal scale is bisected impacts the validity of the dichotomous scale. It is clear from the pattern of association depicted by the blue line that the prevalence of CNS dysfunction associated with the Rank 1 and 2 faces (32% and 36%) are distinct from the prevalence of dysfunction associated with the Rank 3 and 4 faces (50% and 50%) The most clinically valid cut-point to bisect the ordinal scale would be between Ranks 2 and 3. The Canadian and Australian systems used a cut-point between Ranks 3 and 4 to dichotomize the FAS facial phenotype (Present=Rank 4; Absent=Ranks 1, 2 and 3). The Hoyme system used a cut-point halfway through Rank 1 to dichotomize the face (Present=Ranks 2, 3, 4 and half of Rank 1; Absent=the other half of Rank 1) (Figure 3B). Both dichotomous scales (red and black lines) failed to identify the significant correlation that exists between the severity of the FAS facial phenotype and prevalence of severe brain dysfunction (Canadian and Australian: Chi^2=0.5, p=0.46; Hoyme: Chi^2=4.7, p =0.10).

old, the majority of the 407 children with PAE under 6 years of age (n=238) failed to receive a diagnosis under the umbrella of FASD because they presented with moderate dysfunction (ND/AE); a diagnosis excluded from the Canadian and Australian systems. Failure to identify and diagnose FAS/D in children<6 years of age will prevent these high-risk children from receiving the benefits of early intervention.

4. Growth deficiency is significantly associated with PAE, is as prevalent as the FAS facial features and CNS abnormalities, and is a highly predictive of severe CNS dysfunction among infants/toddlers. The Canadian and Australian systems removed growth deficiency as a criterion for FASD, yet growth deficiency was as strong a predictor of severe brain dysfunction in infants with PAE as the FAS facial phenotype and microcephaly. Decades of laboratory and clinical-based studies unequivocally confirm that PAE causes GD [39-43]. While many factors can impact growth, an empirical study conducted by Astley et al., [9] confirmed that postnatal short stature is significantly correlated with PAE (while low birth weight is significantly correlated with prenatal tobacco exposure). The study found growth deficiency was as prevalent as the other core diagnostic features of FASD (FAS facial phenotype and CNS structural abnormalities). Most importantly, growth deficiency among children with PAE is highly predictive of who will present with severe CNS dysfunction. This is especially important in children<8 years of age. Astley et al. [9]) found that among children under 8 years of age with PAE who present with height and/or weight at or below the 10th percentile (Growth Rank 2, 3 or 4); 57% with Growth Rank 2; 67% with Growth Rank 3 and 100% with Growth Rank 4 presented with severe CNS dysfunction after 8 years of age when they were old enough to participate in more sophisticated neuropsychological assessments. Of the 844 children classified as Not FASD, 633 had confirmed PAE. Of the 633 with confirmed PAE, 192 were under 8 years of age and 64 presented with Growth Rank 2, 3 or 4. Roughly 70% of these 64 children with confirmed PAE will likely present with severe CNS dysfunction after the age of 8 years, but are not identified as "At Risk" by the Canadian system. Of the 983 children classified as Not FASD by the Australian system, 773 had confirmed PAE. Of the 773 with confirmed PAE, 435 were under 8 years of age and 126 presented with Growth Rank 2, 3 or 4. Roughly 70% of these 126 children with confirmed PAE will likely present with severe CNS dysfunction after the age of 8 years, but are not identified as "At Risk" by the Australian system.

5. The relaxation of the Hoyme FAS facial phenotype criteria greatly increased the prevalence of FAS and PFAS diagnoses and jeopardized the validity of these FAS and PFAS diagnoses.

   - The Hoyme system classified 10 times more individuals with the FAS facial phenotype (n=552) than the 4-Digit Code (n=54) [10].
   - The Hoyme system produced 14 times more FAS/PFAS diagnoses with unknown alcohol exposure (n=111) than the 4-Digit Code (n=6) [10]. This is particularly concerning because 68 (61%) of these patients had 4-Digit Code Rank 1 or Rank 2 facial phenotypes that are, by our definition, clinically "normal". The Rank 1 and 2 phenotypes have no specificity to PAE [33]. The only reason FASD diagnostic systems permit a diagnosis of FAS to be made when PAE is unknown is because the facial phenotype is so highly specific to (caused only by) PAE, the face serves to confirm the exposure. If the facial phenotype defined by the diagnostic system is not confirmed to be highly specific to alcohol, then: 1) the diagnosis cannot be validly labeled FAS, PFAS or FASD because a causal link cannot be confirmed between the patient's alcohol exposure and their adverse outcomes, and 2) the facial phenotype cannot be validly used to confirm PAE when the history of exposure is unknown.

The 4-Digit Code allows a diagnosis of FAS to be made when PAE is unknown because the 4-Digit Code Rank 4 FAS facial phenotype is confirmed to be >95% specific to PAE [17, 20]. The 4-Digit Code does not allow a diagnosis of PFAS to be made when alcohol exposure is unknown, because the facial criteria for PFAS is relaxed to a Face Rank 3 (2.5 of the 3 features must be present), resulting in a subtle reduction in specificity. To err on the conservative side, the 4-Digit Code requires a confirmed exposure for PFAS

- In our previous study the relaxed Hoyme FAS facial phenotype demonstrated no association with PAE [10]. In contrast, the 4-Digit Code FAS facial phenotype demonstrated a strong, significant, linear association with PAE
- 70% of the 296 Hoyme FAS/PFAS cases had "normal" 4-Digit Code Face Ranks 1 or 2.
- 43% of the 552 patients with the Hoyme FAS face did not receive a diagnosis under the umbrella of FASD using the Hoyme system. In contrast, all 54 individuals with the 4-Digit Code Rank 4 FAS face met criteria for a diagnosis under the umbrella of FASD using the 4-Digit Code.
- Hoyme et al. [7] reports the relaxation of their facial criteria was to improve sensitivity and greater inclusion of children in the complete continuum of FASD. But, as demonstrated in this study, one need not sacrifice specificity for sensitivity to achieve greater inclusion across the full continuum of FASD. By documenting the FAS facial phenotype across its full continuum of expression (4-Digit Code Face Ranks 1, 2, 3 and 4), the 4-Digit Code preserves: 1) the high specificity of the Rank 4 FAS facial phenotype, 2) the clinically vital function of the Rank 3 face to predict severe brain dysfunction, and 3) the increased sensitivity to capture the full spectrum of FASD by inclusion of the Rank 2 face.

Contrasts in diagnostic tools

In addition to the contrasts in diagnostic criteria, the methods and tools used to measure the facial features are also markedly different. The authors of the Hoyme system promote the use of direct examination of facial features over the use of facial photographic software. The 4-Digit Code advises measuring the facial features from 2D digital photos using the FAS Facial Photographic Analysis Software [12]. Empirical studies have confirmed the superior accuracy of the photo versus direct method of facial measurement [13,15]. Significant contrasts also exist between the 4-Digit Code Lip-Philtrum Guide 1 and the Hoyme North American Lip/Philtrum Guide. As illustrated in Figure 3, although the Hoyme North American Lip/Philtrum Guide looks similar in appearance to the 4 Digit Code Lip-Philtrum Guide 1, these are not interchangeable tools. The lips ranked 1 through 5 on the Hoyme Guide do not match the lips ranked 1 through 5 on the 4-Digit Code Guide. The lips on the 4-Digit Code Guide become progressively thinner as Rank increases from 1 to 5. The lips on the Hoyme guide do not become progressively thinner as Rank increases (e.g., the Hoyme Rank 4 lip is thicker than the Hoyme Rank 3 lip). The images used to depict lip thinness for each Rank do not match between the two guides. When the Hoyme lips are mapped onto the 4-Digit Guide based on the objective measure of thinness (circularity), the Hoyme Rank 1, 2, 3, 4, and 5 lips are equivalent to the 4-Digit Code Lip Ranks 2, 2, 3, 2, and rank unknown, respectively. Both systems define the thin upper lip of FAS as Rank 4 or thinner. But the Hoyme Rank 4 lip is substantially thicker than the 4-Digit Rank 4 lip (it is equivalent to the 4-Digit Rank 2 lip).

The introduction of the Hoyme North American Lip/Philtrum Guide serves to further relax the Hoyme FAS facial phenotype. Only 2 of the 3 cardinal features are required and 2 of the 3 features are relaxed relative to the 4-Digit Code. The PFL is relaxed from the 3rd percentile to the 10th percentile and lip thinness is relaxed from Rank 4 to Rank 2 on the 4-Digit Code Lip-Philtrum Guide 1. An individual presenting with PFLs at the 10th percentile, a Rank 1 deeply grooved philtrum, and a 4-Digit Code Rank 2 moderately thick upper lip would meet the Hoyme criteria for the full FAS facial phenotype. The presence of a single, very minor anomaly (PFL at the 10th percentile) does not constitute a dysmorphic facial phenotype. In fact, it would be difficult to justify classifying any of these three features as minor anomalies outside the normal range. Yet, this facial phenotype is used by the Hoyme system to confirm PAE when PAE is unknown. Of the 102 patients with unknown PAE and the Hoyme FAS facial phenotype, 70% had a 4-Digit Code Rank 1 or Rank 2 facial phenotype. By definition, 4-Digit Face Ranks 1 and 2 reflect normal phenotypes with no specificity to PAE. This was clearly illustrated in our FASD MRI study [33]. Sixteen high-functioning adolescents with confirmed absence of PAE were enrolled as controls in that study. Ten presented with Rank 1 facial phenotypes and 6 presented with Rank 2 facial phenotypes (one of which illustrated in Figure 3C). Based on our previously published findings [10], the Hoyme North American Lip/Philtrum Guide is not a valid tool for use with the 4-Digit Code.

The quintessential role of the FAS facial phenotype

Why are the criteria used to define the FAS facial phenotype so important to the medical validity of all diagnoses under the umbrella of FASD, not just the diagnosis of FAS (or FASD with the Face)? When one makes a diagnosis of FAS, one is stating explicitly that the individual has a syndrome caused by PAE [17]. One is also stating explicitly that the biological mother drank alcohol during pregnancy and, as a result, harmed her child. These are bold conclusions to draw and are not without medical, ethical, and even legal consequences. When the FAS face is not specific to FAS and PAE, the validity of the entire FASD diagnostic system collapses. Here is why:

- The terms FAS and "FASD with the Face" are rendered invalid. If the face is NOT specific to (caused only by) alcohol, one can no longer label the condition fetal alcohol syndrome or fetal alcohol spectrum disorder. One can no longer confirm alcohol is causally linked to any of the outcomes (growth, brain, or face) in an individual patient.
- The diagnosis "FAS/Alcohol Unknown" is also rendered invalid. The FAS face can no longer serve as the confirmation of alcohol exposure when the exposure history is unknown.
- The terms "ARND" and "FASD without the Face" remain problematic. Since the CNS structural and functional abnormalities that define ARND and "FASD without the Face" are not specific to (caused only by) prenatal

alcohol, one is in no position to declare an individual's Neurodevelopmental Disorder is "Alcohol-Related" (ARND) or their Spectrum Disorder is caused by Fetal Alcohol (FASD).

With terms like ARND and "FASD without the Face", one feels compelled to require a significant exposure to alcohol to increase the odds that the individual's impairments may be caused, at least in part, by their alcohol exposure. This is a dangerous road to go down.

- Setting a threshold of significant exposure for Alcohol-Related Neurodevelopmental Disorder (ARND) or FASD does not confirm the patient's alcohol exposure caused their disorder.
- Alcohol is never the only risk factor contributing to the disorder.
- One is sending a potentially harmful message that lower levels of alcohol exposure are safe. As we illustrated in our previous publication (Figure 9) [10], individuals with reported PAE below the Hoyme or Canadian thresholds do present with full FAS. Either this individual was particularly vulnerable to the teratogenic insult of alcohol, or the reported exposure was not accurate. In a clinical setting, one is never in a position to know how accurate the exposure is recalled and reported. Setting a threshold implies the details of all reported exposures are accurate and no fetus can be harmed by exposures below the threshold.
- And one is blaming a woman for harming her child, when they have limited ability to make/defend such a claim.

The 4-Digit Code introduced the terms ND/AE and SE/AE back in 1997 [23]. These terms state the verifiable facts; the individual presents with a disorder and the individual was exposed to alcohol in utero. The terminology does not explicitly state their disorder is related to their alcohol exposure. In fact, the 4-Digit Code formally Ranks all other prenatal and postnatal risks factors to make clear that alcohol is never the only risk factor contributing to an individual's neurobehavioral disorder or static encephalopathy. In 2013, the DSM5 [44] took a similar nosological approach when it introduced the new term "Neurodevelopmental disorder / prenatal alcohol exposure" (ND/PAE) as a condition for further study. "ND/PAE is characterized by a range of developmental disabilities following exposure to alcohol in utero." ND/PAE is an example of "Other Specified Neurodevelopmental Disorder (315.8 (F88)).

When is it a FASD?

Fetal Alcohol Spectrum Disorders are, by definition, adverse outcomes caused by PAE. In the absence of an outcome that is specific to (caused only by) PAE (like the Rank 4 FAS facial phenotype), one cannot confirm or rule-out the role PAE played in an individual's CNS dysfunction.

- **Do all individuals with SE/AE, ND/AE, and ARND or "FASD without the Face" have FASD?** Not necessarily. Only the subset of individuals whose CNS dysfunction was caused (in whole or in part) by their alcohol exposure has FASD.
- **Which subset is that?** We currently have no way of knowing. This is why the 4-Digit Code refers to SE/AE and ND/AE as 'broadly" under the umbrella of FASD. Those with SE and ND caused by their alcohol exposure have FASD. Those with SE and ND that was not caused by their alcohol exposure do not have FASD.
- **But if they are exposed to high alcohol levels, can't we just assume alcohol caused their disability?** No. Not everyone exposed to high levels of alcohol presents with adverse outcomes. Among 2,576 alcohol-exposed individuals evaluated in the UW FASDPN Clinic to date, 26 with high exposures presented with full FAS (4-Digit Codes 4444) while 41 with high exposures presented with normal growth, face, and brain development (4-Digit Codes 1114) [17]. We also see discordant outcomes among fraternal twins. Among 20 twin pairs with identical high exposures, 5 had normal CNS function while their twin had moderate to severe CNS dysfunction [18].

  When an individual presents with high alcohol exposure and severe CNS dysfunction, but no FAS facial phenotype,as depicted in the diagnosis SE/AE (4-Digit Code 2134):

  - o If their CNS dysfunction is caused (at least in part) by their alcohol exposure, then their SE/AE is an FASD.
  - o If their CNS dysfunction was caused by other risk factors, not their alcohol exposure, then their SE/AE is NOT an FASD.
  - o The only way we can currently link alcohol to an individual's CNS dysfunction is if they present with a highly specific Rank 4 FAS face (FAS 2434).
- **If we cannot confirm alcohol caused a patient's disabilities, does this impact our ability to provide the patient with appropriate intervention?** No. Intervention recommendations and a patient's access to services and supports are based on their disabilities, not on what caused their disabilities. Twenty years of patient surveys [45] confirmed patients with a diagnosis of ND/AE and SE/AE were as likely to access and benefit from interventions as patients with FAS/PFAS. We did not have to label their disorder FAS or PFAS to qualify them for intervention and support services in Washington State.
- **If we cannot confirm a causal link between PAE and adverse outcomes in an individual patient, does this impact our ability to prevent FASDs?** No. To prevent FASD one must prevent PAE. To confirm efforts to prevent PAE are working, one needs to document PAE in a patient's medical record (regardless of outcome) and track the prevalence of PAE by birth cohort annually [46]. If one is reducing the prevalence of PAE, one is reducing the prevalence of FASD.

The four diagnostic systems produce different outcomes, but which one, if any, is correct?

Validation studies are required to confirm the accuracy, reproducibility, and medical validity of a diagnostic system. Validity is the degree to which a tool (or diagnostic system) is measuring what it purports to measure [47]. When the 4-Digit Code was introduced in 1997 [23,25], it was published as an empirical study confirming its superior performance to the gestalt [48,49] approach it was designed to replace. Since then, two decades of more extensive

laboratory, clinical, and public health empirical studies have comprehensively affirmed the validity of the FASD 4-Digit Code [17]. A clinician's guide for how to fully assess the performance of FASD diagnostic systems was presented in 2013 [17] and replicated with revision below in Table 5. The guide proposes 12 questions clinicians should ask to assess the performance of FASD diagnostic systems. The 4-Digit Code's performance meets all 12 criteria.

CONCLUSION

The needs of individuals and families impacted by FASD are best met when FASD diagnostic systems provide accurate diagnoses: 1) across the lifespan; 2) across the full spectrum of outcome (FAS, SE and ND); 3) across the full continuum of alcohol exposure; and 4) utilize diagnostic nomenclature that accurately reflects the association between outcome and alcohol exposure. These conclusions are supported by the current, published evidence base. In summary:

1. FASD is characterized by a spectrum of outcomes, not just severe outcomes.
   a. As illustrated in a primate model of FASD (Figure 6), PAE causes a full spectrum of outcome with moderate dysfunction (ND/AE) being the most prevalent outcome (59%).

      i) The vast majority (83%) of individuals with ND/ AE have 1 or 2 domains of severe dysfunction and multiple domains of moderate dysfunction. All require and benefit from intervention.
2. FASD is caused by the full continuum of PAE, not just high exposure.
   a. There is no known safe level of alcohol use during pregnancy.
   b. Requiring high PAE implies reported levels of PAE are reliably accurate. They are not.
   c. When high PAE is required for diagnosis, over half of individuals with confirmed PAE and severe CNS abnormalities do not receive a diagnosis of FASD.
   d. Over half of Individuals with the most severe outcome (FAS) have reportedly low to moderate PAE.
   e. The teratogenic impact of PAE is not just dependent on the timing and level of exposure. Twin studies confirm fetal genetics influences fetal vulnerability to PAE.
3. FASD is present at birth and should be diagnosed as early as possible, not after 3 or 6 years of age.
   a. Requiring severe CNS dysfunction prevents a diagnosis of FASD in a child too young to be fully assessed for CNS dysfunction.
   b. Excluding moderate CNS dysfunction from the umbrella of FASD prevents the early identification and intervention of children with confirmed PAE and moderate dysfunction (ND/AE).
   c. Excluding growth deficiency prevents the early identification of children who are at especially high risk for severe CNS dysfunction later in childhood.
   d. Children under 6 years of age with confirmed PAE and moderate dysfunction are not "At Risk" for FASD. Their alcohol exposures and moderate dysfunction have already occurred and warrant a diagnosis that documents their disability and qualifies them for early intervention.
4. FASD is characterized by growth deficiency, FAS facial features, and CNS structural/neurological/and functional abnormalities. Each present along clinically meaningful continuums and each are significantly correlated with PAE.
5. Growth deficiency is a core component of FASD.
   a. Growth deficiency (≤10th percentile) is as prevalent or more prevalent among individuals with PAE (32%) than the FAS facial phenotype (4%) and severe CNS abnormalities (39%).

Table 5. As clinicians assess the performance of FASD diagnostic guidelines, clinicians should ask the following questions [17].

1. Have properly designed studies been published to confirm the case definition for the FAS facial phenotype is highly specific (>95%) to FAS and alcohol (e.g., observed only among individuals with prenatal alcohol exposure and FAS)?
2. Was data used to empirically derive the diagnostic guidelines? Was the data drawn from a large, representative, and population-base?
3. Has the performance of the guidelines been empirically assessed (validated)?
4. Individuals are born with FAS/D. Can the diagnostic system identify FAS/D at birth and across the lifespan?
5. Growth deficiency, the FAS facial phenotype, CNS abnormalities, and alcohol exposure all present along clinically meaningful continuums. The FAS facial phenotype is not just present or absent. The brain is not just normal or abnormal. Do the Guidelines recognize/incorporate these important continuums?
6. Do the guidelines produce clinically distinct subgroups across the full spectrum (FAS, PFAS, SE/AE, ND/AE)?
A. Do brain imaging studies identify statistically significant contrasts between the FASD subgroups?
B. Individuals with FAS have more severe CNS dysfunction than individuals with "ARND". Do the Guidelines generate FAS and "ARND" groups that demonstrate this important contrast?
C. Do individuals who meet the criteria for FAS actually have FAS?
7. Can the guidelines detect unique alcohol exposure patterns between the FASD subgroups?
8. Can the diagnostic system be effectively and efficiently taught to interdisciplinary teams?
9. Are the guidelines confirmed to be reproducible? If two clinics use the guidelines, do they render the same diagnoses?
10. Do families report high satisfaction/confidence with the diagnostic process and outcome?
11. Are the names of the diagnoses (FAS, PFAS, SE/AE, ND/AE, ARND, ARBD, FASD with the Face, FASD without the Face) medically valid? Do they imply causality between alcohol and outcome that cannot be confirmed in the individual patient?
12. Do diagnoses under the umbrella of FASD qualify patients for intervention services that lead to improved outcomes?

b. The 4-Digit Code method for ranking growth deficiency successfully differentiates growth deficiency (postnatal short stature) associated with PAE from growth deficiency (low birth weight) associated with other risk factors like tobacco [9].

c. Growth deficiency (≤10th percentile) in infants/toddlers with PAE is as predictive of severe CNS dysfunction later in childhood as the Rank 4 FAS facial phenotype and microcephaly.

6. The 4-Digit Code Rank 4 FAS facial phenotype is the only outcome confirmed to date that is highly specific to (caused only by) PAE. This high specificity is required:

   a. To render a diagnosis of FAS when PAE is unknown.

   b. To confirm PAE is causally associated with outcomes in an individual patient.

   c. To validly label the disorder FAS or FASD.

7. Diagnostic nomenclature (e.g., ARND, FASD without the Face) should not infer a causal association between a patient's PAE and adverse outcomes when there is no evidence to validate such an inference.

   a. Inferring causation may erringly impugn some birth mothers.

   b. Effective intervention and prevention does not require confirmation of causation.

ETHICAL APPROVAL

This study was approved by the University of Washington Human Subjects Division.

AUTHOR CONTRIBUTION

All authors are members of the interdisciplinary FASD diagnostic team and participated in the interpretation and reporting of the study's outcomes. SJAH conducted the statistical analyses.

ACKNOWLEDGEMENTS

Special thanks are extended to the patients and their families for their benevolent contributions to the University of Washington FASDPN dataset.

COMPETING INTERESTS

The authors do not have any competing interests

SOURCES OF FUNDING

The Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network (FASDPN) has been supported over the past two decades by the following organizations: Centers for Disease Control and Prevention (1992-1997); Western Washington Chapter of the National March of Dimes Birth Defects Foundation (1995); Washington State Department of Social and Health Services through the passage of Senate Bill SB5688 (1997-present); and the Chavez Memorial Fund. Support has also been received from the Center on Human Development and Disability, University of Washington since 1993 (National Institute of Child Health and Human Development: P30 HD02274). The brain imaging data used in this study was obtained through support by the National Institute on Alcohol Abuse and Alcoholism R01-AA12915-01. The primate data used in this study was obtained through support by the National Institute on Alcohol Abuse and Alcoholism R01-AA05616-07.

ABSTRACT

Background: Atypical behavioral responses to sensation are reported in a large proportion of children affected by prenatal alcohol exposure (PAE). Systematic examination of symptoms across the fetal alcohol spectrum in a large clinical sample is needed to inform diagnosis and intervention.
Aims: To describe the prevalence and patterns of atypical sensory processing symptoms in a clinical sample of children with PAE.
Methods: Retrospective analysis of diagnostic clinical data from the University of Washington Fetal Alcohol Syndrome Diagnostic and Prevention Network (FASDPN). Participants were ages 3 through 11 years, had a diagnosis on the fetal alcohol spectrum, and Short Sensory Profile (SSP) assessment. The proportions of children categorized with definite differences on the SSP across selected clinical and demographic features were examined with chi-square analyses.
Outcomes: The sample consisted of 325 children; 73.2 % had SSP total scores in the definite difference range. Atypical sensory processing symptoms were significantly more prevalent among children with higher reported levels of PAE. The prevalence of atypical symptoms was comparably high across age, levels of diagnostic severity, and other prenatal/postnatal risks.
Conclusions: Results lend support for altered sensory processing as another domain of brain function affected by the teratogenic impact of PAE, guiding clinical work and research.

What this paper adds

Clinically significant sensory processing differences were highly prevalent in a large clinical sample of children with prenatal alcohol exposure (PAE) and outcomes consistent with fetal alcohol spectrum disorder. Findings corroborate previous reports of atypical sensory processing in smaller samples of children with PAE. Atypical sensory processing symptoms occurred in similarly high proportions across the full fetal alcohol spectrum, and across severity of key diagnostic features [central nervous system (CNS) function, facial features and growth)]. A higher prevalence of sensory processing differences was positively and significantly associated with children who had higher reported levels PAE. Findings lend support for the neurological processing of sensation as

another neurobehavioral domain that is vulnerable to the teratogenic impact of PAE, and inform diagnosis, intervention and areas for future research.

1. Introduction

Fetal alcohol spectrum disorders (FASD) is an umbrella term that describes the full range of physical, cognitive and behavioral impairments associated with prenatal exposure to alcohol (PAE). FASDs are estimated to occur in at least 1% of the population with prevalence estimates varying based on geography and method of diagnosis (Astley, 2011; Astley, Bledsoe, Davies, & Thorne, 2017; Roozen et al., 2016; Sampson et al., 1997). Diagnoses such as fetal alcohol syndrome (FAS), partial FAS (PFAS), static encephalopathy/alcohol exposed (SE/AE) and neurobehavioral disorder/alcohol exposed (ND/AE) fall broadly under the umbrella of FASD (Astley, 2004). The central nervous system (CNS) impairments associated with these conditions and the subsequent impact of brain-based challenge on daily activities varies among individuals and across the fetal alcohol spectrum, as do the individual strengths, supports and protective factors that foster functional performance and promote resiliency throughout the lifespan (Astley, 2010; Streissguth et al., 2004).

The teratogenic effects of PAE on the central nervous system (CNS) that have functional implications are well-documented and include, but are not limited to, cognitive, motor, memory, executive function and communication impairments (Mattson, Bernes, & Doyle, 2019). Atypical responses to sensation are reported in a large proportion of children with FASD and are widely described clinically (Astley, 2010). However, a systematic examination of the prevalence and patterns of sensory processing symptoms across the fetal alcohol spectrum is lacking. Poorly modulated responses to sensation may be an indicator of CNS dysfunction; and understanding sensory processing patterns can provide insights into maladaptive and dysregulated behaviors and inform intervention (Dunn, Little, Dean, Roberston, & Evans, 2016). The recognition of sensory processing differences in this group of vulnerable and often underserved children has implications for diagnosis and intervention that have not been fully realized due to limited empirical evidence.

Sensory processing is a term used to describe the organization of sensation for use in daily life that involves a continuum of interactions between an individual's neurological thresholds and behavioral responses to sensation (Dunn, 2001, 2007). Behavioral patterns of hyper-responsiveness (e.g., discomfort, irritability) and hypo-responsiveness to sensation (e.g., not noticing or slowed response) have been described within and across sensory domains (e.g., tactile, auditory, vestibular). These atypical or poorly modulated responses to sensation may result in sensory processing or sensory integration disorders (Miller, Anzalone, Lane, Cermak, & Osten, 2007). Sensory processing and sensory integration disorders occur in 5–16 % of children in the general population (Ahn, Miller, Milberger, & McIntosh, 2004) and at much higher proportions (up to 80 %) among children with neurodevelopmental disabilities (Cheung & Siu, 2009). Atypical responses to sensation are well documented, for example, among children with autism spectrum disorder (Ben-Sasson, Hen et al., 2009; Ben-Sasson, Carter, & Briggs-Gowan, 2009; O'Donnell, Deitz, Kartin, Nalty, & Dawson, 2012) and are part of the Diagnostic and Statistical Manual of Mental Disorders (DSM–5) diagnostic criteria for this condition (American Psychiatric Association, 2013).

Previous studies report sensory processing differences among clinical samples of children with PAE including those meeting criteria for FASD (Abele-Webster, Magill-Evans, & Pei, 2012; Carr, Agnihotri, & Keightley, 2010; Franklin, Deitz, Jirikowic, & Astley, 2008; Jirikowic, Olson, & Kartin, 2008; Wengel, Hanlon-Dearman, & Fjeldsted, 2011). Children with FASD have been described as more reactive to touch, visual, and auditory stimuli compared to peers with typical development, and patterns of sensory-seeking behaviors and sensory hypo-responsivity also have been reported (Jirikowic, Olson, & Kartin, 2008). Sensory processing problems have been associated with increased problem behaviors (Franklin, Deitz, Jirikowic, & Astley, 2008) and poorer adaptive functioning among children with FASD (Carr, Agnihotri, & Keightley, 2010; Jirikowic, Olson, & Kartin, 2008). In combination with executive function impairments (behavior dysregulation), sensory processing problems in children with FASD are associated with higher levels of parenting stress among caregivers of children with FASD (Jirikowic, Olson, & Astley, 2012). Sensory processing differences appear to be pervasive among children with FASD and these behaviors have far-reaching impacts on daily life activities and family functioning.

Atypical responses to sensation are also described in prenatally alcohol-exposed animal models (Schneider, Moore, & Adkins, 2011). Schneider et al. (2008, 2011) reported an increased magnitude of withdrawal to tactile stimuli in association with PAE and reduced habituation to sensation in association with prenatal stress in a cohort of rhesus monkeys with prenatal alcohol and stress exposure. Further, symptoms of atypical sensory processing observed in the neonatal phase of development in these animal models were correlated with adult tactile sensory functions, suggesting developmental continuity of sensory processing symptoms (Schneider et al., 2017). Heightened reactivity to more aversive, or mildly painful stimuli has also been reported in rodent models (Rogers, Barron, & Littleton, 2004). The linkage of sensory processing disorder to PAE in animal models coupled with emerging evidence of associated neurophysiological changes and genetic influences (Schneider et al., 2008,2011,2017) bolster the need to more fully understand sensory processing disorders in children affected by PAE.

This study aimed to describe the prevalence of atypical sensory processing behaviors in a large clinical population of children systematically diagnosed with FASD, to explore risk factors associated with atypical sensory processing behaviors, and to explore sensory processing patterns across this population. The following research questions were asked:

1 What is the prevalence of atypical sensory processing behaviors among children with FASD?
2 Does the prevalence of atypical sensory processing behaviors vary by child characteristics [e.g., age, gender, level of alcohol exposure, FASD diagnosis, attention deficit hyperactivity disorder (ADHD)], or other prenatal or postnatal risk factors?

3 What are the patterns of sensory processing behaviors across sensory domains (e.g., tactile, auditory, vestibular) in children with FASD?

2. Materials and methods

2.1. Procedures

A retrospective analysis of clinical data from the Fetal Alcohol Syndrome Diagnostic and Prevention Network (FAS DPN) at the University of Washington was completed. The clinic has provided diagnostic evaluations for FASD, including FAS, since 1993. Patients of all ages (newborn to adult)newborn to adult are evaluated. The FAS DPN database currently contains over 2,000 fields of data (exposures and outcomes) on approximately 3000 patients with prenatal alcohol exposure. Data used for this study were collected with University of Washington Human Subjects approval and patient consent at the time of diagnosis.

All patients in the FAS DPN database were evaluated for FASD using the *4-Digit Diagnostic Code* (updated and coded according to criteria from the most current edition (Astley, 2004), an interdisciplinary approach to diagnosis guided by empirically validated criteria (Astley, 2004, 2013). The four digits of the FASD *4-Digit Diagnostic Code* reflect the magnitude of expression of the four key diagnostic features of FASD, in the following order: 1) growth deficiency, 2) FAS facial phenotype, 3) structural/functional CNS abnormalities, and 4) prenatal alcohol exposure. The magnitude of expression of each feature is ranked independently on a four-point Likert scale, with '1′ reflecting complete absence of the FASD feature and '4' reflecting a strong and classic presentation of the feature. Each Likert rank is specifically case defined. There are 102 4-Digit codes that fall broadly under the umbrella of FASD. These codes cluster into four clinically meaningful FASD diagnostic subcategories (Astley, 2004): fetal alcohol syndrome (FAS); partial FAS (PFAS); static encephalopathy/alcohol exposed (SE/AE); and neurobehavioral disorder/alcohol exposed (ND/AE).

2.2. Participants

Selected data from children who met the following study inclusion criteria were used: a) between 3 and 11 years old at time of diagnostic clinic visit, b) FASD diagnosis (including FAS or PFAS, SE/AE, or ND/AE), and c) completed Short Sensory Profile (SSP; McIntosh, Miller, Shyu, & Dunn, 1999). The FAS DPN began administering the SSP in the year 2000. Subjects with missing data on more than one-third of the items in any SSP domain were excluded.

2.3. Measures

2.3.1. Sensory processing behaviors

Short Sensory Profile (*SSP*: McIntosh et al., 1999) The SSP is a 38-item caregiver questionnaire that measures children's behavioral responses to sensation in daily life. The SSP is the short version of the longer 125-item Sensory Profile that is used for screening and research purposes (Dunn, 1999). The SSP examines behaviors in the sensory domains of Tactile Sensitivity, Taste/Smell Sensitivity, Movement Sensitivity, Under-responsive/Seeks Sensation, Auditory Filtering, Low Energy/ Weak, and Visual/Auditory Sensitivity. Caregivers report how frequently children respond in the way described by each item using a 5-point Likert scale (1 = almost always; 2 = frequently; 3 = occasionally; 4 = seldom; 5 = almost never). The SSP has high internal consistency for the total score (Cronbach's alpha = 0.96) and domain scores (Cronbach's alpha = 0.82 to 0.89). Lower raw scores indicate more atypical sensory processing behaviors. Raw scores are categorized as typical performance (scores at or above -1.0 standard deviation (SD) from the mean), probable differences (scores at or above -2.0 SD but lower than -1.0 from the mean) and 3) definite difference (scores below -2.0 SD from the mean).

2.3.2. FASD diagnosis and features

4-Digit Code FASD Diagnosis (FAS; PFAS; SE/AE; ND/AE). See full description above (Astley, 2004) and rankings for the following diagnostic features.

Growth Deficiency ('Growth Rank': 1 = none; 2 = mild; 3 = moderate; 4 = severe). This variable yields the first digit in the 4-Digit FASD Diagnostic Code and documents the magnitude of prenatal and/or postnatal growth deficiency (Astley, 2004).

FAS Facial Phenotype ('Face Rank': 1 = none; 2 = mild; 3 = moderate; 4 = severe). This variable represents the second digit in the 4-Digit FASD Diagnostic Code and documents the magnitude of expression of FAS facial phenotype defined by short palpebral fissure lengths, a smooth philtrum, and a thin upper lip (Astley, 2004).

CNS Likelihood of Structural Abnormality ('CNS Rank': 1 = unlikely; 2 = possible; 3 = probable; 4 = definite). This variable yields the third digit in the 4-Digit FASD Diagnostic Code. These four ranks document the increasing likelihood of CNS structural abnormality. Alcohol is a teratogen that interferes with the structural development of the fetal brain. This, in turn, can lead to abnormal function. The greater the dysfunction, the higher the probability of CNS structural abnormality (Astley, Aylward et al., 2009; Astley et al., 2009; Astley, 2013). The first three CNS Ranks document the severity of CNS dysfunction (Rank 1-no dysfunction; Rank 2-mild-to-moderate dysfunction; Rank 3-severe dysfunction). CNS Ranks 1–3 are based on brain function (executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention, and activity level) assessed by an interdisciplinary team using standardized psychometric tools. CNS Rank 4 documents the presence of direct evidence of CNS structural and/or neurological abnormalities (e.g., microcephaly, structural brain abnormalities, a seizure disorder of prenatal origin, or other hard neurological signs).

Prenatal Alcohol Exposure ('Alcohol Rank': 1 = confirmed absence of exposure; 2 = unknown exposure; 3 = confirmed exposure; level unknown or moderate; 4 = confirmed exposure; level high). Alcohol exposure is the fourth digit in the 4-Digit FASD Diagnostic Code, which is ranked according to the quantity, timing, frequency, and certainty of exposure during pregnancy. The ranking is determined by available records, maternal report or report from others who observed exposure. A diagnosis under the umbrella of FASD requires a confirmed PAE (Rank 3 or 4) with one exception-FAS. FAS requires the Rank 4 FAS facial phenotype which is so highly specific to (caused only by) PAE that the presence of the Rank 4 FAS facial phenotype offsets the need for an independently confirmed history of alcohol exposure.

2.3.3. Other risk factors

Attention Deficit Hyperactivity Disorder (ADHD) Diagnosis This variable documents a confirmed previous ADHD diagnosis from a qualified provider or as a result of the FAS DPN clinical assessment.

Other Prenatal Risk Rank (1 = no risk; 2 = unknown risk; 3 = some risk; 4 = high risk) (Astley, 2004). Other prenatal risk factors documented in the FAS DPN clinical database include poor prenatal care, pregnancy complications, presence of other syndromes/genetic abnormalities, and prenatal exposure to other substances (e.g., medications, tobacco, illicit drugs, and/or other teratogens). The 4-Digit Code ranks the magnitude of these other prenatal risks in a single composite measure labeled "Other Prenatal Risks Rank." Rank 4 is assigned when there is exposure to another teratogen (e.g., Dilantin) or when another syndrome or genetic condition is present (e.g., Down syndrome, Fragile X, etc.). Rank 3 is assigned to all other prenatal risks. The ranking is determined by available records and caregiver or other report on intake forms and/or clinical interview (Astley, 2004)

Other Postnatal Risk Rank (1 = no risk; 2 = unknown risk; 3 = some risk; and 4 = high risk) (Astley, 2004). Postnatal risk factors documented in the FAS DPN database include perinatal complications, number of home placements, physical and/or sexual abuse, neglect, and trauma. The 4-Digit Code ranks the magnitude of these other postnatal risks in a single composite measure labeled "Other Postnatal Risks Rank". Rank 4 is used to note severe postnatal circumstances that have been shown to have a significant adverse effect on development in most instances. Examples include physical or sexual abuse, multiple home placements, and severe neglect. Rank 3 is used to note conditions akin to those in Rank 4, but the circumstances are less severe. The ranking is determined by available records and caregiver or other report on intake forms and/or clinical interview.

2.4. Data analysis

SPSS version 19.0 (IBM Corp, 2010) and MedCalc for Windows, version 18.6 (MedCalc Software) were used to conduct the analyses. Descriptive statistics (means, standard deviations, proportions) were used to profile the demographic characteristics of the study population and SSP outcomes for the total score and seven domain scores. Relationships between the SSP total score and SSP domain score categories (typical performance, probable difference, and definite difference) and selected child demographics (age, gender, ADHD; co-occurring prenatal and postnatal risk factors) and FASD diagnosis and features were examined using chi-squared (χ^2) and Fisher's exact tests.

To further describe and explore sensory processing patterns, the proportion of item-level behaviors scored by caregivers as occurring always (100 % of the time or more) or frequently (about 75 % of the time) was analyzed. In addition, SSP outcomes were dichotomized into 2 categories: 1) typical performance and probable differences (scores at or above -2.0 SD from the mean) and 2) definite difference (below -2.0 SD from the mean) to explore domain scores and sensory over-responsiveness (SOR) characteristics. A "Sensory Over-Responsiveness (SOR)" score was calculated by combining SSP Tactile Sensitivity items (1–7), Taste/Smell Sensitivity items (8–11), Movement Sensitivity items (12–14), and Visual Auditory Sensitivity items (34–38 (Mazurek et al., 2013). Lower SOR scores indicate more sensory over-responsiveness. Finally, SSP domain scores and prevalence for children with FASD with and without ADHD were contrasted. All results were considered significant at 2-sided p-values of $< .05$. P-values for post-hoc analyses were exploratory and were not corrected for multiple comparisons and should be interpreted with appropriate caution.

3. Results

Records from 325 participants met study inclusion criteria; 43 were missing some SSP data. When item-level data were missing the average of the subject's remaining scores in the incomplete sensory domain was calculated and rounded to the closest whole number. This value replaced the missing score(s) in that domain. The adjusted item scores were rounded to the closest whole number. Clinical and sociodemographic characteristics for the total sample (n = 325) are presented in Table 1. Children had a range of diagnoses on the fetal alcohol spectrum, with the largest proportion diagnosed with ND/AE, followed by SE/AE and then FAS or PFAS (Table 1. The sociodemographic and clinical profile of this study sample is highly representative of the larger FAS DPN population of 3000 patients Astley, 2010).

3.1. Prevalence of atypical sensory processing behaviors

The proportion of children classified in each SSP category (typical performance, probable difference, definite difference) for each of the seven sensory domains and total score is shown in Fig. 1. Results indicated that 73.2 % of children in this sample were categorized with definite differences on the SSP total score. Differences were noted across all sensory domains with the highest proportions of definite differences in the domains of Auditory Filtering (81.8 %) and Under-responsive/Sensation Seeking (80.0 %). Definite differences in other domains associated with sensory over-responsiveness (SOR) were noted, but to a lesser extent (Fig. 1).

3.1.1. Sensory processing differences: FASD diagnostic characteristics

Atypical sensory processing symptoms (SSP total scores in the definite difference category) were significantly more prevalent among children with confirmed PAE at reportedly high levels (Alcohol Rank 4) than among those with confirmed PAE at unknown or reportedly lower levels (Alcohol Rank 3; Table 2). The prevalence of atypical sensory processing (SSP total scores in the definite difference range) was comparably high (72%–77%) across all FASD diagnoses (Table 2). The same pattern of distribution was observed across the four Growth Ranks, Face Ranks and CNS Ranks (data not shown). The prevalence of atypical sensory processing (SSP total scores in the definite difference range) was comparably high (67%–81.7%) across all ranks for growth, face and CNS (data not shown).

3.1.2. Sensory processing differences: child characteristics and risk factors

The prevalence of atypical sensory processing behaviors (SSP total scores in the definite difference range) did not vary significantly by age or clinical ranking of other prenatal risk factors or postnatal risk factors. Although a higher proportion of children with ADHD (73.1 %) had definite differences in the SSP total score than those without ADHD (68.9 %), differences in the total score were not statistically significant ($\chi^2 = 3.2$, $p = .07$). Significant differences by gender were found. Males were significantly more likely (78.1 %) to present with total scores in the definite difference range than females (65.3 %; $\chi^2 = 6.4$, $p = .011$).

3.2. Sensory processing patterns: exploratory analyses across behaviors and domains

Sensory processing patterns were further explored in three ways. Fig. 2 illustrates the proportion of item-level behaviors that were ranked by caregivers as occurring always (100 % of the time) or frequently (about 75 % of the time) within each of the seven sensory processing domains. Data show the frequency of specific sensory processing behaviors that are most problematic in daily life.

Sensory processing patterns were also compared by dichotomizing SSP total score outcomes into 2 categories, those with 1) typical performance and probable differences (scores at or above -2.0 SD from the mean) or 2) definite difference (at or below -2.0 SD from the mean) (see Fig. 3). Children with definite differences on the SSP total score were about twice as likely to have definite differences in both the Under-responsive/Seeks Sensation and Auditory Filtering domains as compared to those without. However, atypical behaviors in these two domains were the predominant symptoms in both groups. In contrast, the proportion of children with definite differences in the other sensory processing domains was consistently higher for those with definite differences on the SSP total score. For example, there was approximately a10-fold increase in the prevalence of definite differences in the domain of Movement Sensitivity; an 8-fold increase in the prevalence of definite differences in the domains of Tactile Sensitivity and Visual and Auditory Sensitivity; and a 4-fold increase in Taste/Smell Sensitivity.

These four sensory processing domain scores have items that comprise a score some have coined as the SOR score (Mazurek et al., 2013). Subsequently, we explored if the distribution of SOR scores differed between those who did and did not receive a total score in the definite difference range. We found the distribution of SOR scores was significantly different between groups (Area under the ROC curve (AUC) 0.935, $p < 0.0001$) and could be used to sort the groups with significant accuracy (81.5 % accuracy at the most accurate cut-point). The distribution of SOR scores differed significantly more between the two groups than either the Auditory Filtering score (AUC 0.860, significantly different than SOR, $p = 0.0092$) or the Under-responsive/Seeks Sensation score (AUC 0.870, significantly different than SOR, $p = 0.0141$).

Finally, because of the high prevalence of co-occurring ADHD in this sample and the atypical sensory processing behaviors that have been documented in other studies of children with ADHD (Panagiotidi, Overton, & Stafford, 2018), we also explored SSP patterns for the children with FASD in this sample who had ADHD compared to those who did not have ADHD (see Fig. 4). While the overall pattern across the seven domains in both groups was similar, definite differences in the Under-responsive/Sensation Seeking domain (89.0 % vs 76.2 %, respectively; $\chi^2 = 8.9$, $p = 012$) and Auditory Filtering domain (88.3 % vs 72.6 %, respectively; $\chi^2 = 11.9$ $p = 001$) were significantly more prevalent in children with co-occurring ADHD relative to those without ADHD, and males were significantly more likely to have a co-occurring diagnosis of ADHD (53.6 %) than females (35.7 %) ($\chi^2 = 9.3$, $p = .002$).

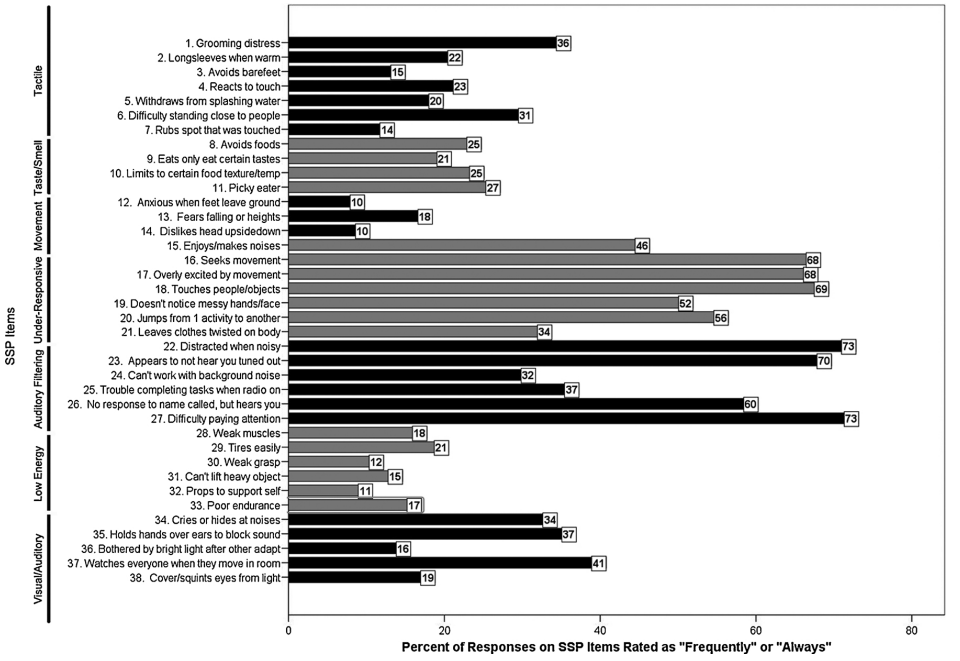

Fig. 2. Proportion of SSP item-level behaviors by domain ranked by caregivers as occuring Always (100% of the time or Frequently (about 75% of the time).

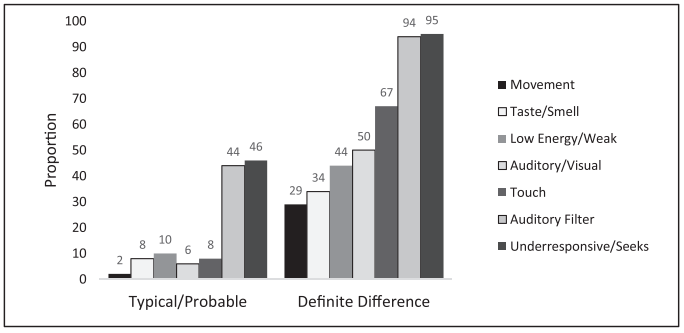

Fig. 3. Comparison of SSP domain scores by total score categories (definite difference vs. typical performance/probable difference. Bars reflect the proportion of the children with definite difference by SSP domain.

4. Discussion

This study is the first to report the prevalence of symptoms of sensory processing dysfunction in a large clinical sample of children with PAE and to demonstrate a significant positive association between prevalence of atypical sensory processing and PAE. Atypical sensory processing symptoms, as determined by total scores in the definite difference category of the SSP were prevalent in a high proportion (73.7 %) of children ages 3–11 years old, and significantly more prevalent among children with higher reported levels of confirmed PAE (Alcohol Rank 4) as compared to children with unknown or lower reported levels of confirmed PAE (Alcohol Rank 3). Males in this sample also had a significantly higher prevalence of sensory processing differences than females, but prevalence did not differ by other selected demographic or risk factors such as age, ADHD diagnosis, or level of other prenatal or postnatal risks. Results from this large clinical sample corroborate and strengthen findings that atypical sensory processing symptoms occur frequently

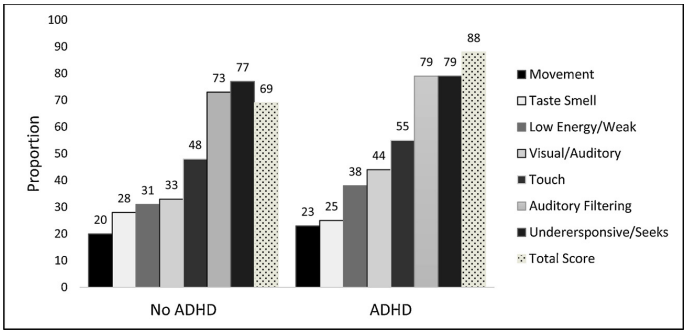

Fig. 4. Comparison of SSP domain scores for children with prenatal alcohol exposure who have co-occurring ADHD and those without ADHD.

among children with PAE, and that higher levels of PAE may induce more impairments in this domain of CNS functioning. While the latter finding needs replication and more research is needed to understand how PAE and sensory processing may be linked, direct associations between PAE and atypical sensory processing behaviors have been shown in alcohol-exposed animal models (Schneider et al., 2008, 2017).

The high prevalence of sensory processing differences across diagnoses on the fetal alcohol spectrum is consistent with prevalence estimates reported in previous studies of children with PAE that used smaller clinical samples (Abele-Webster et al., 2012; Carr, Agnihotri, & Keightley, 2010; Franklin, Deitz, Jirikowic, & Astley, 2008; Jirikowic, Olson, & Kartin, 2008). Even when using the conservative cut-off of -2.0 SD from the mean, almost three quarters (73.7 %) of the children with PAE had atypical responses to sensation. This prevalence falls at the higher end of the range of prevalence estimates (30%–80%) reported for other children with neurodevelopmental disabilities (Ben-Sasson, Hen et al., 2009; Ben-Sasson, Carter et al., 2009; Tomchek & Dunn, 2007). The item-level behaviors analyzed for this study shed light on how these behaviors affect participation in daily activities (e.g., distress during grooming; difficulty functioning with background noise, seeking all sorts of movement). Atypical sensory processing behaviors clearly occur and are a clinically significant problem among children with PAE.

As expected, atypical sensory processing behaviors were highly prevalent across the full fetal alcohol spectrum and severity of diagnostic features. Notably, impaired sensory processing occurred across all levels of CNS dysfunction that ranged from mild to moderate/severe. A striking new finding is that the prevalence of atypical sensory behaviors was significantly higher in children with higher levels of confirmed PAE. This association between PAE and atypical sensory processing behaviors in a large clinical sample lends support for sensory processing and integration as another CNS domain that is vulnerable to the teratogenic impact of alcohol. These clinical findings are substantiated by findings in animal models where less optimal sensory processing function (tactile over-responsivity and vestibular function) has been described in primates exposed to moderate levels of alcohol as compared to non-exposed controls (Schneider et al., 2008,2017, 2011).

Interestingly, the prevalence of atypical sensory processing behaviors in this clinical sample of children did not differ based on reported levels of other prenatal risks (e.g., pregnancy complications, other prenatal exposures, other syndromes/genetic abnormalities) or postnatal risks (e.g., physical/sexual abuse, neglect, trauma). The high prevalence of adverse childhood experiences reported in this clinical sample, coupled with findings by Schneider et al. (2017) that revealed a main effect of prenatal stress exposure in relation to atypical sensory processing in alcohol and stress exposed primate models prompted a post hoc analyses. The analyses explored whether more specific prenatal (i.e., exposure to tobacco or other illicit drugs, pregnancy complications, family history of developmental disorders, etc.) and postnatal (i.e., physical abuse, sexual abuse, neglect, multiple home placements) risks affected sensory processing outcomes. These analyses (data not shown) also did not reveal any significant relationships between SSP outcomes and specific risk factors. It is possible that in both analyses the presence of other prenatal and postnatal risk factors were not reported clinically with sufficient accuracy to detect true relationships with sensory processing outcomes.

Adversity and complex trauma have been implicated as risk factors that alter neurobehavioral development in areas that include self-regulation and sensory processing (van der Kolk, 2003). However, comparable systematic or descriptive clinical studies of sensory processing behaviors in children with complex trauma are limited for comparison. Purvis, Brooks, Cross, and Becker Razuri (2013) reported sensory processing deficits occurred in a small sample (n = 19) of adopted children 3–14 years old with histories of early deprivation or abuse. However, similar to other studies that describe the neurobehavioral implications of adverse childhood experiences and sensory processing in children, the presence (or absence of) PAE is not clearly accounted for (Fraser, MacKenzie, & Versnel, 2017; Rinne-Albers, van der Wee, Lamers-Winkelman, & Vermeiren, 2013). Future research that examines sensory processing in children with PAE who are also at high risk for other adverse childhood experiences such as trauma, abuse and neglect (Price, Cook, Norgate, & Mukherjee, 2017) must account for the potential interaction of both PAE as a teratogen and cumulative environmental risk factors as they collectively may alter developmental outcomes and trajectories.

Males in this sample had a significantly higher prevalence of sensory processing differences than females, but prevalence estimates across the SSP total score did not differ by other selected demographic factors (age or ADHD diagnosis). Gender differences,

developmental implications and the overlap of sensory processing symptoms with other neurobehavioral characteristics (e.g., inattention) are noteworthy because they have been examined in other groups of children with sensory processing problems and neurodevelopmental disabilities, but findings are mixed and inconclusive (Ghanizadeh, 2011; Lane, Reynolds, & Thacker, 2010; Miller, Nielsen, & Schoen, 2012; Panagiotidi et al., 2018). Specific to children with FASD, Abele-Webster et al. (2012) also reported differences in the domains of Under-responsive/Sensation Seeking and Auditory Filtering to be the most prevalent among a small clinical sample (n = 26) of children with FASD, but found only weak correlations between sensory processing and attention problems as measured by the Connors Parent Rating Scales-Revised (1997). More recently, SSP Auditory Filtering behaviors were extensively examined by McLaughlin et al. (2019) as a proxy for listening behaviors among children with FASD. Listening problems, attributed to suprathreshold auditory processing deficits, were highly prevalent across all diagnosis on the fetal alcohol spectrum and occurred in the absence of hearing loss. Auditory Filtering differences were also significantly correlated with age and ADHD.

These relationships and potential shared mechanisms underlying sensory processing impairments are being investigated through biobehavioral studies of children with and without clinical sensory processing deficits. For example, Davies, Chang, and Gavin (2009) measured auditory event-related potential (ERP) responses using electroencephalography (EEG) in children with sensory processing disorders, children with typical development and adults. They reported differences in the maturational trajectories of sensory gating, the brain's capacity to regulate sensitivity to sensory stimuli, between children with and without clinical sensory processing disorders (SPD). The children with SPD also showed a diminished ability to filter repeated auditory input and did not selectively regulate sensitivity to sensory stimuli. Owen et al. (2013) reported disrupted white matter microstructure integrity examined through diffusion tensor imaging (DTI) in a sample of 8–11 year-old males with and without SPD. The differences noted in posterior cerebral tracts were strongly correlated with behavioral measures of atypical sensory processing and integration. The authors concluded that abnormal white matter may be a biomarker for children with SPD with potential to distinguish this disorder from other clinical conditions such as autism and ADHD. Neuroimaging and neurophysiological studies of sensory processing need replication in children with FASD to corroborate behavioral findings, disentangle co-morbid symptoms, and examine these brain-behavior relationships in the presence of PAE as a teratogen.

The predominant patterns of differences in Under-responsive/Sensation Seeking and Auditory Filtering domains coupled with differences, but to a lesser degree, in domains that represent sensory over-responsiveness are congruent with profiles reported in previous studies of children with FASD (Abele-Webster et al., 2012; Carr, Agnihotri, & Keightley, 2010; Franklin, Deitz, Jirikowic, & Astley, 2008). The distinction of subtypes for children with PAE is beyond the scope of the present study and limited by the use of the SSP, however, the robust patterns of under-responsive/sensation seeking tendencies are notable, but wider ranging differences (21%–50%) in sensory domains that represent sensory-over-responsiveness, suggest more analyses of subtypes is an important area of future study. Our exploratory analysis also suggests that the presence of more frequent sensory-over responsive behaviors may potentially differentiate atypical sensory processing from other overlapping symptoms in this population, such as inattention. Clinical sensory processing subtypes and their relation to behavior patterns as well as neurobehavioral and diagnostic characteristics within and between different populations of children are important areas of focus of current research (Little, Dean, Tomchek, & Dunn, 2017; Little, Dean, Tomchek, & Dunn, 2018; Miller, Schoen, Mulligan, & Sullivan, 2017).

Because of the overarching interest in sensory behaviors and sensory processing patterns between different diagnostic groups and the lack of previous studies that include a comparison group of children with FASD, exploratory post hoc contrasts were made using data from a previous study that reported SSP outcomes for children of similar age on the autism spectrum. Fig. 5 shows contrasts between outcomes across the three SSP classification categories of typical, probable and definite differences using outcomes from 42 children with ASD (O'Donnell et al., 2012) in comparison to the current sample of children with FASD.

Notably, the proportion of sensory processing definite differences for the total score and five out of seven domain scores were higher for children with FASD compared to children with ASD. Children with FASD showed more atypical behaviors in the definite difference category across all domains except for the Taste/Smell domain where the children with ASD had a greater proportion of definite differences; and the Movement Sensitivity domain, where the proportion of definite differences was comparable. Results reveal specific sensory domains (e.g., oral sensory processing) that may be different, as well as sensory behaviors that may overlap between children with FASD as compared to children with ASD-a group with well-documented sensory processing differences (Ben-Sasson, Hen et al., 2009; Ben-Sasson, Carter et al., 2009; Caminha & Lampreia, 2012) and diagnostic criteria that includes atypical sensory symptoms. While these exploratory analyses must be interpreted with caution, findings further demonstrate the need to include children with FASD in systematic comparisons of sensory processing with other clinical groups. Systematic comparisons can enrich larger scale research efforts that aim to improve the early identification of sensory processing impairments in children at-risk; inform individualized, targeted interventions; and examine shared neurological mechanisms underlying sensory processing disorders (Little et al., 2018).

4.1. Limitations

One study limitation is the use of caregiver reported outcome to measure sensory processing differences. Caregivers may be biased in their reporting of symptoms. However, caregiver report is an accepted clinical means of measuring ecologically valid behaviors that reflect daily function and responses in different environments. Likewise, the SSP is a short version of a more comprehensive questionnaire. However, the SSP has adequate to good psychometric reliability and validity and has been used extensively in research (Tomchek & Dunn, 2007). Because this was a retrospective study, our data do not reflect the use of the newer and perhaps more refined tools that can measure more and different dimensions of sensory processing (Jorquera-Cabrera, Romero-Ayuso, Rodriguez-Gil, & Triviño-Juárez, 2017). The precise measurement of sensory processing for assessment and intervention purposes remains a

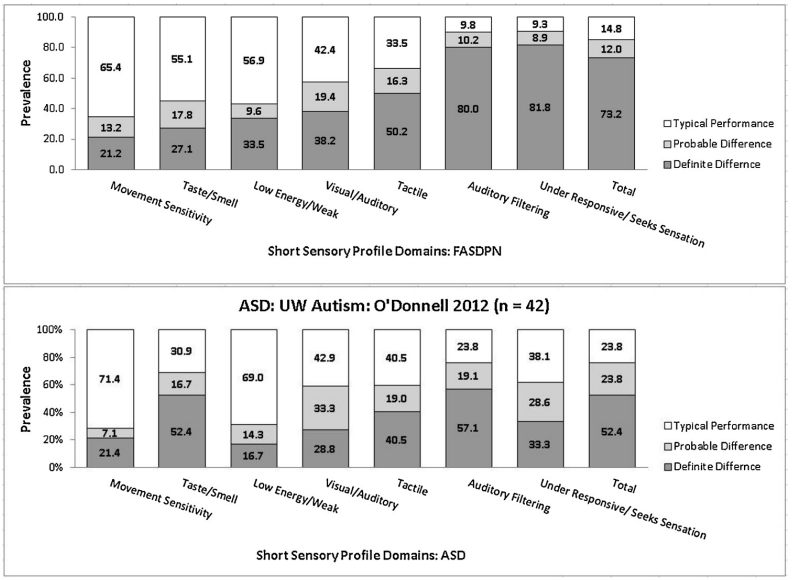

Fig. 5. Comparison of SSP outcomes among A) the 325 children with FASD in the current study and B) 42 children with autism spectrum disorder in a previous published study (O'Donnell et al., 2012). Proportion of of typical performance, probable difference and definite difference across the seven SSP domains and total score.

research and clinical priority, and combined approaches that use questionnaires, direct clinical observation and performance-based assessments are recommended Tvassoli et al. (2019).

5. Conclusion

Results demonstrate that clinically significant sensory processing differences are highly prevalent in a large clinical sample of children with PAE and diagnostic outcomes on the fetal alcohol spectrum. Higher prevalence of sensory processing differences among children with higher levels of PAE suggests that neurological processing of sensation may be vulnerable to the teratogenic impact of PAE. From a clinical standpoint, this reinforces that sensory processing behaviors warrant attention in diagnostic assessments since they occur across the full spectrum of diagnosis. The recognition of sensory processing differences is also an important source of data to inform interventions that can help reframe challenging behaviors, provide positive behavioral supports and accommodations and help tailor environments that enable successful participation in home, school and community.

ADVANCES IN PEDIATRIC RESEARCH

What proportion of the brain structural and functional abnormalities observed among children with fetal alcohol spectrum disorder is explained by their prenatal alcohol exposure and their other prenatal and postnatal risks?

Susan J Astley Hemingway*, Julian K. Davies, Tracy Jirikowic, Erin M. Olson

University of Washington, Seattle, WA, USA

Abstract

Background: Individuals with prenatal alcohol exposure (PAE) often present with a myriad of other prenatal (e.g. exposure to tobacco and other illicit drugs, poor prenatal care) and postnatal risk factors (e.g. multiple home placements, physical/sexual abuse, low socio-economic status)-all of which are likely contributing to their adverse outcomes.

Methods: A comprehensive neuropsychological battery, coupled with magnetic resonance imaging, was administered to children with fetal alcohol spectrum disorders (FASD) in 2009. Study participants diagnosed with FASD by the University of Washington using the FASD 4-Digit Code were compared to typically-developing peers with no PAE. Data from this MRI study were used to explore the proportion of variance in brain structural and functional abnormalities explained by PAE and 14 other prenatal and postnatal risk factors.

Results: PAE was the dominant risk factor explaining the largest proportion of variance in regional brain size (total brain, frontal lobe, caudate, hippocampus and corpus callosum) and brain function (intellect, achievement, memory, language, executive-function, motor, adaptation, behavior-attention and mental health symptoms). Other prenatal and postnatal risk factors were 3 to 7-fold more prevalent than in the general population. Individually, each risk factor explained a statistically significant, but smaller proportion of variance in brain outcome compared to PAE. In combination, the proportion of variance explained by the presence of multiple prenatal and postnatal risks rivaled that of PAE.

Conclusion: A better understanding of the impact other prenatal and postnatal risk factors have on the neurodevelopmental outcomes of individuals with FASD can inform more effective prevention and intervention strategies.

Introduction

Individuals with prenatal alcohol exposure (PAE) often present with a multitude of other prenatal (e.g. exposure to tobacco and other illicit drugs, poor prenatal care, premature birth) and postnatal risk factors (e.g. multiple home placements, physical/sexual abuse, low socio-economic status (SES) [1,2]. Each of these risks individually is known to contribute to adverse neurodevelopmental outcomes [3-9].

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

To date, little research has examined the combined impact of these other prenatal and postnatal exposures on the neurodevelopmental outcomes of children with PAE. Interactions between PAE and prenatal cocaine exposure have been documented in a few studies [10-12]. Streissguth et al., [13] documented more impaired outcomes among individuals with FASD that experienced longer versus shorter durations of adverse postnatal experiences (abuse, violence, neglect). In a literature review, Price et al., [14] identified five studies that investigated the combined impact of trauma in children with PAE. In one of these studies, children with both PAE and trauma were more likely to have deficits in language, attention, memory, intelligence and more severe behavioral problems than children with only one of these adverse exposures [15]. Most recently, Uban et al., [16] assessed the impact of socioeconomic status (SES) on neurostructural development in children with and without PAE. As anticipated, typically developing youth without PAE exhibited increased subcortical volumes with increased SES. But unexpectedly, SES-brain associations were not observed among the youth with PAE.

Two key challenges to researching the adverse impacts of PAE and other prenatal and postnatal risk factors on neurodevelopment are 1) finding reliable documentation of these adverse exposures and experiences; and 2) having access to a study population that have all had the same comprehensive, standardized neuropsychological battery of assessments and MR imaging protocols. PAE along with other prenatal and postnatal risks are typically recorded in past medical, legal and social service records; records that are routinely obtained by FASD diagnostic clinics in preparation for a FASD diagnostic evaluation. Review and documentation of these other risks has always been a priority with the FASD 4-Digit Code, a systematic, validated diagnostic system. These risk factors are formally recorded in the FASD 4-Digit Code Diagnostic Form [17] and ranked on 4-point Likert scales (Prenatal Rank and Postnatal Rank) just like the growth, face, brain and alcohol components of the FASD 4-Digit Code. But FASD diagnostic clinics rarely have the ability to validly administer a single, standardized, comprehensive battery of neuropsychological assessments to all patients. Many factors come into play when selecting the most appropriate battery for an individual patient (their age, clinical presentation, previous participation in neuropsychological assessments, etc.). Comprehensive, standardized neuropsychological assessment batteries and MRI imaging protocols are the mainstay of controlled research studies, not diagnostic clinics.

The present study sought to capitalize on the combined strengths of our clinical and research programs. In 2009, a comprehensive FASD neuropsychological-magnetic resonance imaging study was completed at the University of Washington FAS Diagnostic & Prevention Network (FASDPN) [18-21]. Patients previously diagnosed across the full continuum of FASD were enrolled in the study. The combination of clinical and research protocols produced a study population with the full complement of exposure and outcome measures necessary to explore the proportion of variance in brain structural and functional abnormalities explained by PAE and other prenatal and postnatal risk factors. A better understanding of the impact other prenatal and postnatal risk factors have on the neurodevelopmental outcomes of individuals with FASD can inform more effective primary prevention and intervention strategies.

Research Methodology

Subjects and study groups

The current study is a retrospective exploratory analysis of data collected from a 2009 neuropsychological and magnetic resonance imaging (MRI) study [18-21] comparing central nervous system (CNS) structural and functional outcomes between children with FASD and typically developing peers with confirmed absence of PAE. In the original 2009 study, three FASD groups (defined below) were selected from among 1,200 patients previously diagnosed by an interdisciplinary team in the WA State FAS Diagnostic & Prevention Network (FAS DPN) of clinics using a comprehensive, validated diagnostic system called the FASD 4-Digit Code [17,22,23]. Briefly, the 4 digits of the FASD 4-Digit Code reflect the magnitude of expression of the 4 key diagnostic features of FASD, in the following order:

1. Growth deficiency,
2. FAS facial phenotype,
3. CNS structural/functional abnormalities, and
4. PAE

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

The magnitude of expression of each feature was ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong "classic" presence of the FASD feature. Each Likert rank is specifically case defined (Figure 1). 4-Digit Codes range from 1111 to 4444. Each 4-digit diagnostic code falls into 1 of 22 unique clinical diagnostic categories (labeled A through V). Seven of the 22 diagnostic categories (4-Digit Categories A–C and E–H) fall under the umbrella of FASD (A. FAS/ Alcohol Exposed, B. FAS/Alcohol Exposure Unknown, C. Partial FAS/Alcohol Exposed, E & F. Static Encephalopathy/Alcohol Exposed, and G & H. Neurobehavioral Disorder/Alcohol Exposed).

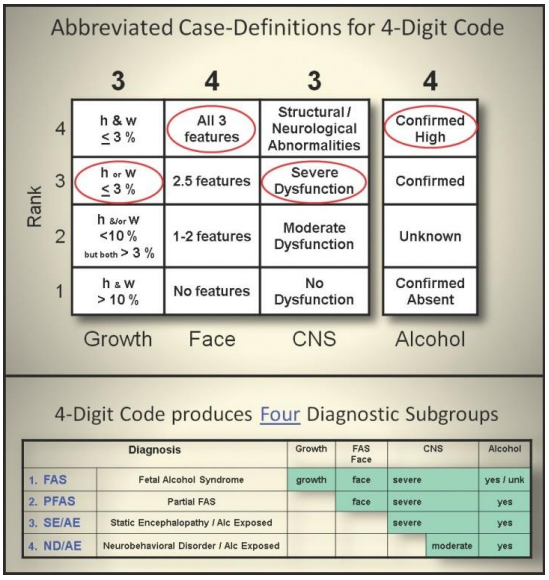

Figure 1. Abbreviated case-definitions of the FASD 4-Digit Code [17,23].
The 4-Digit Code 3434 is one of 12 Codes that fall under the diagnostic category FAS. The 4-Digit Code produces four diagnostic subgroups under the umbrella of FASD: FAS, PFAS, SE/AE, and ND/AE. Abbreviations: Alc alcohol; CNS central nervous system; h height; w weight; % percentile

The control population in the original 2009 study was selected from a large cohort of children enrolled at birth in a University of Washington study of typical development conducted through the Department of Speech and Hearing Sciences. This registry has been maintained over the years to serve as a source of typically developing controls for studies throughout the University. With the enrollment of each child in the FAS/PFAS group, a child matched on age (within 6 months), gender, and race was randomly identified and invited to enroll from the eligible SE/AE, ND/AE and Control populations.

The enrollment procedure for the original 2009 study produced a sample of 81 children. The age range (8 to 15.9 years) included the broadest age range of children that could be administered a comparable psychometric assessment battery and be reasonably capable of participating in the MR scanning. Each of the four study groups had 16-24 subjects successfully balanced on age, gender, and race. The 61 children with FASD in the original study were highly representative of the entire clinic sample of 2,828 from which they were drawn [1].

The diagnostic features specific to each study group were as follows:

1. Children in Group 1 had a 4-Digit diagnosis of FAS or Partial FAS (FAS/PFAS)/ Alcohol Exposed (e.g. 4-Digit Diagnostic Categories A,B,C: with Growth Ranks 1-4, Face Ranks 3-4, CNS Ranks 3 and/or 4, Alcohol Ranks 3-4). In summary, children in Group 1 had severe cognitive/behavioral dysfunction and the FAS facial phenotype.

2. Children in Group 2 had a 4-Digit diagnosis of Static Encephalopathy / Alcohol Exposed (SE/AE) (e.g. 4-Digit Diagnostic Categories E,F: with Growth Ranks 1-4, Face Ranks 1-2, CNS Ranks 3 and/or 4, Alcohol Ranks 3-4). In summary, children in Group 2 had severe cognitive/behavioral dysfunction, comparable to Group 1, but did not have the FAS facial phenotype.

3. Children in Group 3 had a 4-Digit diagnosis of Neurobehavioral Disorder / Alcohol Exposed (ND/AE) (e.g. 4-Digit Diagnostic Categories G, H: with Growth Ranks 1-4, Face Ranks 1-2, CNS Rank 2, Alcohol Ranks 3-4). In summary, children in Group 3 had PAE comparable to Groups 1 and 2, but in comparison to Groups 1 and 2 had only mild to moderate cognitive/behavioral dysfunction, and did not have the FAS facial phenotype.

4. Children in Group 4 (Typically Developing Controls / No Alcohol Exposure) were selected based on parental report that the child was typically developing, and no PAE (e.g. 4-Digit Diagnostic Category V: with Growth Ranks 1-2, FAS Face Ranks 1-4, CNS Ranks 1-2, Alcohol Rank 1). In

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

summary, these were non-exposed, average to high functioning controls.

Socio-demographic and clinical assessment

In the original 2009 study a comprehensive sociodemographic and health/medication history of each child was obtained by parent interview and record review. Information included birth data, growth, and all prenatal and lifetime exposures and adverse events. For subjects with FASD, most information was obtained at the time of their FASD diagnostic evaluation and recorded on the 4-Digit Code FASD Diagnostic Form [17].

Measures of PAE

The following measures of maternal alcohol consumption were collected retrospectively, with a focus on two time points (just before pregnancy and during pregnancy): a) average and maximum number of drinks per drinking occasion, b) average number of drinking days per week, c) type(s) of alcohol consumed (beer, wine, liquor), and d) trimester(s) of exposure.

Other prenatal and postnatal risk factors

Measures of other prenatal and postnatal adverse exposures and experiences were collected from a caregiver interview and/or review of records. Prenatal risks included: maternal use of tobacco, marijuana, cocaine, any illicit drugs and no prenatal care (all measured on a yes/no scale). While illicit drugs other than marijuana and cocaine were reported, the prevalence of each individual drug was too low in this study population to include as separate risk factors. Postnatal risks included: not living with either birth parent, number of foster placements, physical abuse, sexual abuse, SES of current caregiver (e.g. years of education attained, occupation prestige, and gross annual family income level). All SES measures were based on the subject's current primary caregiver participating in the study. Education and occupation were codified in accordance with the Hollingshead Four-Factor Index of SES [24] as follows. The parent ' s education was rated on a 7-point scale with 1 equal to less than a 7th grade education; 4 equal to a high school education and 7 equal to graduate/ professional training. The parent ' s occupational code was rated on a 9-point scale from 1 equal to farm laborers, menial service workers, students, housewives; 6 equal to technicians, semi-professionals, small business owners, to 9 equal to higher executive, proprietor of large businesses, major professionals. The scale score for education is multiplied by a weight of three; the scale score for occupation is multiplied by a weight of 5. Annual income was coded < $50,000 reflecting roughly twice the U.S. Health and Human Services Poverty Guidelines for a family of four in 2009 [25].

All children had a standardized digital facial photograph taken at the time of enrollment in the original 2009 study. The facial photographs were analyzed using the FAS Facial Analysis Software [26] to generate two measures of the magnitude of expression of the FAS facial phenotype: 1) the 4-Digit Code Facial Rank (1 to 4) [23] and 2) the continuous FAS facial D-score [27]. The D-score documents the severity of the FAS facial phenotype on a continuous scale. The higher the D-score, the more FAS-like the facial phenotype. A D-score > 0.8 is equivalent to a Rank 4 FAS facial phenotype.

Neuropsychological / Psychiatric assessments

In the original 2009 study, a comprehensive, standardized neuropsychological battery was administered to each child and their primary caregiver by a psychologist masked to group assignment (Table 1). Based on an extensive review of the prior literature, the assessment battery was designed to capture the domains of potential neuropsychological deficit and mental health conditions seen as the result of the typically diffuse brain damage arising from alcohol teratogenesis [28-30]. Key outcome measures (composite and subtest scores) from the battery of assessments were selected in the original study to represent the different domains of deficit (Figure 2). These same outcome measures served as the primary dependent variables for brain function in the current study [31-75].

Magnetic resonance evaluation

The MRI components of this study are reported separately [19]. Briefly, all scans were acquired using a General Electric 1.5 Tesla scanner in the Diagnostic Imaging Sciences Center at the University of Washington. MRI was used to measure the size (volumes and/or midsagittal areas) of the following structures: total brain, frontal lobe, caudate, putamen hippocampus, corpus callosum, and cerebellar vermis. These outcomes served as the primary dependent variables for brain structure.

Statistical analyses

Descriptive statistics (means, SDs, proportions) were used to summarize the sociodemographic and clinical profiles of the four study groups (Table 1). For comparisons between groups, chi-square was used for categorical variables and ANOVA was used for continuous variables. When ANOVA was employed, the overall f- statistic was used to test if differences existed among the four group means. When the overall f-statistic was statistically significant, the Duncan post hoc range test was used to identify which group means differed. The

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

Duncan test makes pairwise comparisons using a stepwise procedure. Means are ordered from highest to lowest, and extreme differences are tested first. The Duncan test identifies homogeneous subsets of means that are not different from one another. For example, when the mean head circumference was compared across the 4 study groups, the outcome was depicted 1,23,4 (group 1 was significantly smaller than groups 2 and 3, and group 4 was significantly larger than groups 1, 2 and 3. SPSS [31] linear regression with forward entry (probability of F to enter <0.05) was used in this exploratory analysis to identify which risk factor(s) explained a statistically significant proportion of the variance in CNS structural and functional outcomes. With forward entry, independent variables are added to the equation one at a time. At each step, the variable not in the equation with the smallest probability of F is entered if the value is smaller than .05. The order in which independent variables are entered into the equation provides insight about the quality of the predictor variables. Separate regressions were conducted for each CNS brain region and each neuropsychological measure within each functional domain (Figure 2). These separate regressions were conducted, in part, to explore if similar patterns of risk factors explained the different neuropsychological outcomes within a domain of function (e.g. were similar patterns of risk identified across the five WISC-III subtests within the General Intellectual Function domain) (Figure 2). Also of interest was whether similar patterns of risk were identified between brain regions and functions often attributed to those brain regions (e.g. hippocampus and memory, caudate and cognition). Only cases with valid data across all variables were included in each regression analysis (SPSS missing = list wise procedure). All regressions met the following goodness of fit and collinearity parameters: dependent variables normally distributed; independent variables: tolerance >0.1, Variance Inflation Factor <10, variance decomposition proportions: no two variables >0.90 and Condition Index <50. Partial and standardized residual plots were used to validate assumptions of normality, linearity and equality of variances. The proportion of variation in the dependent variable (brain region sizes and neuropsychological assessment scores) attributable to each risk factor is reported as the adjusted R^2. The adjusted R^2 is a modified version of R^2 that has been adjusted for the number of predictors in the model. P-values were not adjusted for multiple comparisons in this exploratory analysis, thus should be interpreted accordingly.

Results

Study population

Of the 81 subjects enrolled in the original MRI study, 50 presented with complete data across all independent and dependent variables needed for this current study. Although presence or absence of PAE was reliably documented for all subjects; more detailed information such as quantity, frequency, and duration of PAE was only available on 53 of the 65 alcohol-exposed subjects. This is not atypical, as accurate, detailed alcohol histories are frequently unavailable on patients presenting to a FASD diagnostic clinic. The regression analyses described below confirmed that the more detailed measures of quantity, frequency and timing of PAE (not just the presence or absence of PAE) were necessary to detect the correlations between PAE and brain outcomes. It is for this reason the study sample was restricted to those with this level of detail available. All controls had a reported absence of PAE per birth mother report. This subset of 50 subjects (11 FAS/PFAS, 12 SE/AE, 11 NE/AE and 16 Controls) (Table 2) was highly representative of the larger study group of 81 subjects in the original 2009 study [19,20] as well as the entire clinical population of 2,828 patients evaluated to date in the FASDPN clinic [1,32] from which they were selected.

Sexual abuse, n (%)	4 (36.4)	3 (25.0)	5 (45.5)	0 (0.0)			17.7 (.007)

Notations: **A**. Four of the 11 subjects in the FAS/PFAS group had full FAS using the 4-Digit Code. **B**. One subject with PFAS had agenesis of the corpus callosum. **C.** Between groups degrees of freedom = 3; within groups df = total sample size minus 4. **D**. Caucasian versus not Caucasian. **E**. No growth deficiency versus mild to severe growth deficiency. **F**. Definition of Rank 4 FAS Face: palpebral fissure lengths 2 or more SDs below the mean, and lip and philtrum are Rank 4 or 5 on University of Washington Lip-Philtrum Guide. **G**. No child had hypo-or hypertelorism that could impact the validity of the D-score. **H**. Both children with moderate functional impairment had structural evidence of brain abnormality (microcephaly). **I.** Chi-square for FAS/PFAS versus SE/AE. **J**. Chi-square for FAS/PFAS versus SE/AE. **K.** The 4 digits represent the rank for growth, face, brain and alcohol, in that order. **L** Reflects Level 9 Hollingshead occupation: higher executive/proprietor of large businesses.

Abbreviations: Chi2: chi-square test across the four study groups, unless otherwise specified. Duncan: The Duncan multiple comparison range test is reported if the overall ANOVA is statistically significant; commas separate groups with homogeneous means at $p < 0.05$. F: F statistic. FAS/PFAS: FAS/partial FAS. L: left. ND/AE: Neurodevelopmental Disorder/Alcohol Exposed; Occup. Occupation; OFC: occipital frontal circumference. Overall: Overall assessment of between-group means using ANOVA. p: p-value. R: right. SD: standard deviation. SE/AE: Static Encephalopathy/Alcohol Exposed. Unk: unknown. Z-score: number of standard deviations above/below the population-based mean. $: United States dollars.

Prevalence of risk factors

Among the subjects with FASD, all had confirmed PAE (88% with high Rank 4 alcohol exposures) (Table 2). Seventy-nine percent had prenatal tobacco exposure and 56% had prenatal exposure to illicit drugs (marijuana 38%, cocaine, 27%, heroine 6%, quaaludes 3%, methamphetamines 3%). Seventy-four percent were not living with their birth parents and had on average 4.3 out-of-home placements with the first placement starting at 3.8 years of age on average. Twenty-nine percent were physically abused; 35% were sexually abused. Household annual income was less than $50,000 US dollars in 2009 for 42%. Forty-six percent of their primary caregivers had a high-school degree or less. Although the presence of other risk factors was not restricted for enrollment of controls, the prevalence of other prenatal and postnatal risk factors was significantly lower among the Controls (no prenatal exposure to tobacco or illicit drugs, only one subject (6%) had one out-of-home placement, 19% had a primary caregiver with a high-school degree or less, 6% had an annual household income less than $50, 000, and no reported physical or sexual abuse)..

Prenatal alcohol exposure explained the highest proportion of variance in brain structure and function. Other risk factors explained a significant, but smaller proportion of variance

Prenatal alcohol exposure accounted for up to 34% of the variance (adjusted R^2) in regional brain volumes, up to 52% of the variance in CNS function and up to 51% of the variance in mental health symptoms (Figure 2). Of the various measures of quantity, frequency and timing of PAE available for entry into the regressions, "days per week of drinking during pregnancy" and "drank all three trimesters" demonstrated the strongest, significant correlations with brain outcomes. Other prenatal and postnatal risk factors that met criteria for entry into the regression equations each explained an additional 5-15% of the variance (Figure 2). All correlations between risk factors and brain outcomes were in the direction anticipated (the more severe the risk factor, the more severe the brain outcome). When patient gender entered the equation, being male was associated with more severe functional outcomes and larger brain volumes relative to females.

The order of entry of each risk factor into the regression equation (depicted by the numbers 1, 2, 3 or 4 in the boxes in Figure 2) documents which risk factors explained the greatest proportion of variance in the brain structural, functional or mental health outcomes. For example: of all 14 prenatal and postnatal risk factors available for entry into the regression equation (Figure 2), the number of days/ week of drinking during pregnancy explained the greatest proportion of variation (46%) in the WISC-III Full Scale Intelligence Quotient (FSIQ) [33] score and thus was the first statistically significant risk factor ($p<.05$) to enter into the regression equation. Caregiver's years of education explained the 2nd greatest and statistically significant proportion of variance of the FSIQ (an additional 8% of variance). These two risk factors together explained 54% of the variance in the FSIQ. Maternal drinking through all three trimesters was the third and final statistically significant risk factor to enter the equation, explaining an additional 4% of variance. The three risk factors together explained a total of 58% of the variance in the FSIQ. The regression equation produced was WISC-III FSIQ standard score = 86.9 -2.75 (average number of days/week drinking during pregnancy) +1.7 (Hollingshead's Score for caregiver's years of education (3 through 21 with <7th grade = 3 and post graduate = 21) – 12.4 (drank all 3 trimesters (yes = 1, no = 0)). Higher levels of prenatal alcohol use were correlated with lower FSIQ scores. Higher parental education levels were correlated with higher FSIQ scores.

Figure 2. Proportion of variance in brain structure and function explained by prenatal and postnatal risks. The order of entry of each risk into the regression equation (depicted by the numbers 1,2,3 or 4 in the colored boxes) documents which risks explained the greatest proportion of variance in the brain structural, functional or mental health outcomes. For example: of 14 prenatal and postnatal risks available for entry into the regression equation, the number of days/week of drinking during pregnancy explained the greatest proportion of variation (46%) in the WISC-III FSIQ score and thus was the first significant risk factor ($p < .05$) to enter into the regression equation. Caregiver's years of education explained the 2nd greatest and statistically significant proportion of variance of the FSIQ (8% additional variance). These two risks together explained 54% of the variance in FSIQ. Maternal drinking all three trimesters was the third and final statistically significant risk to enter the equation, explaining an additional 4% of variance. The three risk factors together explained 58% of the variance in the FSIQ. To further aid interpretation, prenatal and postnatal risks were collapsed into 5 categories depicted by colored boxes: (PAE black; gender green, other prenatal exposures brown, postnatal home environment and caregiver SES blue, and trauma orange). Using this color scheme, one can quickly see how often a particular category of risk explained a significant proportion of variation in brain outcomes. *One subject with PFAS and agenesis of the corpus callosum was removed from the analysis in parentheses. **Abbreviations**: cm centimeters; edu education; L left; mj marijuana; occup occupation; OFC occipital frontal circumference; R right; SES socioeconomic status; ss standard or scaled score; T t-score; Tri trimesters; wk week; # homes number of home placements. See Table 1 for test names.

ADVANCES IN PEDIATRIC RESEARCH

To aid in the interpretation of Figure 2, the 14 prenatal and postnatal risk factors were collapsed into 5 categories of risk depicted by the following color scheme: prenatal alcohol is depicted with black boxes; gender with green boxes, other prenatal exposures with brown boxes, postnatal home environment and caregiver SES with blue boxes, and postnatal trauma with orange boxes. Using this color scheme, one can quickly see how often a particular category of risk explained a significant proportion of variation in brain outcomes. Prenatal alcohol exposure explained the greatest proportion of variance (was the first risk factor to be entered into the regression equation) 31% of the time across all brain outcome measures. In other words, 43 of the 138 cells under the two alcohol measures in Figure 2 are black boxes with a number 1 inside the box (43/138 = 31%). In contrast, the remaining risk factor categories (depicted by green, brown, blue and orange boxes) were first to enter the equation as follows: gender 1.4% of the time; other prenatal exposures risks 2.2%; postnatal home environment and SES risks 2.6% and postnatal trauma 7.2%. Prenatal alcohol exposure was also the most common risk factor to enter into a regression equation, irrespective of the order of entry into the equation. In other words, a measure of PAE entered into a regression equation 40% of the time (55 of the 138 cells for PAE in Figure 2 have black boxes). In contrast, the remaining risk factor categories (depicted by green, brown, blue and orange boxes) entered into the equations as follows: gender 11.6% of the time; other prenatal exposures risks 6.2%; postnatal home environment and SES risks 8.7% and postnatal trauma 12.3%.

Discussion

Individuals with PAE often present with a multitude of other prenatal and postnatal risk factors. Based on the outcomes of this study:

1. PAE was the dominant risk factor explaining the largest proportion of variance across the greatest number of brain structural and functional measures. PAE was not the only risk factor influencing brain outcomes.

2. Other prenatal and postnatal risk factors were prevalent and contributed significantly to the adverse brain outcomes. Individually, each risk factor explained a statistically significant, but smaller proportion of variance in brain outcome compared to PAE. In combination, however, the proportion of variance explained by the presence of multiple prenatal and postnatal risks rivaled that of PAE.

These findings pose important implications for prevention and intervention. The proportion of variance explained by each risk factor can help guide which risk factors (when prevented) will have the greatest positive impact on outcome. Clearly, the greatest positive impact on brain outcome is achieved through prevention of both prenatal and postnatal risk factors. But when prevention of prenatal risks does not occur, Figure 2 illustrate the clear benefits of an early FASD diagnosis; maximizing the opportunity to mitigate postnatal risks. The outcomes of this study also illustrate the importance of documenting and addressing the multitude of other prenatal and postnatal risk when diagnosing FASD. The prenatal and postnatal risk factors used to conduct this study were collected during the child's FASD diagnostic evaluation using the FASD 4-Digit Code. These risk factors are formally documented in the electronic 4-Digit Code FASD Diagnostic Form [17] and ranked on 4-point Likert scales (Prenatal Rank and Postnatal Rank) just like the growth, face, brain and alcohol components of the FASD 4-Digit Code.

The prevalence of PAE and other prenatal and postnatal risk factors in a FASD diagnostic clinical population is substantially greater than in the general population. The reported prevalence of these risk factors in the general U.S. population, current study population, and the entire clinical population of 2,461 individuals with PAE evaluated at the University of Washington FASDPN clinic to date, respectively, are as follows: PAE (15%, 100%, 100%), PAE all three trimesters (8%, 62%, 48%); prenatal tobacco exposure (25%, 79%, 71%); marijuana exposure (7%, 38, 36%); cocaine exposure (0.3%, 26%, 34%); any illicit drug exposure (6%, 56%, 42%); foster placement (0.6%, 74%, 64%); physical abuse (8%, 32%, 31%) sexual abuse (10%, 35%, 31%) [34-38].

The patterns of risk that significantly influenced brain structure and function observed in the current exploratory study (Figure 2) present with interesting corollaries in the FASD, trauma, illicit drug exposure and SES literature. These corroborative findings represent an important incremental step toward supporting/validating the outcomes observed in this study. Of particular note was an unexpected inverse correlation observed in the current study between corpus callosum size and

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

sexual abuse (Figure 2). Interestingly, this finding is well documented in the trauma literature. Both Rinne-Albers et al., [5] and Teicher et al., [39] found that sexual abuse was the strongest factor influencing reduced corpus callosum size; a correlation observed only among girls. Upon further evaluation of our data, we too found the inverse correlation between corpus callosum size and sexual abuse was only among females (Figure 3). It is theorized that early traumatization is likely to have a major influence on the corpus callosum, as the process of myelinization and selective pruning are typically influenced by stress hormones [6,39,40]. The prevalence of sexual abuse in the current FASD study population is 4-fold higher (35%) than in the general population (10%) [41].

Tobacco is the most commonly used substance during pregnancy-in 2004, up to 25% of U.S. women smoked cigarettes during pregnancy [38]. Carbon monoxide and nicotine from tobacco smoke may interfere with the oxygen supply to the fetus. Nicotine also readily crosses the placenta, and concentrations in the blood of the fetus can be as much as 15% higher than in the mother [3].

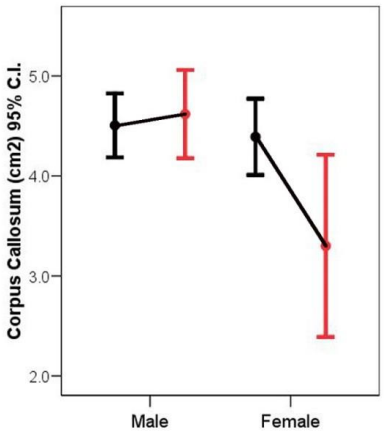

Figure 3. Sexual abuse was the strongest factor influencing reduced corpus callosum size (midsagittal area). As documented in the literature (Rinne-Albers et al., [5], the association in the current study was observed only among females. The mean midsagittal area of the corpus callosum was significantly smaller (3.3, 1.2 SD) among females that experienced sexual abuse compared to females (4.4, 0.9 SD) that did not experience sexual abuse (T = 2.5; p = .03). Key: Error bars reflect the mean and 95% confidence interval. Black: no sexual abuse; Red: sexual abuse

Maternal smoking during pregnancy has been associated with numerous adverse outcomes among offspring including reduced birth weight, inattention, hyperactivity and impulse and emotion control [42,43]. Ekblad, et al., [44] report prenatal smoking exposure was associated with significantly smaller frontal lobe and cerebellar volumes in brains of preterm infants. ADHD has been shown to be related to decreased brain volumes, especially cerebellar volume [45,46]. Consistent with these findings, maternal smoking during pregnancy in the current study was significantly correlated with inattention, reduced cerebellar volume and low birth weight among the offspring. Prenatal tobacco was the strongest significant factor influencing visual and auditory attention and the midsagittal size of cerebellar vermal lobules VIII-X (Figure 2). And although birth weight was not a focus of the current study, we recently found that tobacco exposure (not PAE) was the single strongest factor influencing birth weight centile in a large sample of individuals with FASD (n = 1,814) from our clinical dataset [2]. When we repeated the analysis in the current dataset (using the same array of prenatal and postnatal risk factors and regression model parameters used for the current study),tobacco exposure, once again was the single strongest factor influencing birth weight centile (adjusted R^2 = .17, F 10.2, p =.003). Maternal smoking during pregnancy was 7-fold more prevalent (79%) among the current FASD study population than in the general population of pregnant women (7%).

Child physical abuse is the second most common form of child maltreatment (second to neglect), being reported by 8% of the U.S. adult population [47]. The deleterious effects of child physical abuse on later mental health have been extensively recognized. A history of child physical abuse has been associated with an increased risk of emotional and behavioral problems [7,48], and several psychiatric disorders, including major depression, posttraumatic stress disorder (PTSD), conduct disorder, oppositional defiant disorder, agoraphobia, and generalized anxiety disorder [7,49]. Physical abuse was 4-fold more prevalent (32%) among the current FASD study population than in the general population (8%). In the current study, physical abuse was often the primary factor explaining behavioral problems and six of the eleven childhood psychiatric disorders.

According to a national survey conducted in the United States in 2012 [50], 5.8% of pregnant women used illicit drugs. Marijuana is generally the most commonly used drug during pregnancy, followed by cocaine and opiates. Associations have been found between marijuana use during pregnancy and developmental and hyperactivity disorders among

OPEN ACCESS Freely available online

ADVANCES IN PEDIATRIC RESEARCH

children [51-54] and evidence of low birth weight [55]. Prenatal cocaine exposure is related to subtle cognitive, behavioral and physiological differences, including working memory, attention, low birth weight, reduced brain volumes [4] and reduced caudate volumes [56]. In our current study, illicit drug exposure was significantly correlated with behavioral problems and reduced size of several brain regions, most notably the caudate. Of the illicit drugs reported in the current study, marijuana was most common, followed by cocaine. There was no reported prenatal exposure to opiates in this study population born between 1988 and 1996. Illicit drug exposure among the children with FASD was 10-fold higher (56%) than in the general population (6%).

Research shows that lower SES is associated with a wide array of adverse structural and functional brain outcomes in children across development [57]. Functional impairments include language, executive function and memory [8]. Structural abnormalities include smaller volumes of gray matter in hypocampi, middle temporal gyri and occipito-temporal gyri as well as lower diffusivity of the corpus callosum [58]. These findings are highly congruent with our observations. We observed associations between lower SES and impaired neuropsychological function across all domains of function (Figure 2). We also observed an association between lower SES and reduced volume of the corpus callosum. In a recent study focused on a group of children with FASD, Uban et al., [16], typically developing youth with no PAE exhibited increased subcortical brain volumes with increased SES, but surprisingly, the relationship was absent in adolescents with PAE (Figure 2) [16]. We replicated their univariate analysis to see if we too failed to observe a univariate correlation between SES and brain region volume between our Controls and subjects with FASD (Figure 4). It is important to note that 86% of our adolescents with FASD had high (Rank 4) PAE and spanned the full spectrum of FASD (FAS/PFAS, SE/AE and ND/AE). The subjects in the Uban et al., study had confirmed moderate to high PAE, but the severity of their cognitive outcomes or FASD diagnoses was not reported. We observed a somewhat weaker positive association between SES and frontal volume among our FASD group relative to our Control group (Figure 4A). But when we subdivided our FASD group into three groups from most severe to least severe (FAS/PFAS, SE/AE and ND/AE) the positive correlation between SES and frontal lobe volume was actually stronger among the FAS/PFAS than among the Controls (Figure 4B). The strength of the correlation decreased as the severity of FASD decreased from FASD/PFAS to SE/AE to ND/AE. When SES was regressed on WISC FSIQ, significant positive correlations were observed for both Control and FASD study groups (Figure 4C). Within the FASD study group, the strength of the correlation decreased once again as the severity of FASD decreased from FASD/PFAS to SE/AE to ND/AE (Figure 4D). These outcomes provide a potential explanation for why the Uban et al., study did not observe an SES-brain region correlation among the adolescents with PAE. The association could have been missed if the FASD study sample included too few individuals with severe FASD outcomes

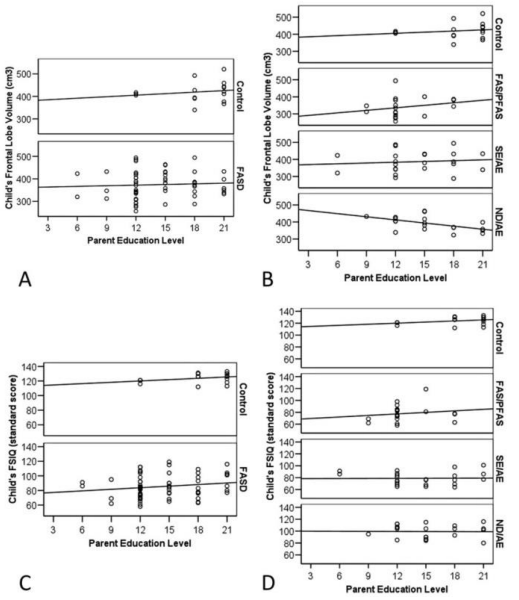

Figure 4. Scatterplots illustrating SES-brain associations for frontal lobe volume and the full scale intelligence quotient. The educational level of the current caregiver is codified in accordance with Hollingshead [24] with 3 reflecting<7th grade education and 21 reflecting a postgraduate education. A) A positive correlation between SES and frontal lobe volume is observed in the Control group, but not the FASD group, consistent with the findings of Uban et al., [16]. B) When the FASD group was subdivided into its three diagnostic categories, it became clear that a strong positive SES-frontal lobe correlation existed in the subgroup with the most severe FASD (the FAS/PFAS subgroup). Weaker correlations were observed among the less severe subgroups (SE/AE and ND/AE groups). The strong positive SES-frontal lobe correlation among children with FAS/PFAS may be masked if combined with children with less severe forms of FASD. C & D) Similar patterns of correlation were observed between SES and Full Scale IQ (FSIQ) with the strongest positive correlations observed among the FAS/PFAS group

ADVANCES IN PEDIATRIC RESEARCH

Strengths and limitations

The observations in the current study are based on a small, but rigorous and comprehensive set of data. Replication in other datasets will be important to support/validate the outcomes observed in this exploratory study. To that end, we ran a few internal validation analyses on this current dataset to see if we could replicate findings observed in our larger clinical dataset. For example, as described in the Discussion section, we documented that prenatal tobacco exposure (not PAE) was the single FASD from the University of Washington FASDPN clinic [2]. When we replicated that analysis in the current dataset, once again, prenatal tobacco exposure was the single strongest factor influencing birth weight (adjusted R^2 = 0.17, F 10.2, p =.003). Another correlation that is well documented in our large clinical dataset [23] as well as our large population-based foster care FAS screening dataset [59] is the specificity of the Rank 4 FAS facial phenotype to PAE. When we regressed the same array of prenatal risk factors on a continuous measure of the FAS facial phenotype severity (the FAS facial d-score [27], as hypothesized, only PAE (days/week of drinking during pregnancy) explained a significant proportion of the variance in the FAS facial phenotype (adjusted R^2 = .16, F 10.1, p = .003). Finally, when we conducted a regression analysis in our larger clinical dataset using the same 14 prenatal and postnatal risk factors and regression model parameters to predict FSIQ, maternal drinking through the 3rd trimester explained the largest proportion of variance, with birth mother's years of education entering second and child neglect entering third explaining a total of 23.6% of the variance in FSIQ. This outcome was near identical to the outcome observed in the current study despite the fact that different metrics were used to document the prenatal and postnatal risk factors and the FSIQ was derived from various versions of the WISC (as is typical for a clinical dataset). Although 14 prenatal and postnatal risk factors were assessed in the current study, many other risks exist (e.g. pregnancy complications, prematurity, family genetics, parental verbal abuse, witnessing domestic violence, neglect, etc.). Understanding the interplay between risk factors and outcomes is complex. Teicher and Samson [9] present a series of questions that help convey this complexity and serve as a guide for future studies. 1) Does childhood abuse affect brain structure and function? 2) Does the type of maltreatment matter or are they all stressors? 3) Does age at the time of abuse matter? 4) What is the temporal association between exposure and brain changes? 5) Are boys and girls affected in the same way? 6) Do the observed structural and functional consequences make more sense as adaptive responses or as nonspecific damage? 7) Are the neurobiological consequences of childhood maltreatment reversible? 8) What is the relationship between childhood abuse, brain changes and psychiatric illness?

Conclusion

In conclusion, individuals with PAE present with a multitude of other prenatal and postnatal risk factors. The prevalence of these risk factors is often 3 to 7-fold higher than in the general population. PAE was the dominant risk factor explaining the largest proportion of variance in brain structural and functional outcomes in this study. Individually, each of the other risk factors explained a statistically significant, but smaller proportion of variance in brain outcome compared to PAE. In combination, however, the proportion of variance explained by the presence of multiple prenatal and postnatal risks rivaled that of PAE. A better understanding of the impact other prenatal and postnatal risk factors have on the neurodevelopmental outcomes of individuals with FASD can inform more effective primary prevention and intervention strategies.

Research Article

High facial specificity and positive predictive value are required to diagnose fetal alcohol syndrome when prenatal alcohol exposure is unknown

Susan J Astley Hemingway*

Departments of Pediatrics and Epidemiology, University of Washington, Seattle, WA, USA

ABSTRACT

Background: Facial criteria with high specificity and positive predictive value (PPV) to prenatal alcohol exposure (PAE) are required to diagnose fetal alcohol syndrome (FAS) when documentation of PAE is unavailable. Not all fetal alcohol spectrum disorder (FASD) diagnostic guidelines appear to meet these criteria.

Methods: A dataset generated from a 10-year FAS screening of 1,602 children in fostercare conducted by the University of Washington FAS Diagnostic & Prevention Network was used to determine how well the FAS facial phenotype, microcephaly and growth deficiency (individually and in combination at varying levels of magnitude) predicted PAE.

Results: The 4-Digit-Code Rank 4 FAS facial phenotype was the only outcome that provided sufficient PPV and specificity to PAE (100%) to allow the facial phenotype to serve as confirmation of PAE in a diagnostic setting when PAE is unknown. Even minimal relaxation of the phenotype (e.g., Face Rank 3) resulted in PPV (35%) and specificity (88.7%) values too low to use as confirmation of PAE. Further relaxation of the facial criteria, as defined by the Hoyme et al., FASD guidelines, resulted in even lower PPV (17.9%) and specificity (76.6%); both too low to serve as confirmation of PAE in a diagnostic setting. The presence of all three physical features of FAS (Hoyme et al. FAS facial phenotype, growth and OFC ≤10th percentile) did not increase PPV beyond chance (52%).

Conclusion: FASD diagnostic guidelines that use relaxed criteria for the FAS facial phenotype risk misdiagnosing and over-diagnosing FAS and partial FAS when PAE is unknown.

Competing interests: The author does not have any competing interests.

Funding: Data collection for this study was funded in part by: the Washington State Department of Social and Health Services; the Center on Human Development and Disability, University of Washington (National Institute of Child Health and Human Development: P30 HD02274) and the National Institute on Alcohol Abuse and Alcoholism R01-AA12915-01.

Introduction

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by prenatal alcohol exposure (PAE). FAS is characterized by growth deficiency, a unique facial phenotype and structural and/or functional brain abnormalities [1,2]. To date, all fetal alcohol spectrum disorder (FASD) diagnostic guidelines permit a diagnosis of FAS and/or partial FAS (pFAS) to be rendered when a history of prenatal alcohol exposure is unknown [2-7]. Why? For most guidelines, it is because the diagnostic criteria for FAS require the presence of the FAS facial phenotype and the "FAS" facial phenotype is so unique to (caused only by) PAE, its presence serves as confirmation of PAE when written or verbal documentation of PAE is unavailable [2,8-10].

There are four screening metrics used in medicine to quantify how well the presence of a feature (e.g., the FAS facial phenotype) predicts the presence/absence of an exposure (e.g. PAE), and how well an exposure (e.g. PAE) predicts the presence/absence of an outcome (e.g., the FAS facial phenotype). These four metrics (positive predictive value (PPV), negative predictive value (NPV), sensitivity and specificity) are defined in Figure 1 [11,12].

If PAE is the only cause of the FAS facial phenotype [8,9,13], one would expect these two conditions to be true:

		True Exposure		
		Prenatal Alcohol Exposure Documented	Prenatal Alcohol Exposure Not Documented	
Predicted Exposure based on the face	FAS Face Present (Face Rank 4)	True Positive (TP) = **20**	False Positive (FP) = **0**	**Positive Predictive Value (PPV) = 100%** = TP/ (TP + FP) = 20 / (20 + 0)
	FAS Face Absent (Face Ranks 1,2,3)	False Negative (FN) = **207**	True Negative (TN) = **1375**	**Negative Predictive Value (NPV) = 87.0%** = TN/ (FN + TN) = 1375 / (207 + 1375)
		Sensitivity 8.8% = TP / (TP + FN) = 20 / (20 + 207)	**Specificity 100.0%** = TN / (FP + TN) = 1375 / (0 + 1375)	

Figure 1. Demonstration: The ability of the Rank 4 FAS facial phenotype to correctly predict prenatal alcohol exposure.
Among 1,602 children in foster care, 14.2% had documented prenatal alcohol exposure (PAE). If the 4-Digit Code Rank 4 FAS facial phenotype is to be used to confirm PAE when a written or verbal history of exposure is not available, then the FAS facial phenotype must have a high PPV (all individuals with the facial phenotype have a documented PAE) and high specificity (the Rank 4 FAS face is never present in an individual with confirmed absence of PAE).
PPV: Probability that a subject with the FAS facial phenotype has PAE.
NPV: Probability that a subject without the FAS facial phenotype does not have PAE.
Sensitivity: Probability that a subject with PAE has the FAS facial phenotype.
Specificity: Probability that a subject without PAE does not have the FAS facial phenotype.

1. All individuals with the FAS facial phenotype will have PAE (PPV = 100%).
2. No individual with a confirmed absence of PAE will have the FAS facial phenotype (specificity = 100%).

And if, as research supports [14-17], the FAS facial phenotype is caused by prenatal alcohol exposure during a very narrow window of time (~weeks 2 and 3 of pregnancy, gastrulation stage of fetal development), one would expect these two conditions to be true:

1. Absence of the FAS facial phenotype would not confirm absence of PAE (NPV will be low).
2. Not all individuals with PAE would have the FAS facial phenotype (sensitivity will be very low).

While all FASD diagnostic systems allow a diagnosis of FAS to be rendered in the absence of a confirmed PAE, not all FASD diagnostic systems use the same clinical criteria for the FAS facial phenotype. The Australian 2016 [5] and Canadian 2015 [4] systems use the Rank 4 FAS facial phenotype as defined by the 4-Digit Code [3] (three facial features must be present (palpebral fissure lengths (PFL) at or below the 3rd percentile; a smooth philtrum (Rank 4 or 5 on the University of Washington (UW) Lip-Philtrum Guides) and a thin upper lip (Rank 4 or 5 on the UW Lip-Philtrum Guides)). The CDC 2004 guidelines use the 4-Digit Code criteria with one exception (the PFL criteria is relaxed to ≤10th percentile) [6]. The criteria for the FAS facial phenotype used by the Hoyme et al., 2016 [7] FASD diagnostic system is the most relaxed (only 2 of the 3 facial features must be present and 2 of the 3 facial features are relaxed in their magnitude relative to the 4-Digit Code (PFLs ≤ 10th percentile; a smooth philtrum (Rank 4 or 5 on the Hoyme et al., Lip/Philtrum Guides) and/or a thin upper lip (Rank 4 or 5 on the Hoyme et al., Lip/Philtrum Guides)). The Rank 4 thin upper lip on the Hoyme et al., North American Lip/Philtrum Guide is confirmed equivalent to the Rank 2 moderately thick upper lip on the UW Lip-Philtrum Guide [18,19].

When the 4-Digit-Code Rank 4 FAS facial phenotype was first identified and case-defined in a small, but rigorous split-half empirical study, PPV and specificity to FAS and PAE were 100% [20]. Subsequent studies in large clinical, foster care and general populations continued to document high PPV and specificity to PAE (> 95%) [8,9,13]. The specificity of the more relaxed Hoyme et al., FAS facial phenotype ranges from 71% to 75% as reported by the authors of the guidelines [21] and replicated in the FASDPN datasets [18,19]. A facial specificity of 71% to 75% is not sufficient to allow a valid diagnosis of FAS to be rendered when written or verbal documentation of PAE is unavailable. A specificity of 75% means 25% of individuals who present with the Hoyme et al., FAS facial phenotype do not have PAE. This was illustrated among twelve high functioning children (mean full scale IQ = 120) with confirmed absence of PAE enrolled as controls in a FASD MRI study [22]. Due to the relaxation of the facial criteria, 3 of the twelve children (25%) met the criteria for the Hoyme et al., FAS facial phenotype despite confirmed absence of PAE.

If a FAS facial phenotype with low specificity and PPV is used to confirm PAE, birth mothers are at risk of being wrongly accused of drinking during pregnancy and harming their unborn child; FAS will be misdiagnosed and over-diagnosed, and studies designed to generate population-based estimates of the prevalence of FAS will lead to inaccurate over-estimates [10].

If the criteria used to define the FAS facial phenotype do not have sufficiently high specificity and PPV to confirm PAE, can the specificity and PPV be increased by requiring additional FAS physical features be present? For example, what is the specificity and PPV to PAE when an individual presents with the FAS facial phenotype and microcephaly and growth deficiency? To answer this question, a dataset generated from a 10-yr population-based FAS screening of 1,602 children in foster care was used [9]. The screening activity collected height, weight, head circumference, computerized facial measures from facial photographs and presence/absence of documented PAE for each child.

The primary objective of this study was to determine how well the FAS facial phenotype, microcephaly and growth deficiency (individually and in combination at varying levels of magnitude) predict prenatal alcohol exposure. The following outcomes were postulated:

1. If the FAS facial phenotype is to be used to confirm PAE when a written or verbal history of exposure is not available, then the FAS facial phenotype must have 100% PPV (all people with the facial phenotype have PAE) and 100% specificity (the Rank 4 FAS face is never present in a person with confirmed absence of PAE).
2. Relaxation of the FAS facial phenotype criteria will cause a sharp drop in specificity and PPV to PAE.
3. The majority of individuals with PAE will not present with the FAS facial phenotype because there is a very narrow window of vulnerability in which PAE can cause the FAS facial features during fetal development (gestational weeks 2-3: the gastrulation stage) [16,17]. The sensitivity of the FAS

facial phenotype to predict PAE will be very low. If one were to use the FAS facial phenotype to screen a population for PAE, most of the individuals with PAE would be missed.

4. Since the majority of children in this foster care population are not expected to have the FAS facial phenotype and the majority will not have a documented PAE, the absence of the FAS facial phenotype will correctly predict the absence of PAE in the majority of the children in this foster care population by chance alone. NPV values will be uniformly higher under these circumstances as described more fully below, but this does not mean the absence of the FAS facial phenotype can be used to accurately rule-out PAE. NPV will not be 100%. It is well understood that the majority of individuals with PAE do not present with the FAS facial phenotype due to the narrow window of vulnerability in which PAE can cause the FAS facial phenotype.
5. Growth deficiency and microcephaly are caused by PAE but are not unique to (caused only by) PAE. PPV will be very low.
6. If the criteria for the FAS facial phenotype are relaxed, the combined presence of the relaxed facial phenotype, growth deficiency and microcephaly should increase specificity and PPV to PAE, but may not increase it sufficiently (> 95%) to serve as diagnostic confirmation of PAE when a verbal or written confirmation of PAE is not available.

Research Methodology

The dataset used for this study was generated from a 10-year FAS screening study of 1,602 children in foster care conducted by the University of Washington Fetal Alcohol Syndrome Diagnostic & Prevention Network (FASDPN) and the King County Washington Foster Care Passport Program (FCPP) between 1999 and 2009. Detailed methods and the outcomes of the first 600 children screened were reported in 2004 [9].

Enrollment into the foster care passport program

Briefly, all children, who were legally dependent with the State of Washington and enrolled in the Foster Care Passport Program (FCPP) in King County, Washington between 1999 and 2009 were eligible to participate in the FAS screening [9]. To be enrolled in the FCPP, a child had to be: a) legally supervised by the Department of Social and Family Services; b) 0-12 years of age at the time of enrollment, but may remain in the program after their 12th birthday; c) dependent and d) in out-of-home placement. Upon enrollment in the FCPP, each child's health and social service history from birth to present was abstracted from the child's medical records by a FCPP public health nurse and entered into a foster care Health & Education database. The database was used to produce a summary medical report for each child (a Health and Education "passport") along with health recommendations to be shared with the social worker, the foster parent and the child's health care provider(s). The "passport" included measures of height, weight and head circumference, medical conditions/concerns, and prenatal exposures.

Enrollment into the FAS screening

The FCPP identified all eligible children, obtained written consent from the child's legal guardian (Department of Child and Family Services social worker), sent the child's foster parents a letter that explained the purpose and process of the FAS screening, and sent the FASDPN clinic the list of all newly eligible, consented children, weekly. The FASDPN scheduler called each foster parent to schedule a photography appointment with the FASDPN photographer. The photographer measured the child's head size (occipital frontal circumference) and took 3 digital standardized facial photographs (frontal, oblique, and lateral) with a ¾ inch round paper sticker placed between the child's eyebrows to serve as an internal measure of scale (Figure 2A). The facial photographs were analyzed by the author using the FAS Facial Photographic Analysis Software, masked to the child's PAE status [23]. Over 95% of eligible children participated in the FAS screening program over a 10-year period [9].

Screen-positive criteria

A child screened positive for FAS if they presented with the Rank 4 FAS facial phenotype as defined by the FASD 4-Digit Code. This facial phenotype is defined below and illustrated in Figure 2.

All children who screened positive were eligible to receive a comprehensive diagnostic evaluation and treatment plan at the FASDPN clinic by an interdisciplinary team (pediatrician, psychologist, speech language pathologist, occupational therapist, social worker and family advocate) using the 4-Digit Diagnostic Code. The screening activity was approved by the Human Research Review Boards of Washington State and the University of Washington. The outcomes of the screening program are reported separately [9].

Study dataset

The following fields of data from the 10-year FAS screening study were used in the current study.

- The 3 individual facial features of FAS were measured from digital facial photographs using the FAS Facial Photographic Analysis Software [23] (Figure 2). A brief video demonstration of the software is provided at this weblink: http://depts.washington.edu/fasdpn/movie/software1024-768cd2.mp4

  1. Palpebral fissure lengths in mm.
  2. Philtrum smoothness: 5-point Likert Rank on the UW Lip-Philtrum Guides
  3. Lip thinness (circularity) was measured by outlining the perimeter of the upper lip using the FAS Facial Photographic Analysis Software [23]. Circularity equals perimeter2/area. The thinner the upper lip, the larger the circularity. The circularity tables printed on the backside of each Lip-Philtrum Guide (Figure 2B) were used to convert lip circularity into lip rank.

- Height (cm) and weight (kg) at enrollment into the screening study and at earlier time points when available in the medical records. The WHO [24] and CDC [25] growth charts were used to generate height and weight percentiles adjusted for age and gender. The FASD 4-Digit Code ranks growth deficiency on a 4-point Likert scale (Rank 1 normal; Rank 2, mild; Rank 3 moderate and Rank 4 severe) in

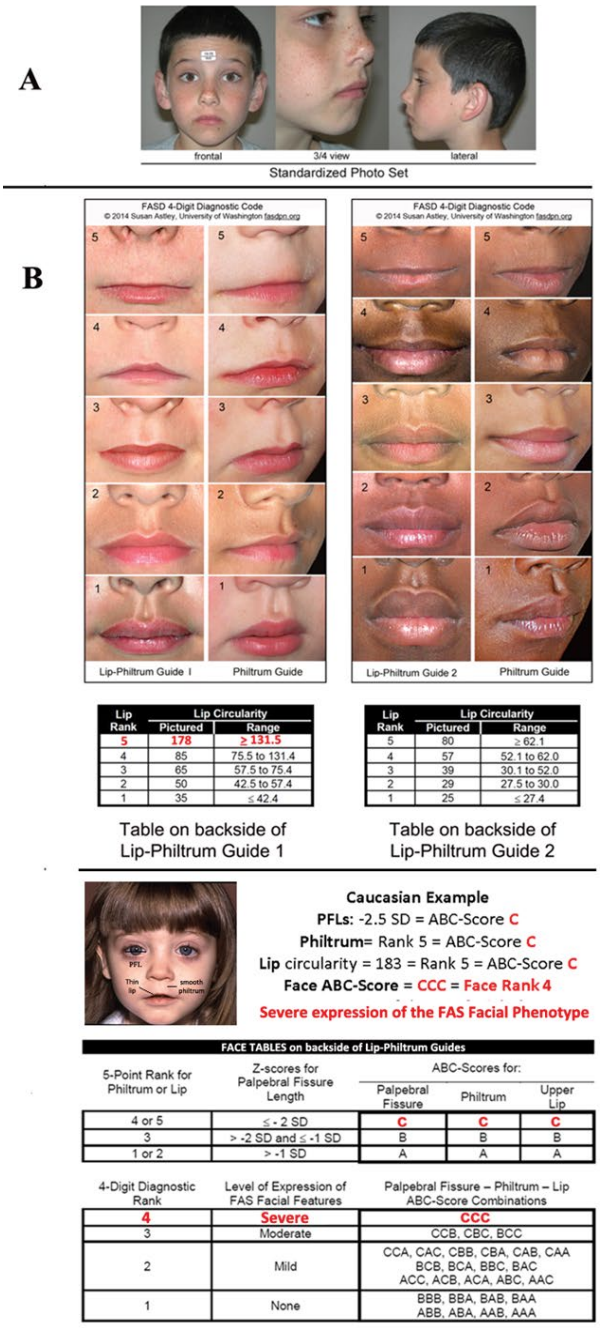

Figure 2. The FASD 4-Digit Code method for measuring the FAS facial phenotype using the FAS Facial Photographic Analysis Software [3,10,23]. The Rank 4 FAS facial phenotype is defined by 3 features: short PFLs ≤ -2 SDs, smooth philtrum Rank 4 or 5 and thin upper lip Rank 4 or 5 on the University of Washington Lip-Philtrum Guides. A) Three digital facial photographs are obtained with a ¾ inch adhesive sticker serving as an internal measure of scale. B) The PFL is measured in mm by clicking the mouse on the inner and outer corners of each eye. Using the Face Tables, the software converts the PFL in mm to a z-score and then to a PFL ABC-Score. The red perimeter of the upper lip is traced with the mouse to compute lip circularity (perimeter^2/area). The software converts lip circularity to lip rank and then to a lip ABC-Score. Finally, the software converts the philtrum rank to a philtrum ABC-Score. The 3 individual ABC-scores are combined in the order PFL-Philtrum-Lip to create the overall Facial ABC-Score. Highlighted in red font is an example of a child with PFL -2.5 SDs, philtrum Rank 5 and lip circularity 183. These three features produce a facial ABC-Score of CCC, representing the severe expression of the FAS facial phenotype (Face Rank 4). The FAS facial phenotype presents on a continuum: Rank 1: none of the 3 features present; Rank 2: 1 or 2 features present; Rank 3: 2.5 of the 3 features present; and Rank 4: all 3 features present. A video demonstration of the facial software is presented at this weblink: https://depts.washington.edu/fasdpn/movie/software1024-768cd2.mp4 Copyright Susan Astley Hemingway University of Washington

accordance with the Growth Tables printed on the backside of the Lip-Philtrum Guides (Figure 3). The Hoyme et al., FASD guidelines dichotomize growth deficiency as present (height and/or weight ≤ 10th percentile) or absent.

- Occipital frontal circumference (OFC) in cm at the time of enrollment in the screening and earlier time points when available in the medical records. The WHO [24] and CDC [25] growth charts were used to generate OFC percentiles adjusted for age and gender. The 4-Digit Code defines microcephaly as OFC ≤ 3rd percentile. The Hoyme et al., FASD guidelines define "microcephaly" as OFC ≤ 10th percentile.
- PAE (documented, not documented) from review of all medical and social service records from birth to present.
- Gender
- Age in years at screening
- Race/ethnicity

The 3 FAS facial features (PFL in mm, philtrum rank, and lip circularity) were used to generate the following FAS facial phenotypes in accordance with the 4-Digit Code [2,3] and Hoyme et al., 2016 [7] FASD diagnostic systems:

4-Digit Code FAS facial phenotype:

The magnitude of expression of the FAS facial phenotype is ranked on a 4-point Likert scale in accordance with the lip circularity and face tables printed on the backside of each Lip-Philtrum Guide (Figure 2B). The FAS facial phenotype (Face Rank 4) requires the presence of all three facial features: 1) palpebral fissure lengths ≤ 3rd percentile, 2) a smooth philtrum (Likert rank 4 or 5 on the UW Lip-Philtrum Guide) and 3) a thin upper lip (Likert rank 4 or 5 on the 5-point Lip-Philtrum Guide) (Figure 2B). The Iosub [26] PFL growth charts were used to generate PFL percentiles by gender and age for all full and mixed race African American children. The Stromland Scandinavian [27] PFL growth charts were used for all other races. The UW Lip-Philtrum Guide 1 was used to Rank lip thinness and philtrum smoothness for Caucasians and all races that indigenously present with thinner lips like Caucasians. The UW Lip-Philtrum Guide 2 was used to Rank lip thinness and philtrum smoothness for African Americans and all races (e.g., aboriginal Australians and some east Asian populations) that indigenously present with thicker lips like African Americans. Based on the racial makeup of the current study population, Lip-Philtrum Guide 2 was used on all full and mixed-race African Americans; Lip-Philtrum Guide 1 was used on all other races. The 27 Asian children in this study were not east Asian.

Hoyme et al., 2016 FAS Facial Phenotype:

The Hoyme et al., FAS facial phenotype is classified on a dichotomous scale (present/absent). The Hoyme et al., FAS facial phenotype requires 2 of the following 3 facial features (PFLs ≤ 10th percentile; smooth philtrum (Rank 4 or 5 on the Hoyme et al., Lip/Philtrum Guides); thin upper lip (Rank 4 or 5 on the Hoyme et al., Lip/Philtrum Guides)) [7]. Hoyme et al., provide two Lip/Philtrum Guides; one for South African Cape Coloured [28] and one for North Americans [7]. The Cape Coloured Lip/Philtrum Guide is not appropriate for use on African Americans, for it was

GROWTH TABLES

Percentile Range	ABC-Scores for: Height	Weight
≤ 3rd	C	C
> 3rd and ≤ 10th	B	B
> 10th	A	A

4-Digit Diagnostic Rank	Growth Deficiency Category	Height-Weight ABC-Score Combinations
4	Severe	CC
3	Moderate	CB, BC, CA, AC
2	Mild	BA, BB, AB
1	None	AA

Example
Height: 8th percentile = ABC-Score B
Weight: 2nd percentile = ABC-Score C
Height-Weight ABC-Score = BC = Growth Rank 3
Moderate Growth Deficiency

Figure 3. FASD 4-Digit Code growth tables for converting height and weight percentiles into Growth Ranks.

The FASD 4-Digit Code documents growth deficiency on a 4-point Likert scale from Rank 1 normal growth to Rank 4 severe growth deficiency. Highlighted in red font is an example of an individual who presented with a height at the 8th percentile and weight at the 2nd percentile. Using the Growth Tables printed on the backside of the Lip-Philtrum Guides, these growth percentiles would translate into a Growth Rank 3, moderate growth deficiency.

developed by Hoyme et al. specifically for the Cape Coloured (mixed race) population in the Western Cape Province of South Africa. The investigators reported that neither of the University of Washington Caucasian or African American Lip-Philtrum Guides were an exact "fit" for the Cape Coloured population. Due to the absence of a Hoyme et al. Lip/Philtrum guide appropriate for use on African Americans, the Hoyme et al., FAS facial phenotype was not generated for subjects in this study that were full or mixed race African American. For all other races, the Hoyme et al., North American Lip/Philtrum Guide was used to Rank lip thinness and philtrum smoothness. Based on a previous study [18], the Rank 4 lip on the Hoyme et al., North American Lip/Philtrum Guide has a circularity of 52.5 (see video demonstration at this weblink: http://depts.washington.edu/fasdpn/movie/Fig2Cvideo.mp4). Thus, all lips with circularity ≥ 52.5 met the Hoyme et al., FAS facial phenotype criteria for a "thin upper lip". The Stromland [27] PFL normal growth charts were used to generate PFL percentiles adjusted for gender and age.

Specificity, sensitivity, PPV and NPV were calculated in accordance with Figure 1 to determine how accurately the FAS facial phenotype, microcephaly and growth deficiency (individually and in combination at varying levels of magnitude) predict PAE. Confidence intervals for sensitivity and specificity are "exact" Clopper-Pearson confidence intervals [29]. Confidence intervals for the predictive values are the standard logit confidence intervals given by Mercaldo et al. [30].

Sensitivity: (true positive rate) The proportion of people with documented PAE that have the FAS facial phenotype. We expect sensitivity to be very low; most people with PAE do not present with the FAS facial phenotype. If the FAS facial phenotype was used to screen for individuals with PAE, most individuals with PAE would be missed.

Specificity: (true negative rate) The proportion of people with no documented PAE that do not have the FAS facial phenotype. We expect specificity to be very high. If PAE is the only cause of the FAS facial phenotype, then a person cannot have the FAS facial phenotype if they were not exposed to alcohol.

PPV: The probability that a person with the FAS facial phenotype has a documented PAE. We expect this to be very high. If PAE is the only cause of the FAS facial phenotype, then a person with the FAS facial phenotype must have been exposed to alcohol in-utero.

NPV: The probability that a person without the FAS facial phenotype has no documented PAE. We expect this to be relatively high for the reasons outlined below.

Sensitivity and specificity are attributes of the diagnostic test. They are not influenced by the prevalence of PAE in the population. PPV and NPV are influenced by the sensitivity and specificity of the test and by the prevalence of PAE in the study population. As the prevalence of PAE decreases, the PPV (the ability of the FAS facial phenotype to correctly predict PAE) decreases because there will be more false positives for every true positive. This is because one is hunting for a "needle in a haystack" (e.g. only 14% of the children in this foster care have documented PAE). Since there are so many more children without documented PAE (86%) in this foster population, chance alone dictates one has a greater probability of selecting a child without documented PAE, than one with documented PAE. As the prevalence of PAE decreases, the NPV (the ability of the absence of the facial phenotype to correctly predict the absence of PAE) increases because there will be more true negatives for every false negative. Again, since there are so many more children without documented PAE (86%) in this foster care population, chance alone dictates one has a greater probability of selecting an individual without documented PAE, than one with PAE.

Results

Sociodemographic and FASD clinical profiles

The sociodemographic and FASD clinical profiles of the 1,602 children in foster care that participated in the FAS screening are presented in Table 1. The population was predominantly Caucasian (52%) and full or mixed race African American (31%); ranged in age from 3 months to 17 years old with 47% under 4 years of age. Roughly half (49%) were female.

Growth deficiency (height and/or weight ≤ 10th percentile) was observed in 14% of the population.

The 4-Digit Code Rank 4 FAS facial phenotype was observed in 20 (1.2%) of 1,602 children across all races (13 (2.6%) among the 502 African American; 7 (0.6%) among the remaining 1,100 children from all other races). The prevalence of PAE was highest (18.5%) among the 502 African American; 12.1% among all other races. Of the 20 with the Rank 4 FAS facial phenotype, 100% had documented PAE. The Hoyme et al., FAS facial phenotype was observed in 274 (25%) of the 1,093 children from all races except African Americans (exclusion of African Americans is explained above). Of the 274 with the Hoyme et al., FAS facial phenotype, 17.9% had documented PAE.

OFC ≤ 3rd percentile (microcephaly) was observed among 6.6% of the 1,602 children. OFC ≤ 10th percentile was observed among 11.7% of the children.

Prenatal alcohol exposure was documented in 227 (14.2%) of the 1,602 children.

Specificity, sensitivity, PPV and NPV

The PPV, NPV, specificity and sensitivity documenting how well the FAS facial phenotype, microcephaly and/or growth deficiency (individually and in combination at varying levels of magnitude) predicted prenatal alcohol exposure is presented in Table 2.

Table 1. Sociodemographic and clinical profile of the 1,602 children that participated in the foster care FAS screening.

Characteristic		Total N 1,602	
Race (n, %)	Caucasian	828	51.7
	African American (full or mixed-race)	502	31.3
	Native American	157	9.8
	Hispanic	26	1.6
	Asian	27	1.7
	All others including mixed race	62	3.9
Age years (n, %)	0-3.9	756	47.2
	4-5.9	210	13.1
	6-8.9	235	14.7
	9-12.9	328	20.5
	13-17.4	73	4.6
	mean (SD) range	5.5 (4.2)	0.3-17.4
Gender (n, %)	female	778	48.5
Growth Rank[A] (n, %)	normal (height & weight > 10th percentile): Rank 1	1383	86.3
	mild (height and/or weight 4-9th percentile): Rank 2	146	9.1
	moderate (height or weight ≤ 3rd percentile): Rank 3	32	2
	severe (height & weight ≤ 3rd percentile): Rank 4	41	2.6
	height and/or weight ≤ 10th percentile	219	13.7

FAS face Rank[A] (n, %)	normal (none of the 3 features): Rank 1	776	48.4
	mild (1 or 2 of the 3 features): Rank 2	685	42.8
	moderate (2.5 of the 3 features): Rank 3	121	7.6
	severe (all 3 features): Rank 4	20	1.2
Head Circumference (n, %)	microcephaly: OFC ≤ 3rd percentile	95	6.6
	microcephaly: OFC ≤ 3rd percentile & PAE	35	2.4
	OFC ≤ 10th percentile	167	11.7
	OFC ≤ 10th percentile & PAE	43	3
Prenatal alcohol exposure (n, %)	none documented	1,375	85.8
	documented	227	14.2

A. See Figures 2 and 3 for how growth and face are Ranked by the FASD 4-Digit Code.

Abbreviations: OFC: occipital frontal head circumference; PAE: prenatal alcohol exposure

Specificity and PPV of the FAS facial phenotype

The 4-Digit-Code Rank 4 FAS facial phenotype was 100% specific to PAE and 100% PPV for PAE. Twenty children presented with the Rank 4 FAS facial phenotype; all 20 had documented PAE (100% PPV). Of the 1,330 children with no documented PAE; none presented with the Rank 4 FAS facial phenotype (100% specificity).

Of the 274 children that presented with the Hoyme et al., FAS facial phenotype; only 49 had documented PAE (17.9% PPV). The Hoyme et al., FAS facial phenotype was not predictive of PAE. The vast majority (82.1%) with the Hoyme et al., FAS facial phenotype did not have documented PAE. Of the 960 children with no documented PAE; 735 did not have the FAS facial phenotype (76.6% specificity). In other words, 23.4% of the children with no documented PAE presented with the Hoyme et al., FAS facial phenotype. If the University of Washington Lip-Philtrum Guide 1 for Caucasians was used instead of the Hoyme et al., North American Lip-Philtrum Guide, 121 children presented with the Hoyme et al., FAS facial phenotype. Of these 121 children; only 36 had documented PAE (29.8% PPV). Relaxation of the PFL to the 10th percentile and requiring only two of the three facial features continued to produce a FAS facial phenotype that was not predictive of PAE.

Since the magnitude of expression of the 4-Digit Code FAS facial phenotype is ranked on a 4-point Likert scale from Rank 1 (absent) to Rank 4 (fully present), the specificity, sensitivity, PPV and NPV were calculated for each Rank to assess how incremental relaxation of the FAS facial phenotype impacts the phenotype's ability to predict PAE (PPV). When the mild Rank 2, moderate Rank 3 and severe Rank 4 expressions of the FAS facial phenotype were compared to Rank 1 (complete absence of the FAS facial phenotype), the ability of the FAS facial phenotype to predict PAE (PPV) dropped precipitously from 100% for the Rank 4 face to 26.5% for the Rank 3 face (Table 2). The PPV for the Rank 2 face dropped even further to 13.7%. Another clinically meaningful way to assess the predictive value was to compare each Face Rank to all Face Ranks below it. Again, as the magnitude of expression of the FAS facial phenotype was reduced, the PPV dropped precipitously. One additional clinically meaningful way to assess the predictive value of the FAS facial phenotype was to dichotomize the 4-point facial Likert scale into a present/absent scale, splitting it in half at different cut-points. For example, using the current definition of the FAS facial phenotype: present equals Rank 4 and absent equals Ranks 1, 2 and 3; the Rank 4 phenotype is 100% predictive of PAE (all children with the Rank 4 Face have a documented PAE). If the 4-Digit Code FAS facial phenotype was relaxed: redefined as present equals Ranks 4 and 3 and absent equals Ranks 2 and 1; the PPV drops to 36.9%. Only 36.9% of subjects with Rank 3 or 4 faces had documented PAE. If the facial phenotype was further relaxed; redefined as present equals Ranks 4, 3 and 2 and absent equals Rank 1; PPV drops to 17.7%. This PPV is essentially identical to the PPV of the Hoyme et al., facial phenotype (17.9%). In a previous study [18], the relaxation of the Hoyme et al., facial phenotype was confirmed to be equivalent to 4-Digit Facial Ranks 2, 3 and 4 combined.

Specificity and PPV for the combined presence of the FAS facial phenotype, growth deficiency and microcephaly

When all three physical features of FAS were present in accordance with the Hoyme et al., 2016 FASD guidelines (the Hoyme et al., FAS facial phenotype, growth deficiency ≤ 10th percentile and OFC ≤ 10th percentile), PPV only reached 52%. Twenty-one children presented with all three physical features (FAS facial phenotype, growth deficiency and small OFC); but only 11 of the 21 had a documented PAE (52% PPV). The presence of all three physical features failed to predict PAE above random chance (50%). Specificity to PAE increased to 99% (all 3 features were absent in 99% of children with no documented PAE).

Specificity and PPV of growth deficiency and microcephaly

The PPV for growth deficiency, even at the most severe level (height and weight ≤ 3rd percentile: Growth Rank 4), never rose above 48.5% (no better than random chance). Only 20 of 41 children with Rank 4 growth deficiency had documented PAE. The PPV for microcephaly (OFC ≤ 3rd percentile) was 36.8%; only 35 of the 95 children with microcephaly had documented PAE. These outcomes were anticipated, as it is well documented in the medical literature that PAE is not the only cause of growth deficiency and microcephaly.

Sensitivity and NPV

Since the majority of individuals with PAE do not present with the Rank 4 FAS facial phenotype, growth deficiency and/or microcephaly, as postulated, sensitivity was quite low. If one used these features to screen for PAE in a population, most individuals with PAE would be missed.

Table 2. How well the FAS facial phenotype, microcephaly and/or growth deficiency predict prenatal alcohol exposure.

FAS Physical Features	N Group1 vs. 2	PPV	95% C.I.	NPV	95% C.I.	Specificity	95% C.I.	Sensitivity	95% CI

A. See Figures 2 and 3 for how growth and face are ranked by the FASD 4-Digit Code.

B. This outcome is portrayed in Figure 1.

C. The study population used to assess the Hoyme et al., FASD criteria does not include African Americans as detailed in the Methods section.

D. Hoyme et al., 2016 FASD guidelines [7] require 2 physical features be present to diagnose PFAS when PAE is unknown (the FAS facial phenotype and growth ≤ 10th percentile or the FAS facial phenotype and OFC ≤ 10th percentile).

E. Hoyme et al., 2016 FASD guidelines require 3 physical features be present to diagnose FAS when PAE is unknown (the FAS facial phenotype and growth ≤ 10th percentile and OFC ≤ 10th percentile).

Abbreviations: CI: confidence interval; NPV: negative predictive value; OFC: occipital frontal circumference (head circumference); PPV: positive predictive value; UW: University of Washington.; vs: versus

As anticipated, NPV was uniformly high (83.5% to 89.6%) across each of the physical features (the FAS facial phenotype, growth deficiency ≤ 10th percentile and OFC ≤ 10th percentile). The absence of one or more features correctly predicted the absence of PAE 83% to 89% of the time. But it is important to remember that NPV is influenced by the prevalence of PAE in the study population. As the prevalence of PAE decreases, the probability of correctly predicting the absence of PAE increases.

Discussion

The observed outcomes in this study were concordant with the postulated outcomes. The Rank 4 FAS facial phenotype, as defined by the FASD 4-Digit Code [3], was the only physical outcome that provided sufficient PPV and specificity to PAE (100%) to allow the facial phenotype to be used as confirmation of PAE in a diagnostic setting when a written or verbal documentation of PAE is not available. Even minimal relaxation of the facial phenotype criteria (e.g., Face Rank 3) resulted in a precipitous decrease in PPV (35%) and specificity (88.7%), rendering the relaxed phenotypes incapable of serving as confirmation of PAE. It is for this reason that the FASD 4-Digit Code requires confirmed PAE for all diagnoses with the exception of FAS. The high PPV and

specificity metrics generated from the current study are consistent with the PPV and specificity metrics generated from our previous studies dating back to 1995 [8,9,20,31].

The FAS facial phenotype as defined by the Hoyme et al., 2016 FASD guidelines resulted in a very low PPV (17.9%) and low specificity (76.6%), both far too low to serve as valid confirmation of PAE in a diagnostic setting when written or verbal confirmation of PAE is unavailable. Requiring the presence of all three physical features of FAS (the Hoyme et al., FAS facial phenotype and growth ≤ 10th percentile and OFC ≤ 10th percentile) did not increase PPV sufficiently to allow the cluster of physical features to serve as diagnostic confirmation of PAE. PPV increased only to 52%. Of the 21 children that presented with all three of these physical features, only 52% had a documented PAE. The presence of all three features predicted PAE no better than chance (50%). It is important not to misinterpret this finding. The low PPV associated with growth deficiency and OFC ≤ 10th percentile does not mean PAE does not cause growth deficiency and microcephaly. The low PPV simply reflects the fact that there are many risk factors (not just PAE) that cause growth deficiency and reduced head circumference, especially in this high-risk foster population. Growth deficiency and microcephaly are strongly correlated with PAE, highly predictive of cognitive/behavioral dysfunction and essential to the diagnosis of FASD [32].

It is important to clarify that high PPV and specificity are required to confirm PAE in a FASD diagnostic setting. Diagnostic evaluations provide definitive information about the presence or absence of a condition or exposure. In contrast, lower levels (~80%) of PPV and specificity may be deemed acceptable in a FASD screening setting, when the goal is to identify individuals at risk for adverse outcomes caused by PAE. In a screening activity, one may be more willing to accept PAE false-positives so as not to miss PAE true-positives. One would expect the false positives to be corrected in the diagnostic phase of a screening. A recent study by Goh et al., [33] serves as a good example of a screening tool developed to determine which children with neurodevelopmental problems were likely to be affected by PAE and require clinical follow-up. The tool screens for different combinations of outcomes (e.g., IQ, measures from the Child Behavior Checklist [34] and Vineland Adaptive Behavior Scales [35], 1 or more of the 3 Hoyme et al., FAS facial features, ptosis, incomplete extension of one or more digits, and growth or head circumference ≤ 10th percentile) in hierarchical fashion to predict PAE. When the screening tool was administered to a group of 454 children, in which 145 (32%) had PAE, the tool performed with the following metrics: PPV = 70.7%, NPV 86.7, specificity 80.6%, and sensitivity 79.2%. The PPV of 70.7% means 29.3% of the children predicted to have PAE, did not have PAE (e.g. 29.3% were false positives, their birth mothers did not drink during pregnancy). A false-positive rate of this magnitude could be deemed acceptable in a screening activity; but would be unacceptable in a diagnostic clinic.

FASD diagnostic guidelines that use relaxed criteria for the FAS facial phenotype risk misdiagnosing and over-diagnosing FAS and partial FAS when PAE is unknown. These misdiagnoses can lead to over-estimates of the prevalence of FAS and PFAS in FASD screening/surveillance activities that target populations where confirmation of PAE is difficult to obtain. For example, May et al., [36] conducted a FASD screening among first grade students in a Midwestern U.S. community. Screen positives received FASD diagnostic evaluations in accordance with the Hoyme et al., [37] criteria that permit diagnosis of FAS and PFAS when PAE is unknown. The relaxed facial, growth and head circumference criteria for FAS and PFAS are identical between the Hoyme et al., 2005 [37] and Hoyme et al., 2016 [7] FASD diagnostic systems. The authors reported alcohol use during the index pregnancy was confirmed in only 33% of the cases diagnosed with FAS and 61% of the cases diagnosed with PFAS. It is unclear what feature(s) were present among two thirds of the FAS cases and one third of the PFAS cases that allowed these diagnoses to be rendered with unknown PAE. The authors concluded *"The prevalence of FAS cases in this study of first grade children in this general population is likely 6 to 9 per 1000. It is significantly higher than older, previously accepted estimates of FAS (0.2 to 3 per 1000) that were generated from less representative samples that did not use active case ascertainment. But these findings are similar to recent rates published for the United States, Italy, and Croatia, 2 to 7 per 1000, which used similar, active methods of case identification and ascertainment. For FAS and PFAS combined, the likely maximum range of rates is 17 to 26 per 1000, and for total FASD, the rates range from 24 to 48 per 1000. Therefore, rates from this study are all well above the old estimate of 1% for total FASD* [38]."

The outcomes of the current study continue to support that the Rank 4 FAS facial phenotype is unique to (caused only by) PAE. Nevertheless, updates in genetic testing technologies such as chromosomal microarray analysis suggest some of the physical and neurobehavioral abnormalities observed in FASD overlap with those observed among individuals with chromosomal disorders. Chromosomal microarray abnormalities occur among 15-20% of individuals with unexplained developmental disability/intellectual disability, autism spectrum disorder and multiple congenital anomalies [39]. Chromosomal abnormalities (often chromosomal micro-deletions or micro-duplications) have been reported in 8-14% of individuals with FASD [39-44]. But to date, these studies have been descriptive, not empirical in design. To empirically confirm chromosomal abnormalities serve as an alternate etiology for the Rank 4 FAS facial phenotype, one would have to identify a sufficiently large group of individuals who present the Rank 4 FAS facial phenotype, have the chromosomal abnormality and have a confirmed absence of PAE. As proffered by Kahila et al., [41], are chromosomal abnormalities an alternate etiology for the physical and neurobehavioral abnormalities observed among individuals with PAE or are the chromosomal abnormalities the consequence of PAE? Halsted et al. [45] suggested that alcohol consumption decreases the amount of folate, which is needed for cells' methionine cycle. Thus, alcohol could reduce the production of methyl groups for DNA and histone methylation, cause hypomethylation, and consequently decrease the stability of the chromosomes [41]. To date, there have been no reports of the Rank 4 FAS facial phenotype present in an individual with chromosomal abnormalities and confirmed absence of PAE.

Study strengths and limitations

Documentation of PAE was both a strength and limitation in this study. PAE is inherently difficult to accurately confirm or rule-out in any population. Due to the stigma associated with drinking

during pregnancy, birth mothers are typically reluctant to report their alcohol use during pregnancy. The most frequent source of confirmation of PAE in the FASDPN clinic is past birth, medical and social service records [46]. It takes time and effort to obtain these records, but in so doing, one is likely obtaining the most accurate record of PAE available. If there is error in the "true exposure" status of a study population, the classification/prediction parameters derived from that "true exposure" classification can be impacted. The strength of this study was the thoroughness with which all records were obtained and reviewed by the foster care program to identify, as accurately as possible, the "true PAE" status of each child.

Conclusion

FASD diagnostic guidelines that use relaxed criteria for the FAS facial phenotype risk misdiagnosing and over-diagnosing FAS and partial FAS when PAE is unknown. These misdiagnoses can lead to over-estimates of the prevalence of FAS and PFAS in FASD screening activities that target populations where confirmation of PAE is difficult to obtain.

Ethical Approval

FASD diagnostic guidelines that use relaxed criteria for the FAS facial phenotype risk misdiagnosing and over-diagnosing FAS and partial FAS when PAE is unknown. These misdiagnoses can lead to over-estimates of the prevalence of FAS and PFAS in FASD screening activities that target populations where confirmation of PAE is difficult to obtain.

Author Contributions

The author was the principal investigator for the original study and conducted all analyses and manuscript preparation for the current study.

Abstract: Caregiver-reported assessments provide opportunities for caregivers to share concerns and identify the strengths of their infant/toddler regarding prenatal alcohol exposure (PAE). These insights may reveal under-recognized concerns and inform a strengths-based approach to early intervention. The purpose of this study was to describe the type and frequency of caregiver-reported concerns and strengths in a sample of infants/toddlers at the time of their fetal alcohol spectrum disorder (FASD) diagnostic evaluation. Caregivers' concerns and strengths were identified in the context of two parent-report questionnaires, the Infant Toddler Sensory Profile and Child Behavior Checklist/1$^1/_2$-5. By using content analysis, caregivers' open-ended responses were identified, coded, and analyzed. The frequencies of all the coded concerns and strengths were counted. The data were compared across the two age groups (<2 years and ≥2 years) and caregiver status. Caregivers (n = 117) identified numerous concerns and strengths across multiple categories. The most frequently reported concerns were related to aggressive behavior, language/communication, and sensory processing. The most frequently reported strengths were related to happiness, sociability, and love. The type of concerns and strengths reported were relatively consistent across age and caregiver status. These findings reinforce the value of caregivers' perspectives and offer a reminder to practitioners that infants/toddlers with PAE and their caregivers have many strengths that can be harnessed, in addition to a range of challenges that must be addressed.

1. Introduction

Prenatal alcohol exposure (PAE) can disrupt the neurodevelopmental and behavioral trajectory of infants/toddlers with lasting impacts on learning, mental health, and overall well-being [1,2]. Fetal alcohol spectrum disorder (FASD) is a term used to describe the full range of physical, cognitive, and behavioral impairments caused by PAE, which are estimated to occur in at least 1% of children and youth in the general population [3,4]. Infants/toddlers with PAE are a heterogeneous group of children who may experience a wide range of delays in development, sensory processing, and/or emotional and behavioral functioning [5]. Challenges in any one of these developmental domains can limit participation in everyday routines and activities and negatively influence the quality of parent–child interactions and early relationships [6,7]. Conversely, infants/toddlers with PAE also possess individual strengths and positive attributes [8] that can serve as protective factors and support whole child development.

Early interventions that target risk factors and build on individual strengths can alter the course of development in a positive direction. Findings from decades of developmental and intervention science have demonstrated the substantial benefits of early intervention on child development and family well-being [9]. The first three years of life have

been recognized as an incredibly important time for child development, given the brain's capacity for change and sensitivity to environmental influences [10]. With an emphasis on promoting healthy parent–child interactions and strengthening family adaptation, a family-centered early intervention approach is well-suited to respond to the diverse needs of infants/toddlers with PAE [6,11].

Although early identification and diagnosis may be the best way to positively influence outcomes in young children with PAE [12], PAE appears to be under-recognized by early childhood practitioners [11]. The early identification of infants/toddlers with PAE is complicated in several ways. Challenges by multiple systems of care (i.e., health care, child welfare, early intervention, and infant mental health) to initiate and conduct universal screenings or identification processes for prenatal exposures may be, in part, inhibiting earlier referrals for FASD diagnosis [13]. In addition, not all infants/toddlers with PAE present with easy-to-recognize symptoms, such as characteristic physical findings (e.g., growth problems, FAS facial features, structural brain abnormalities, etc.) or severe neurodevelopmental/behavioral delays [14]. Instead, many infants/toddlers may have more subtle developmental or behavioral indicators [15,16] that are not as easily recognized by early childhood practitioners, thus translating into a missed opportunity for early identification and intervention.

Caregivers, on the other hand, are often the first to raise concerns about their child's development or behavior and can, therefore, serve as a critical step in identifying early delays or problems that may arise from PAE. Directing attention to caregiver-reported assessments, which constitute a valuable component of early childhood assessment, is one way to learn about caregiver concerns. Standardized caregiver-report measures that are commonly used to assess infant sensory processing and behavior provide a way for parents or guardians to examine and report child behaviors. They permit caregivers to express their concerns through rating scales and responses to open-ended questions. Although clinicians tend to focus their attention on rating scale outcomes, using open-ended questions to ask about parent concerns can often lead to responses that are more spontaneous and personal [17]. It is through open-ended questions that new or under-recognized concerns related to PAE may be uncovered, as caregivers provide responses in their own words and are not constrained by predetermined responses [18].

By the nature of their role and relationship, primary caregivers have a unique vantage point that makes them acutely aware of the day-to-day challenges faced by their child. This increased awareness makes caregivers a vital resource for identifying children whose development and behavior do not appear typical. Previous research with caregivers of children with PAE or FASD demonstrates caregivers' vigilance to variations in their child's development and behavior. In a study of 1400 structured interviews of caregivers raising children impacted by PAE, the outcomes confirmed caregivers were highly preceptive in differentiating the cognitive and behavioral challenges of children across the continuum of FASD [19]. In a second study on the foster mothers of children (ages 2–16 years), a multitude of problems was reported, including concerns related to child cognition, behavior management, and coping with the daily realities of life [20]. Likewise, a third study describing the lived experiences of eight birth mothers of a child/ren with FASD (8–30 years) reported cognitive concerns (i.e., problems with attention, comprehension, and memory) and problem behaviors (i.e., excessive crying or no crying, hyperactivity, aggressiveness), in addition to health issues and delayed developmental milestones [21]. A fourth study emphasized the concerns faced by caregivers, including FASD-related stigma, family stress, and a lack of knowledge by professionals [22]. Finally, in a study by Pruner et al. [8], caregivers were asked to reflect on the challenges faced by their children with PAE during their first three years of life. Caregivers reported a diversity of concerns spanning across all domains of development and further reflected on how early interventions met (or did not meet) those needs. Collectively, these studies recognize caregivers' valuable observation skills and insights into their children's developmental needs. In accordance with this, the Academy of Pediatrics recommends that health professionals ask about and

attend to caregiver concerns as a first step toward the developmental surveillance of infants and young children [23,24].

The recent literature has emphasized a need for a strengths-based approach to assessment and intervention regarding children with FASD [25,26]. Guiding caregivers to identify child strengths during a clinical encounter can extend benefits to both caregivers and practitioners [27]. A strengths-based approach can offer parents a sense of hope, alleviate child-related stress, and strengthen parenting capacity [28–30]. When early childhood practitioners appreciate the variety of child strengths identified by caregivers in this population, it may enable them to recognize and celebrate these assets more easily and in partnership with caregivers. In a parallel process, a strengths-based approach can enhance the bond between the practitioner, the caregiver, and the child, thus building effective working relationships and perhaps reducing FASD-related stigma [28,31,32]. To this end, 20 years of caregiver surveys of patients diagnosed with FASD at the University of Washington Fetal Alcohol Syndrome Diagnostic and Prevention Network (FASDPN) clinic confirmed that caregivers were highly satisfied with the strength-based approach to assessment and intervention [33].

Understanding the types of strengths and positive attributes of infants/toddlers with PAE from the perspective of their caregivers can inform strengths-based interventions. While an extensive amount of research has documented the challenges and impairments experienced by individuals with FASD across their lifespan, less research has focused on identifying strengths at any age [26,34]. Four studies were identified that described caregiver perceptions of child strengths. One study found that the caregivers of children aged 5–21 years recognized many positive traits (i.e., friendliness, hard-working, compassion, etc.) and abilities (e.g., artistic, athletic, etc.) in their child [35]. A second study identified the relative strengths in personal selfcare and household chore activities compared with other adaptive skills for children ages 5–8 years [36]. Third, the caregivers of school-age children reported a range of personal strengths in the context of students' educational experiences, describing their child as being artistic, having strong verbal skills. or having good work habits [37]. In a fourth study, all caregivers were eager to share what they enjoyed most about their child during the early intervention period, including moments of affection, love, and laughter [8]. Notably, Olson and Montague [38] reported the strengths of young children with FASD based on informal reports, which "are filled with descriptions of how engaging, innocent, straightforward, amusing, curious and social young children with an FASD can be". When taken together, these studies and informal reports highlight caregivers' awareness of child strengths and their willingness to communicate these strengths to others.

The present study was designed to address the following questions: (1) What are the concerns and strengths reported by caregivers regarding their infant/toddler (ages 7–42 months) with PAE? (2) From a descriptive perspective, do there appear to be patterns between caregiver types (birth parent, foster/adoptive parent, or other biological relatives) or child age (less than 2 years or 2 years and older) and the type or frequency of reported concerns and strengths? Examining caregiver-reported concerns may yield useful information regarding delays in child development or problem behaviors that warrant the attention of practitioners, signal the need for diagnostic referral, and/or lend important insight into the impact of these concerns on families. Understanding how child age or caregiver status can influence the reporting of concerns may facilitate a more targeted approach for practitioners when inquiring about caregiver concerns and for knowing what kinds of child development information and education certain families might need. In addition, the identification of child strengths and positive characteristics can provide opportunities to enhance parent–child interactions, incorporate these strengths into interventions, and help build caregiver-practitioner partnerships.

2. Materials and Methods

The data for the current study were collected as part of a larger retrospective chart review of diagnostic assessment data from 125 infants/toddlers seen at the University of Washington FASDPN clinic between 2009 and 2019. This clinic does not require patients to present with a concern or delay, only a confirmed PAE at any level. Two linked studies were generated from this chart review, including (1) a descriptive study that examined the developmental, sensory processing, and behavioral outcomes of infants/toddlers with PAE [5]; and (2) the current study, which described caregivers' early concerns and perceptions of their infant/toddlers' strengths, based on data from two standardized caregiver questionnaires, the Infant/Toddler Sensory Profile (ITSP), and the Child Behavior Checklist/1½-5 (CBCL). All study activities were conducted with the University of Washington Human Subjects approval and caregiver consent at the time of their child's FASD diagnostic evaluation.

2.1. Participants

Caregivers were included in this study if their infant/toddler met the inclusion criteria for the prior study [5] and they completed the ITSP questionnaire and/or the CBCL as part of their child's FASD diagnostic evaluation. Child inclusion criteria for the first study were as follows: (1) age 1 month to 3.5 years—at the time of their FASD diagnostic evaluation; (2) received one of the following FASD 4-Digit Code diagnostic classifications (diagnostic categories A–C, D–J) reflecting the full continuum of outcomes observed among individuals with prenatal alcohol exposure (a) fetal alcohol syndrome (FAS; A,B) or partial fetal alcohol syndrome (PFAS; C), (b) static encephalopathy/alcohol exposed (SE/AE; E,F), (c) neurobehavioral disorder/alcohol exposed (ND/AE; G,H), (d) sentinel physical findings/alcohol exposed (I), or (e) no physical findings or central nervous system (CNS) abnormalities detected/alcohol exposed (Normal CNS/AE; (J) (see [39] for details about the FASD 4-Digit Diagnostic Code and [5] for detailed demographics of the prior study sample); and (3) had complete data on at least two domains of the Bayley Scales of Infant and Toddler Development (Bayley-III, [40]). Standardized parent questionnaires were completed by the primary caregiver prior to the scheduled diagnostic clinic date. Time, effort, or other demands placed on a caregiver may have resulted in some caregiver-report measures (i.e., Bayley-III Social-Emotional and Adaptive Behavior domains, ITSP, and CBCL) not being fully completed.

2.2. Measures

The data for this study were collected as part of a standard intake and diagnostic process for the FASDPN diagnostic clinic visit. The measures used for this study are described below.

Infant Toddler Sensory Profile (ITSP [41]). The ITSP is a 48-item caregiver questionnaire that measures sensory modulation abilities in daily life for infants/toddlers (7–36 months). Caregivers rate the frequency of infant/toddler sensory behaviors on a 5-point Likert scale. Caregivers also have the opportunity to respond to two open-ended questions: "What do you see as your child's strengths?" and "What are your concerns?". It is relevant to note that infants/toddlers older than 36 months were administered the Short Sensory Profile (SSP; [42]), which does not have open-ended questions as part of the questionnaire. Therefore, caregivers of infants/toddlers older than 36 months were included in this study if they completed the Child Behavior Checklist 1½–5 years only.

Child Behavior Checklist 1½–5 years (CBCL [43]). The CBCL is a 100-item caregiver questionnaire used to identify a range of emotional and behavioral problems in young children ages 1.5–5 years. Caregivers use a rating scale to determine the presence or absence of emotional and behavioral problems based on the preceding 2 months. Caregivers also have the opportunity to respond to two open-ended questions: "What concerns you most about your child?" and "Please describe the best things about your child".

2.3. Descriptive Information for Participants

Three salient features from the FASD 4-Digit Diagnostic Code used in this study are briefly described below. See [39] for a more comprehensive description of these diagnostic features.

The FASD 4-Digit Diagnostic Code generates the following clinical diagnoses. FAS, PFAS, SE/AE, ND/AE, Sentinel Physical Findings/AE; No Physical or CNS Abnormalities/AE.

Central Nervous System (CNS) Functional Rank. Rank 1 = no dysfunction; Rank 2 = mild-to-moderate dysfunction; Rank 3 = severe dysfunction [39]. CNS functional ranks 1–3 document the severity of CNS dysfunction and are based on brain function (executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention, and activity level) assessed by an interdisciplinary team using standardized psychometric tools.

Postnatal Risks. Rank: 1 = no risk; 2 = unknown risk; 3 = some risk; and 4 = high risk) [39]. Individuals with PAE often present with a multitude of postnatal risks that could also be adversely impacting their development. Postnatal risk factors documented in the FASDPN database include perinatal complications, number of home placements, physical and/or sexual abuse, neglect, and trauma. The ranking is determined by clinical judgment at the time of the FASD evaluation and is based on available records and caregiver or other reports on intake forms and/or clinical interviews.

2.4. Data Analysis Plan

This study used a directed content analysis approach [44] to identify, categorize, and describe all instances of concerns and strengths reported by caregivers at the time of their child's diagnostic evaluation. The directed approach begins with a framework for collecting and analyzing the data but allows for new insights to emerge through a process of inductive category development [43]. In this study, researchers aimed to validate an existing framework (domains commonly assessed in early childhood) in a new context (describing caregivers' concerns and strengths). When the data did not fit into the existing framework, new categories were added to capture all possible instances of caregiver concerns and strengths [44,45].

The written responses to the two questions from the ITSP and two questions from the CBCL were extracted verbatim, excluding any identifying information. A coding system was developed that had multiple levels. First, responses were separated into two groups based on question type—concerns versus strengths/best things. Next, the researchers read all the caregiver comments related to concerns and organized the responses into broad categories. These broad categories arose from the data to reflect general areas of function or development (i.e., Development, Behavior, General/Medical, and Caregiving). After the data related to concerns were sorted, the data within each broad category were analyzed further to create subcategories reflecting the different examples of concerns within each broad category. Some of these subcategories were based on domains commonly assessed in early childhood or contained within the ITSP or CBCL measures, while others arose from the data (these are identified in Appendix A). A similar analysis was conducted with the strengths/best things data, with the broad categories being Development, Personality Traits, Interests, and Caregiving, and the subcategories within each of these are reported in Appendix B.

Two researchers (MP, JM) separately coded 50% of caregiver responses using the initial coding systems. They compared their results, and any discrepancies with how well the categories fit the data were discussed, and adjustments to the category structure were made. This process was repeated until consensus was reached, and all of the data total responses were coded. Once the coding systems were finalized, the first author coded the remaining responses.

Frequency counts for each coded category were calculated. Responses that were left blank or completed with statements such as "no concerns at this time" or "none" were also tracked. When a response contained multiple words or phrases that were suggestive

of a concern/strength, it was only coded once. For example, the description "my child is extremely social, charming and loves other kids", was coded under Sociability one time. On the few (n = 10) occasions that a response fell under two categories, the response was coded twice. For example, the description "doesn't seem to understand" was coded under the two categories of Cognitive and Language concerns because the reason for the comprehension problems was not specified (i.e., whether it was a cognitive or language problem). Another example, "my child is easily over-stimulated", was coded under the two categories of Regulatory and Sensory Processing because of the overlapping nature of this concern. When a caregiver completed both measures and shared similar concerns or strengths on both questionnaires, the responses were coded only one time. As a last step, the quantitative data were descriptively compared across age groups (i.e., <2 years and ≥2 years of age) and caregiver status (i.e., biological parent, foster/adoptive parent, other biological family).

3. Results

Records from 117 caregivers of infants/toddlers with PAE (ages 7–42 months) met the inclusion criteria for this study. Of these caregivers, 32% were birth parents, 44% were foster/adoptive parents, and 25% were extended relatives of the child (e.g., grandparent, aunt). An overwhelming majority of the sample (91%) presented with at least some level of postnatal risk in addition to their PAE. A total of 80% percent of caregivers in the sample completed the ITSP (7–36 months), while 57% completed the CBCL (1.5–3.5 years). See Table 1 for participant characteristics.

Table 1. Demographic and clinical characteristics of the 117 participants.

Caregiver and Child Characteristic	N	(Valid %)
Respondent		
Biological mother	34	(29.1)
Biological father	3	(2.6)
Other biological family member	29	(24.7)
Foster parent	44	(37.6)
Adoptive parent	7	(6.0)

Notes: Infant toddler sensory profile 7–36 months (ITSP); child behavior checklist 1.5–5 years (CBCL); fetal alcohol spectrum disorder (FASD); fetal alcohol syndrome (FAS); partial FAS (PFAS); static encephalopathy/alcohol-exposed (SE/AE); neurobehavioral disorder/alcohol-exposed (ND/AE).

3.1. Concerns Identified

The coding process used for this study generated a list of 19 unique concerns expressed by caregivers (Appendix A). Caregivers reported an average of 2.5 concerns per child, ranging from 0–7 concerns per child. A total of 293 concerns were reported across the study sample. The five most frequently reported concerns were related to developmental and behavioral challenges and included aggressive behavior (27%), language/communication (22%), sensory processing (21%), internalizing problems (19%), and regulation (18%). Twenty-four (24%) caregivers did not report a concern for their child for either measure. The proportion of caregivers who did not report a concern was comparable across all three caregiver groups. The frequency of reported concerns across categories is presented in Table 2.

Table 2. Prevalence of reported concerns.

No concerns reported	28 (23.9)	16 (27.1)	13 (22.4)	10 (30.3)	11 (31.4)	7 (26.9)

Notes. Bolded numbers indicate the top 5 (total sample) or the top 3 concerns (age and caregiver categories).

Concerns were explored across age groups. For younger infants/toddlers (<2 years), the caregiver concerns expressed most often were aggressive behavior (25%; *screams at high pitches; extreme temper*), sensory processing behaviors (24%; *sensitivity to sounds, lights,*

and clothes), and motor skills (20%; *isn't sitting up on his own*). For older infants/toddlers (≥2 years), caregivers reported the most concerns with language/communication skills (29%; *slow speech; doesn't talk in more than three-word sentences*), aggressive behavior (29%; *can throw a fit that lasts for some time*) and internalizing problems (19%; *whiny, fussy, and sudden mood changes*). Notably, aggressive behaviors were reported with the most frequency across both age groups.

Concerns across caregiver status were also explored. Birth parents had the most concerns for PAE and other drug exposures (23%; *he was born addicted*), aggressive behavior (20%; *abusive*), and language/communication (18%; *worried about speech development*). The most common concerns reported by foster/adoptive parents were aggressive behavior (34%; *head butts, pulls out gobs of her own hair and even tries to pull mine out*), language /communication (25%; excessively repeats herself, doesn't talk in more than three-word sentences), and sensory processing behaviors (26%; *has extremes in responses to stimuli*). The top concerns noted among other biological family members were language /communication (27%; *speech; constant chatter*), aggressive behavior (27%; *tantrums that are hard to calm down from*), and sensory processing (22%; *becomes inconsolable as soon as caregiver . . . introduces new sensation*). Aggressive behaviors were a top concern that was common across all three caregiver types.

3.2. Strengths Identified

The coding process generated a list of 20 unique strengths (Appendix B). Caregivers identified an average of 3.0 perceived strengths per child, ranging from 0–7 coded strengths each. A total of 352 strengths were coded across the study sample. The most frequent strengths or best things reported were reflective of personality traits: happiness (33%), sociability (30%), love/loving (28%), and curiosity (26%), and for developmental competencies, cognitive ability (22%). In contrast, strengths related to adaptive behavior (1%), eating/feeding (3%), and regulation (3%) were rarely reported. Strengths in the child's interests (14%) and caregiver experience (3–5%) categories were also endorsed less frequently. A total of 25% of caregivers did not report a strength for either measure. The proportion of caregivers who did not report a strength was comparable across all three caregiver groups. Table 3 shows the frequency of reported strengths across categories.

Perceived strengths were explored across two age bands. For infants/toddlers (<2 years), caregivers frequently reported the following personality traits: curiosity (37%; *observant; curious*), happiness (31%; *very happy; happy most of the time*), and love/loving (29%; *child is lovable*). For older infants/toddlers (2–3.5 years), many caregivers described their child as happy (35%; *very happy girl*), social (35%; *loves to interact with me and other children*) and love/loving (30%; *very loving*).

Perceived strengths were also explored across caregiver status. Birth parents reported the most child strengths in the categories of happiness (27%; *happy baby*), love/loving (24%; *she is so loving*), and sociability (21%; *he's a charmer*). Likewise, the most common strengths reported by foster/adoptive parents were happiness (43%; *she brings a lot of happiness to our lives*), sociability (32%; *friendly and outgoing*), and love/loving (27%; *loves her siblings*). The strengths expressed most often by other biological family members were love/loving (37%; *loving boy*), sociability (33%; *her smile and ability to get along with others*), and curiosity (33%; *tries everything, observant*). Sociability and love/loving were perceived strengths common across all three caregiver types.

Table 3. Prevalence of reported strengths or best things.

Notes. Bolded numbers in the total sample column indicate the top 5 concerns, and bolded numbers in age and caregiver columns indicate the top 3 concerns.

4. Discussion

In this retrospective study of clinical data, the caregivers of infants/toddlers with PAE described a diversity of concerns and strengths in the context of two developmental questionnaires administered as part of their child's FASD diagnostic evaluation. Our primary findings were that (a) caregivers' predominate concerns fell into the categories of aggressive behavior and language/communication, while sensory processing and internalizing behaviors were also commonly reported; (b) the caregiver-perceived strengths spanned across numerous categories, with positive personality traits related to happiness, sociability, and love expressed most often, and (c) the type and frequency of reported concerns and strengths were relatively consistent across age and caregiver status. The findings from this study recognize the value of caregivers' perspectives and offer an important reminder to practitioners that infants/toddlers with PAE and their caregivers have strengths that can be harnessed, in addition to a range of challenges that must be addressed.

Caregivers reported a broad array of concerns, reflecting the diversity of neurodevelopmental and behavioral outcomes known to be associated with PAE during early childhood [46,47]. Aggressive behaviors such as kicking and screaming, head banging, and prolonged temper tantrums raised the most concerns across both age groups and were relatively consistent across caregiver groups. Previous studies that examined behavior functioning found greater negative effects among infants [1] and preschool-age children with PAE [48,49], as well as a difficult temperament [50] and conduct-based problems [51] among preschoolers. Caregivers' frequent concerns about language/communication are substantiated by studies that described delayed language abilities in infants with PAE [52–54]. Atypical sensory processing behaviors and internalizing problems were commonly described by caregivers in this study and, likewise, have been reported in the literature among infants/toddlers with PAE [15,55–57]. Concerns related to selfregulation, such as difficulty soothing or sleep complaints, were also consistent with selfregulatory difficulties seen in this population [58].

Overall, it appears that caregivers raised concerns that correspond closely to the outcomes from the standardized measures of development, sensory processing, and behavior in the existing literature. The findings demonstrate that caregivers can be an important source of information regarding their children. Explicitly asking caregivers about their concerns may aid in the earlier identification of delays or problems that may arise from PAE, especially when incorporated into an early routine screening or comprehensive clinical assessment [23].

Although most caregiver-reported concerns were coded using the categories from the core developmental domains, ITSP, and CBCL scales, there were a few exceptions. For example, concerns related to parenting were identified by 15% of caregivers, yet the ITSP or CBCL did not explicitly prompt caregivers to consider these concerns. Along the same lines, other concerns (e.g., PAE and other drug exposures and physical and health problems) were reported that were not captured on the questionnaires caregivers had previously completed. While many caregivers' developmental, behavioral, and clinical concerns would have been assessed and/or detected at the time of their child's FASD diagnostic evaluation, it is possible that the concerns related to parenting may have been missed if it were not for the open-ended questions. Caregivers who are struggling with the day-to-day stressors of raising an infant/toddler with PAE often require additional support to engage in sensitive and responsive parenting. With this goal in mind, these findings offer a reminder to practitioners that a combination of assessment approaches is needed to ensure that caregivers have more than one avenue to share concerns. Practitioners need to understand the complex problems facing caregivers, as well as their priorities and desired outcomes, to design treatment plans that are congruent with caregiver goals.

An overwhelming majority of caregivers (88%) shared one or more strengths/best things about their infant/toddler. Happiness, sociability, and love were the strengths reported most often, suggesting many caregivers believed these personality traits were worth knowing about and communicating with others. The finding that caregivers endorsed happiness and sociability among their top two strengths is consistent with a large meta-analysis examining the benefits of frequent positive affect in individuals across multiple life domains, which found happiness to be positively correlated with sociability [59]. Based on previous research on parents of neurotypical children (ages 3–9), love was also a frequently endorsed character trait [60]. For early childhood practitioners, this is useful information for initiating a working relationship with all types of caregivers, regardless of the child's age. Recognized strengths, such as happiness, sociability, and love, may be perceived as a healthy indicator of parent–child connectedness and a starting point for noticing and exploring these perceptions, which is especially important for family-centered care and relationship-focused approaches [61,62]. Alternatively, when caregivers struggle to identify strengths in their child, this may signal to practitioners a need to promote attuned and positive exchanges between caregiver and child. A strengths-based approach is particularly important given the stigma associated with FASD. Both the biological, as well as nonbiological parents of children with PAE experience stigmatization when they are perceived as responsible for their child's negative behavior or delayed development [32]. Cultivating child and caregiver strengths is in alignment with guiding principles of early intervention practice [9], as well as practice guidelines specific to families impacted by substance use [63]. Elevating strengths-based approaches for young children with known or suspected PAE and focusing on child strengths may work towards reducing stigma among caregivers and foster earlier identification and intervention as critical protective factors as early in life as possible [64].

Caregivers identified a few characteristics in both a positive and negative light. For example, the personality trait "zest" was reported by 16% of caregivers when they used phrases such as "my child's personality is larger than life" or "he's a firecracker". In contrast, it appeared some caregivers perceived their child's high energy and excitement as a problem related to attention or hyperactivity (i.e., she is very driven . . . very hyperactive, causing her to fall or run into things often). Furthermore, caregivers reported sociability

as frequent strength, yet they also identified language/communication problems as a frequent concern. While concerns related to the use of language/communication are fundamentally different than the personality trait of sociability, practitioners can play a role in leveraging a child's strong social skills toward the goal of developing language and communication skills. Indeed, building on strengths to compensate for child difficulties is a central intervention principle used with families raising children with FASD [65].

The following are study limitations. Since this was a retrospective chart review, the data were limited to the written responses reported on the assessment forms. As such, we were not able to probe for further detail or ask for clarification about any of the caregiver responses or follow up with those who did not respond. Responses to these questions were optional, and thus there may be bias or differences among caregivers who responded to the open-ended questions compared with those who did not. Caregivers of all types reported strengths and challenges on both measures; however, we cannot generalize results to all young children with PAE and caregivers due to the inherent limitation of a clinical sample. In order to gain a more thorough understanding of caregivers' concerns and child strengths, future research should use a more systematic approach, such as guided interviews or focus groups that pose similar open-ended questions, with the opportunity to ask directed questions about strengths and challenges so that all participants have an equal ability to respond.

5. Conclusions

Caregivers identified concerns that warrant the attention and action of early childhood providers, demonstrating their attunement to the early challenges faced by their children. Caregivers also perceived their children to have many strengths across multiple areas. These findings suggest the importance of understanding the range of concerns and strengths that caregivers perceive in their day-to-day interactions with their children, which can enhance the development of family-centered interventions, strengthen parent–child connectedness, and build effective working relationships between early childhood practitioners and families impacted by PAE.

Appendix A. Final Coding System Documenting 19 Unique Concerns

Table A1. Final Coding System Documenting 19 Unique Concerns.

Broad Categories	Subcategories	Definition	Example(s)
Development	Overall Development	Concerns with development in general	Child is developmentally behind despite interventions
	Cognitive *	Concerns with comprehension, intelligence, and learning	Slow processing, doesn't know shapes, colors, or letters
	Language/Communication *	Concerns with speech, language, receptive/expressive and social communication	She can't express what she wants, babbles like an infant

Table A1. *Cont.*

Broad Categories	Subcategories	Definition	Example(s)
	Motor/Movement *	Concerns with fine and gross motor skills, movement	Not walking, doesn't sit up
	Social-emotional *		
	Regulation	Difficulty coping with discomforting emotions	Cannot quiet or calm self, easily over-stimulated
	Attachment	Difficulty bonding, seeking comfort and closeness	Difficulty bonding, when's he's away from us he won't engage in play
	Adaptive behavior *	Concerns related to activities of daily living	Baths don't go well, hard time participating in everyday, normal activities
	Sleep	Sleep-related disturbances	Can't fall asleep, only sleeps 2 h at a time
	Eating/feeding	Concerns with feeding, eating, mealtimes	Reflux, poor eating habits, gagging
Behavior	Internalizing problems **	Emotionally reactive, anxious/depressed, somatic complaints and withdrawn behaviors	Quick switches between fury and happy, fussy
	Externalizing problems **		
	Attention problems	Problems with inattention, hyperactivity, or impulsivity	Unable to sit still or focus, frequently trips over objects
	Aggressive behavior	Problems managing frustration, may hurt others or self	Head banging, kicking, prolonged tantrums, screaming
	Sensory processing ***	Sensory behaviors that interfere with daily life	Sensitive to sound, high pain tolerance, doesn't respond to name
	Behavioral inflexibility	Difficulties adapting to changes in routine	Does NOT have transitioning skills, needs a structured environment
	Safety awareness problems	Lack of safety awareness	Will walk off with stranger, fearless, impulsive
General/Medical	Prenatal alcohol & other drug exposures	Concerns related to PAE & other drugs	I drank frequently when pregnant and chewed tobacco
	FAS physical findings	Concerns related to growth deficiency, microcephaly, or FAS facial features	Small size, poor weight gain, small head, thin lip
	Physical or health problems	Concerns related to physical or health problems	Failure to thrive, low muscle tone, born premature
Caregiving	Caregiving concerns	Concerns related to parenting, questions that arise and perceptions about their child's future	Exhausted, worry that child will be unable to catch up with peers, why is he delayed, it's hard to tell if this is normal for his age

Notes. * Categories based on the Bayley-III domains; ** Categories based on the CBCL scales; *** Category based on the ITSP.

Appendix B. Final Coding System Documenting 20 Unique Strengths or Best Things

Table A2. Final Coding System Documenting 20 Unique Strengths or Best Things.

Broad Categories	Subcategories	Definition	Example(s)
Development	Cognitive *	Capacities related to intelligence and learning	Smart, bright, problem-solver
	Language/Communication *	Capacities related to speech, language, receptive/expressive, and social communication	Strong communicator, voices' own opinion
	Motor *	Capacities related to motor skills and movement	Loves to run, athletic, strong
	Social-emotional *		

Table A2. *Cont.*

Broad Categories	Subcategories	Definition	Example(s)
	Regulation	Capacities related to coping with discomforting emotions	Selfsoothes, loves to be cuddled, and really likes deep pressure
	Attachment	Capacities related to bonding, seeking comfort and closeness	Hooked on mama, devoted to brother
	Adaptive behavior *	Capacities related to everyday tasks and activities of daily living (bathing, grooming, toileting, sleep, etc.).	likes to put shoes and socks on by herself
	Eating/feeding	Capacities related to feeding, eating, drinking, and mealtimes	Loves food, not afraid to try different foods
Personality Traits	Happiness	Always happy, joyful, cheerful	Happy child
	Love/loving	Loving and lovable	Very loving
	Kindness	Eager to help and give to others, compassionate	Caring, gentle with younger brother
	Affectionate	Expressing fondness for others	Gives kisses, loves snuggling
	Humor	likes to laugh and bring smiles to others	Jokester, always smiling and laughing
	Sociability	Social engagement and competence	Charming, outgoing, friendly
	Curiosity	Explores and is interested in trying new things	Inquisitive, observant
	Courage	Brave, perseverance, resilient	Fearless, very determined and persistent
	Zest	Approaching life with energy and excitement	Enthusiasm, larger than life, firecracker
	Adaptable	Adapts well, patient, compliant	Mild-tempered, easy going
Interests	Child interests	Interests that capture the child's attention, motivating activities	she loves animals and art, loves to be outside
Caregiving	Confidence with parenting	Responses that show a caregiver's confidence with parenting and knowing their child	we've gotten used to the things he doesn't like; child responds well to structure
	Appreciation for positive change	Responses that show appreciation for child and positive changes	great to have in my life, seems to be progressing

Notes. * Categories based on the Bayley-III domains.

Washington and Alaska Statewide Fetal Alcohol Spectrum Disorder Diagnostic Clinical Networks: Comparison of Three Decades of 4-Digit Code Diagnostic Outcomes and Prenatal Alcohol Exposure Histories

Susan J (Astley) Hemingway[1*], Michael Baldwin[2], Marilyn Pierce-Bulger[3]

[1]Department of Epidemiology and Pediatrics, University of Washington, Seattle, WA 98195, USA; [2]Alaska Mental Health Trust Authority, 3745 Community Park Loop, Anchorage Alaska 99508 USA; [3]Pioneer Consulting LLC, 9089 Nuthatch Place, Anchorage Alaska, 99507 USA

ABSTRACT

Background: Fetal Alcohol Spectrum Disorder (FASD) screening, diagnosis, intervention, research and prevention hinges on establishment of interdisciplinary FASD diagnostic clinics using an evidence-based method of diagnosis. In 1993, Washington State opened the first interdisciplinary FASD diagnostic clinic sponsored by the CDC as a FASD primary prevention study. Clinic data was used to develop the evidence-based FASD 4-Digit Diagnostic Code, paving the way for the clinic's expansion into a Statewide network of FASD diagnostic clinics (Washington Fetal Alcohol Syndrome Diagnostic & Prevention Network), now in its 30th year. Alaska adopted this Washington model in 1999. Both States have also participated in the CDC Pregnancy Risk Assessment Monitoring System and Behavioral Risk Factor Surveillance System since the 1990s. Study objectives were to describe the two Statewide FASD diagnostic networks; graphically compare the 4-Digit-Code FASD diagnoses and Prenatal Alcohol Exposure (PAE) over 2-3 decades and illustrate how network data helped guide FASD public health policies and track successful prevention efforts.

Methods: Retrospective descriptive study.

Results: FASD diagnostic outcomes were similar across 2,532 Washington and 2,469 Alaskan patients. PAE in each State followed similar annual trajectories from 1991-2020. Both States documented significant decreases in FAS and PAE in the 1990s. Clinic data helped guide public health policies.

Conclusions: Both States demonstrated the feasibility and value of establishing Statewide interdisciplinary FASD diagnostic clinical networks using the FASD 4-Digit-Code. Legislative support, centralized data collection, and use of a single, evidence-based FASD diagnostic system have been key to the long-term, ongoing success of these two diagnostic networks.

Keywords: Fetal alcohol spectrum disorder; FASD 4-Digit Diagnostic Code; Statewide interdisciplinary clinical networks; Prenatal alcohol exposure; PRAMS/BRFSS

INTRODUCTION

Fetal Alcohol Spectrum Disorder (FASD) is a spectrum of physical and neurodevelopmental abnormalities caused by prenatal alcohol exposure [1]. Meaningful progress in FASD screening, diagnosis, intervention, surveillance, public health policy, research and ultimately prevention hinges on establishment of interdisciplinary FASD diagnostic clinics using a single evidence-based, comprehensive and reproducible

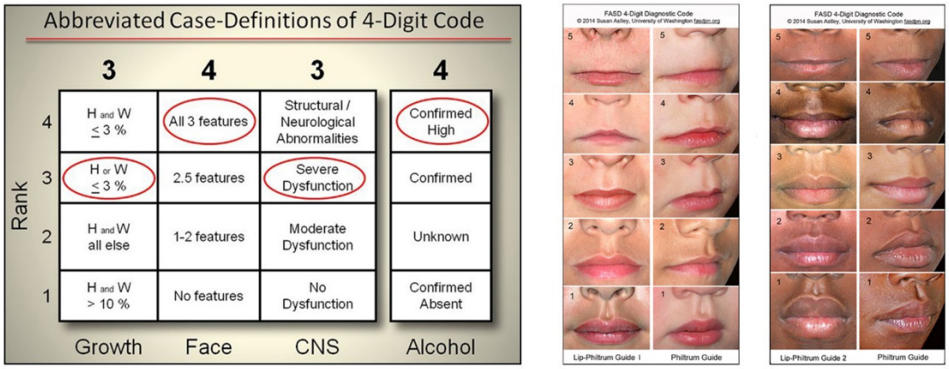
method of diagnosis [2-4]. In 1993, the University of Washington in Seattle Washington (WA) opened the first interdisciplinary FASD diagnostic clinic sponsored by the Center for Disease Control (CDC) as a FASD primary prevention study [2,3,5,6]. Data collected in the clinic was used to develop and validate the FASD 4-Digit Diagnostic Code in 1997 [4,7-9]. Creation of the diagnostic system paved the way for legislative expansion of the clinic through Senate Bill 5688 into a Statewide network of FASD diagnostic clinics, the WA Fetal Alcohol Syndrome Diagnostic & Prevention Network (FASDPN) [10,11]. The WA FASDPN is now in its 30th year of operation. This interdisciplinary Statewide FASD diagnostic system and model was adopted by Alaska (AK) in 1999 and continues to this date [12-14]. The WA interdisciplinary model and 4-Digit Code have been adopted worldwide. Over 1,700 clinicians from 35 countries have completed the FASD 4-Digit Diagnostic Code online course [15,16]. The primary objective of this study was to demonstrate the feasibility and value of establishing long term, Statewide interdisciplinary FASD diagnostic clinics using the FASD 4-Digit Diagnostic Code. To meet this objective:

1. The WA and AK Statewide FASD diagnostic network models are described.
2. The 4-Digit Code FASD diagnostic outcomes and CDC Pregnancy Risk Assessment Monitoring System [17-19] and CDC Behavioral Risk Factor Surveillance System [20,21] prenatal alcohol exposure histories documented over 2-3 decades are graphically summarized.
3. The impact data from these networks have had on helping: A) guide FASD public health policy and B) track successful prevention efforts is illustrated.

MATERIALS AND METHODS

Subjects

The diagnostic outcomes of all individuals (birth through adult) with confirmed prenatal alcohol exposure at any level, evaluated by the WA FASDPN from 1993-2021 (n=2,532) and the AK Department of Health and Social Services (now known as the Department of Health) FASD diagnostic teams from 1999-2021 (n=2,469) are graphically compared in this study. These diagnostic outcomes include 4-Digit Code Diagnostic Categories A-C, E-J as defined in Figure 1 and Table 1. All data was collected with Institutional Human Subjects approval.



4-Digit Code produces 4 Diagnostic Subgroups

Diagnosis		Growth	FAS Face	CNS		Alcohol
1. FAS	Fetal Alcohol Syndrome	growth	face	severe		alc
2. PFAS	Partial FAS		face	severe		alc
3. SE/AE	Static Encephalopathy / Alc Exposed			severe		alc
4. ND/AE	Neurobehavioral Disorder / Alc Exposed				moderate	alc

Figure 1: Abbreviated case-definitions of the FASD 4-digit code. The 4-digit code 3434 is one of 12 codes that fall under the diagnostic category Fetal Alcohol Spectrum (FAS). The 4-digit code produces four diagnostic subgroups broadly under the umbrella of Fetal Alcohol Spectrum Disorder (FASD): FAS (categories A, B), PFAS (category C), SE/AE (categories E-F), and ND/AE (Categories G-H) (Table 1). **Note:** Growth ranks are based on height and weight percentile. The 3 facial features of FAS are palpebral fissure lengths 2 or more Standard Deviation (SDs) below the mean, and a rank 4 or 5 smooth philtrum and thin upper lip using Lip-Philtrum quides 1 or 2. The Central Nervous System (CNS) scale reflects the probability of underlying CNS damage based on structural, neurological, and/or functional evidence. The higher the rank, the stronger the evidence or higher the probability that there is underlying CNS damage. CNS rank 1 (unlikely CNS damage) is selected when there is no evidence of dysfunction. CNS rank 2 (possible damage) is selected when there is moderate dysfunction (1 or 2 domains of brain function 2 or more SDs below the mean or multiple domains 1.5 SDs below the mean). Rank 3 (probable damage) is selected when there is severe dysfunction defined as 3 or more domains of brain function 2 or more SDs below the mean. Rank 4 (definite damage) is selected when structural/neurological abnormalities are present (microcephaly, abnormal Magnetic Resonance Imaging (MRI), etc.). Rank 4 alcohol reflects an exposure pattern consistent with the medical literature placing the fetus at "high risk" (generally high peak blood alcohol concentrations delivered at least weekly in early pregnancy). Rank 3 alcohol reflects a confirmed prenatal alcohol exposure at a level less than rank 4 or at a level that is unknown [7,8].

Table 1: 4-Digit diagnostic codes within each diagnostic category.

Category	Diagnostic name and codes
A	Fetal alcohol syndrome (alcohol exposed)
	2433 2434 2443 2444 3433 3434 3443 3444
	4433 4434 4443 4444
B	Fetal alcohol syndrome (alcohol exposure unknown)
	2432 2442 3432 3442 4432 4442
C	Partial fetal alcohol syndrome (alcohol exposed)
	1333 1334 1343 1344 1433 1434 1443 1444 2333 2334 2343 2344
	2333 2334 2343 2344 3333 3334 3343 3344 4333 4334 4343 4344
E	Sentinel physical finding(s)/static encephalopathy (alcohol exposed)
	3133 3134 3143 3144 3233 3234 3243 3244
	4133 4134 4143 4144 4233 4234 4243 4244
F	Static encephalopathy (alcohol exposed)
	1133 1134 1143 1144 1233 1234 1243 1244
	2133 2134 2143 2144 2233 2234 2243 2244
G	Sentinel physical finding(s)/neurobehavioral disorder (alcohol exposed)
	1323 1324 1423 1424 2323 2324 2423 2424 3123 3124 3223 3224
	3323 3324 3423 3424 4123 4124 4223 4224 4323 4324 4423 4424
H	Neurobehavioral disorder (alcohol exposed)
	1123 1124 1223 1224 2123 2124 2223 2224
I	Sentinel physical finding(s) (alcohol exposed)

J	No physical findings or CNS abnormalities detected (alcohol exposed)
	1113 1114 1213 1214 2113 2114 2213 2214

Note: CNS: Central Nervous System.

FASD 4-Digit Code

All subjects were diagnosed by interdisciplinary teams in WA and AK using a comprehensive, validated diagnostic system called the FASD 4-Digit Code, depicted in Figure 1 and Table 1 [7,8]. Briefly, the 4 digits of the FASD 4-Digit Code reflect the magnitude of expression of the 4 key diagnostic features of FASD, in the following order: 1. growth deficiency, 2. FAS facial phenotype, 3. CNS structural/functional abnormalities, and 4. Prenatal Alcohol Exposure (PAE). The magnitude of expression of each feature is ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong "classic" presence of the FASD feature. Each Likert rank is specifically case defined [7]. 4-Digit Codes range from 1111 to 4444. Each 4-digit diagnostic code falls into 1 of 22 unique clinical diagnostic categories (labeled A through V). Seven of the 22 diagnostic categories (4-Digit Categories A-C and E-H) fall broadly under the umbrella of FASD (A: FAS/ alcohol exposed; B: FAS/alcohol exposure unknown; C: Partial FAS/alcohol exposed; E&F: Static encephalopathy/ alcohol exposed, and G&H: Neurobehavioral disorder/alcohol exposed). Diagnostic categories I and J are also included in this study for they reflect the subset of patients with confirmed PAE that present only with growth deficiency and/or the FAS facial features (I: Sentinel physical findings/alcohol-exposed) or present with normal outcomes (J: No sentinel physical findings or CNS abnormalities/alcohol-exposed). Categories I and J are not considered under the umbrella of FASD in accordance with the FASD 4-Digit Code.

Prenatal alcohol exposure

Measures of prenatal alcohol exposure were obtained from three sources. The first source was each patient's 4-Digit Code prenatal alcohol exposure 4-point Rank documented at the time of their FASD diagnostic evaluation (Figure 1, Table 1) [7,8]. Alcohol exposure histories reported to the clinics typically come from the birth mother, other family members and/or past medical and social service records. The second and third sources of PAE were obtained from two national CDC surveillance systems, the Pregnancy Risk Assessment Monitoring System (PRAMS) and Behavioral Risk Factors Surveillance System (BRFSS) [17 - 21]. The PRAMS and BRFSS surveillance systems document the annual prevalence of alcohol use during pregnancy across representative samples of each State's general population. Over the decades, some of the questions on the PRAMS and BRFSS

surveys changed preventing one from tracking the same alcohol metric across the entire time period 1991-2015. In addition, not all States chose to include the same alcohol metrics in their annual surveys. PRAMS and BRFSS PAE metrics that were available from both States over the same period of years are presented in this study.

Analyses

Descriptive analyses (proportions) were used to graphically summarize the sociodemographics, FASD diagnostic outcomes and reported prenatal alcohol exposures for each State. It was not the intent of this study to hypothesize and empirically assess how exposures and FASD outcomes may differ between the two States or change over time. The FASD diagnostic outcomes are derived from clinical populations that are typically not representative of the general population. For example, hypothetically, if the prevalence of FAS was higher in the WA clinical population than the AK clinical population, that would not necessarily mean WA had a higher prevalence of FAS in its general population. There are many factors that influence which individuals request and receive an FASD diagnosis (access to diagnostic services, knowledge of prenatal alcohol exposure, caregiver willingness to participate in a FASD diagnostic evaluation, medical insurance coverage, etc.). One factor that is not influencing potential contrasts between the WA and AK FASD outcomes is their use of a single FASD diagnostic system, the FASD 4-Digit Code. In contrast to the FASD diagnostic outcomes, the prenatal alcohol exposure data generated by the CDC PRAMS and BRFSS surveillance programs are designed to be representative of each State's general population. The purpose of including these measures of PAE was to provide a context or background from which to qualitatively interpret the WA and AK FASD outcomes, visually compare the drinking patterns between the two States and allow Readers to compare the drinking patterns documented in WA and AK to other States participating in PRAMS and/or BRFSS. Empirically contrasting the WA and AK PRAMS and BRFSS prenatal alcohol exposure patterns would warrant a separate study.

RESULTS

Objective 1: Establishment and description of the WA and AK Statewide FASD diagnostic clinical networks

Washington state: The term FAS was first coined in WA State at the University of Washington in 1973 [22,23]. Over the next 50 years, WA State engaged in an extensive, multifaceted effort to screen, diagnose, treat, track and ultimately prevent FASD. A comprehensive history of these efforts is posted on the WA State FASD website [24]. Although diagnostic services in WA commenced as early as 1973, diagnosis was typically conducted by a geneticist or dysmorphologist relying largely on clinical impression of physical features. In 1993, the University of Washington opened the first interdisciplinary FASD diagnostic clinic sponsored by the CDC as a FASD primary prevention study [2,3,5]. In 1995, the WA Legislature through Senate Bill 5688 expanded the clinic into a Statewide network of FASD diagnostic clinics (Figure 2) led by the core clinical/research/training clinic at the University of Washington in Seattle, WA [11]. Susan J. (Astley) Hemingway, Ph.D., Professor of Epidemiology/Pediatrics, directs the FASDPN. All WA FASDPN clinics use an interdisciplinary approach to diagnosis guided by the FASD 4-Digit Diagnostic Code and submit data to the core clinic at the University of Washington with patient consent and human subject's approval. The interdisciplinary team includes a medical doctor, psychologist, speech language pathologist, occupational therapist, social worker, family advocate and public health professional. All team members complete the FASD 4-Digit Code Online Course [15]. Individuals across the lifespan with a confirmed prenatal alcohol exposure at any level or the full Rank 4 FAS facial phenotype are eligible for an evaluation. A FASD diagnostic evaluation is conducted in a single 4-hour evaluation. In preparation for the evaluation, all birth, medical, school, and social service records are collected on the patient. These records provide important data (growth, medical, neuropsychological test scores, other adverse prenatal/postnatal exposures) that are critical to deriving an accurate FASD diagnosis. On the day of the evaluation, the caregivers participate in a joint interview with the medical doctor and social worker while the patient is assessed by the psychologist, speech-language pathologist and occupational therapist. Standardized neuropsychological assessments are administered to assess all aspects of brain function (cognition, executive function, memory, language, attention, adaptation, motor, sensory, etc.). Height, weight, head circumference and facial features are also measured. The team uses data collected in the clinic as well as the data from past records to derive the FASD 4-Digit Code. They also compose a comprehensive intervention plan addressing medical, behavioral, educational, placement and safety issues. The team shares the diagnosis and intervention plan with the family and submits an 8 to 10-page comprehensive medical summary to the patient's medical record. All phases of data collection and report generation are documented on standardized, electronic templates available on the FASDPN website [25]. The team conducts two diagnostic evaluations per clinic, one in the morning and one in the afternoon. Twenty years of patient surveys confirmed the FASDPN interdisciplinary diagnosis model using the 4-Digit Code affords patients and their families substantial access to interventions that meet their needs across the spectrum of FASD diagnoses [26]. The mission of the FASDPN is prevention of FASD through diagnosis, intervention, screening, surveillance, training, public health policy and research. The WA State FASDPN, now in its 30th year, has achieved each of these missions [27]. The FASDPN has diagnosed over 3,000 patients with PAE across the lifespan. It has also established one of the world's largest clinical/research databases with patient consent, leading to over 100 peer-reviewed publications [28,29]. The WA FASDPN has expanded both nationally and internationally through the training of over 1,700 clinicians in 35 countries. The FASDPN has provided FASD training to over 10,000 WA State community professionals over the 30 years with particular focus on student professionals commencing their careers in public service [30].

Alaska State: Since 1999, the Alaska Department of Health and Social Services (DHSS), now the Alaska Department of Health, has coordinated and funded a Statewide network of community-based FASD diagnostic teams [12]. The number and location of FASD diagnostic teams around the State has varied over time as shown in Figure 2. Originally, 17 teams were trained to serve across the State. In 2023, there are three teams. Diagnosis of FASD is conducted by these interdisciplinary teams using the FASD 4-digit diagnostic code [7]. Team members are trained by completing the FASD 4-Digit code online course [15]. Ideally within this model, an interdisciplinary team of

clinicians (i.e., medical provider, psychologist, speech language pathologist, occupational therapist, and family advocate) is required to diagnose FASD because the damage caused by prenatal alcohol exposure impacts all aspects of an individual's growth and brain development. Challenges with maintaining all these professionals on a team, especially in rural settings, have required flexibility in functioning [12]. In the event a psychologist, speech language pathologist, or occupational therapist is not available, teams have been allowed to use testing and assessment information from professionals with similar assessment skills and from service entities that may be involved with the individual (e.g., school Individualized Education Program (IEP) documents, other private practice professionals' reports, etc.). The expertise of a medical provider is required to assess and interpret the physical and neurological components of the disorder (i.e., growth deficits, facial anomalies, seizure disorders). The expertise of a psychologist, speech language pathologist, and occupational therapist is required to assess the CNS functional component of the disorder as described above. Team members are trained by completing the FASD 4-digit code online course [15]. Over the past 20 years, there have been an estimated 3,000 to 4,000 individuals evaluated by the FASD diagnostic teams; assessment data for about 3,000 of these individuals were reported to the State of Alaska [12].

Objective 2: WA and AK FASD outcomes and prenatal alcohol exposures

Sociodemographics: The distribution of patient age at diagnosis, type of caregiver at diagnosis, sex at birth and race are compared between the 2,469 individuals evaluated in Alaska and the 2,532 individuals evaluated in WA as shown in Figure 3. AK and WA evaluated individuals across the lifespan with the majority between 6.0 and 12.9 years of age. WA evaluated a higher proportion (14.9%) of infant/toddlers (birth to 2.9 years of age) than AK (4.2%). Both States evaluated a comparably higher proportion of males than females. The racial distribution of the patient populations cannot be meaningfully compared between the two States because 53.7% of the patients from Alaska did not have race recorded. Whites appeared to be underrepresented (47.8%) in the clinical population evaluated in the WA FASDPN clinics when compared to the 2020 census for WA (7.7 million total population: White (alone) 77%, American Indian/Alaska Native (alone) 2%, Black (alone) 5%, other (alone) and mixed race 16%). For reference, the 2020 census for AK was as follows: (0.7 million total population: White (alone) 65%, American Indian/Alaska Native (alone) 16%, Black (alone) 4%, other (alone) and mixed race 15%). The majority of patients evaluated in both States were in out-of-home care at the time of diagnosis with only 10.3% and 17.2% still in the care of their birth mother in AK and WA respectively [31].

Figure 2: Geographic distribution of FASD diagnostic services in Washington (WA) and Alaska (AK): Location of Fetal Alcohol Spectrum Disorder (FASD) diagnostic clinics in WA over 30 years. Number of assessments by Behavioral Health Region in AK since 1999 [12].

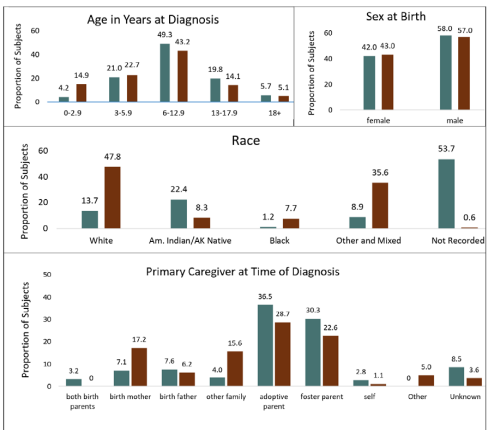

Figure 3: Sociodemographic profiles of the Alaska (AK) and Washington (WA) Fetal Alcohol Spectrum Disorder (FASD) clinical populations: The race categories represent White (alone), American Indian/Alaska Native (alone), Black (alone), other race (alone) which includes Asian, Native Hawaiians and other Pacific Islanders, mixed (2 or more races). Over 95% of the "other and mixed" race category is mixed race. **Note:** ( ) Alaska (n=2,469), ( ) Washington (n=2,532).

Growth, Face, CNS and Alcohol Ranks: The distribution of the 4-digit code ranks for growth, face, CNS and prenatal alcohol exposure for the AK and WA clinical populations are presented in Figure 4. The proportion of patients presenting with moderate and high PAE (ranks 3,4) was near identical between the two States. Roughly 20-30 percent of the AK and WA patients presented with mild to severe growth deficiency (height and/or weight at or below the 10th percentile). The moderate to severe expression of the FAS facial phenotype (ranks 3, 4) was observed in 14 to 30 percent of the two clinical populations. The WA clinical population was more likely to present with moderate CNS dysfunction (52.2% CNS rank 2) than severe CNS dysfunction (22.7% CNS rank 3). In contrast, the AK clinical population was more likely to present with severe CNS dysfunction (47.5% CNS rank 3) than moderate CNS dysfunction (32.5% CNS rank 2). This is explained in part by the higher proportion of infant/toddlers (birth to 3 years of age) attending the WA clinics (14.9%) relative to the AK clinics (4.2%). Infants/toddlers are less likely to meet criteria for severe CNS dysfunction because they are too young to assess higher order brain functions like memory, executive function and language that have not yet fully matured. Severe CNS dysfunction (rank 3) requires 3 or more domains of dysfunction 2 or more SDs below the mean. Moderate CNS dysfunction (rank 2) requires only 1 or 2 domains of dysfunction 2 or more SDs below the mean or multiple domains 1.5 SDs below the mean.

Prenatal alcohol exposure: The annual prevalence of alcohol use during pregnancy appeared fairly comparable between AK and WA over the decades based on data from two Statewide CDC surveillance systems Pregnancy Risk Assessment Monitoring System and Behavioral Risk Factors Surveillance Systems and the 4-Digit Code prenatal alcohol exposure Rank based on records available at the time of the FASD diagnostic evaluations (Figure 4 and 5) [7,8,17-21]. The PRAMS and BRFSS Statewide surveillance systems strive to document alcohol use during pregnancy across representative samples of the general population. The prevalence of any level of alcohol use during pregnancy reported annually to PRAMS by both States decreased from 1993-1998 (Figure 5A). This decrease is discussed in more detail below under objective 3B. The decrease in both States coincided with the establishment of the WA and AK FASD diagnostic and prevention programs that included substantial Statewide efforts to educate the public about the risks of drinking during pregnancy [12,27]. By 1994, both States met or exceeded the healthy people 2000 goal of no more than 10% of women drinking during pregnancy. AK went on to meet the health people 2010 goal of no more than 6% of women drinking during pregnancy from 2000-2010 [32]. WA experienced an increase in drinking from 2000-2010 but remained below the healthy people 2000 goal of 10%. Neither State met the healthy people 2020 goal of 1.7% by 2015. In 2016, the CDC PRAMS survey was revised to document heavy drinking (>8 drinks per week) three months prior to pregnancy, a metric that likely reflects prenatal alcohol exposure before a woman knows she is pregnant (Figure 5B). The prevalence of heavy drinking (>8 drinks per week) three months prior to pregnancy between 2016 and 2020 was comparably stable (2% to 4%) between the two States as documented by PRAMS [17]. The proportion of pregnant women reporting any level of drinking between 2005 and 2021 was higher in WA than AK and closely reflected outcomes documented by PRAMS in the same time period (Figure 5C). The proportion of pregnant women reporting binge drinking (>=4 drinks per occasion) appeared to increase from 1% to 5% between 2006 and 2021 in both States (Figure 5D) [20]. Once again, the data collected by PRAMS and BRFSS appeared roughly comparable across the years. The CDC healthy people 2020 target for pregnant women abstaining from binge drinking in the past 30 days was 100%. Comparable levels of prenatal alcohol exposure were also observed between the WA and AK FASD diagnostic clinic populations. Fifty-one percent of all patients evaluated in each State's FASD diagnostic clinics had documented high prenatal alcohol exposure (4-Digit Code rank 4) (Figure 4). When these patients were sorted by the year they were born (1991 through 2015), the proportion with high rank 4 exposure within each birth cohort was comparable between both States, fluctuating between 45% to 55%. (Figure 5E).

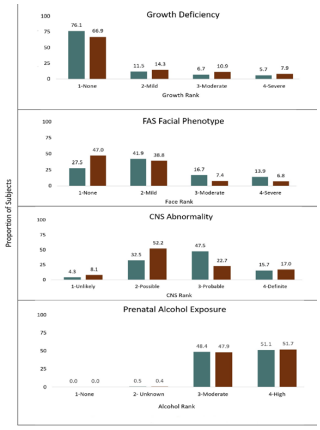

Figure 4: Distribution of growth, face, brain and alcohol ranks for Alaska (AK) and Washington (WA): Distribution of the 4-digit code ranks for growth, face, Central Nervous System (CNS) and prenatal alcohol exposure are compared between the 2,469 individuals diagnosed in Alaska and the 2,532 individuals diagnosed in WA. **Note:** ( ) Alaska, ( ) Washington.

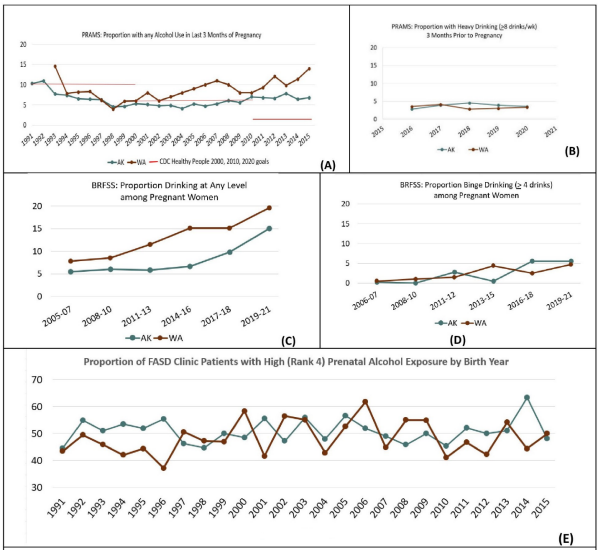

Figure 5: Prevalence of reported maternal drinking during pregnancy in Alaska (AK) and Washington (WA): Proportion of pregnancies in AK and WA with A, B, C, D, E. **Note:** ( ) AK, ( ) WK; (A) any level of alcohol use in the last 3 months of pregnancy, (B) heavy drinking (>=8 drinks per week) 3 months prior to pregnancy, (C) Any level of drinking while pregnant, (D) binge level drinking (>=4 drinks/occasion) while pregnant, (E) Proportion of patients evaluated in the WA and AK clinics with high (4-Digit Code Rank 4) prenatal alcohol exposure sorted by birth cohort. Red lines reflect Center for Disease Control (CDC) Healthy People 2000 (10%), 2010 (6%), and 2020 (1.7%) goals for the proportion of pregnant women reporting alcohol use. Over the decades, the Pregnancy Risk Assessment Monitoring System (PRAMS) and Behavioral Risk Factors Surveillance System (BRFSS) questionnaires have been updated/revised, thus comparable fields of data are not always available across all years [18,19,21,32,50,51].

FASD diagnostic outcomes by age: FASD diagnostic outcomes by age group for WA and AK are presented in Figure 6. The proportion of patients with FAS appears comparable between WA and AK and comparable between each age group ranging from 2.0% to 8.3%. AK documented a higher proportion of PFAS (15% to 24%) across all age groups relative to WA (4% to 6%). Both States documented a higher proportion of ND/AE than SE/AE among young patients and a higher proportion of SE/AE than ND/AE among older patients. This would be expected since patients under 8-9 years of age are too young to assess higher order brain functions like memory, executive function and language that have not yet fully matured. A diagnosis of Static Encephalopathy/Alcohol-Exposed (SE/AE) requires standardized psychometric evidence of three or more domains of brain function, 2 or more Standard Deviations (SDs) below the mean. In contrast, a diagnosis of Neurobehavioral Disorder/Alcohol-Exposed (ND/AE) requires 1 to 2 domains of brain function 2 SDs below the mean or multiple domains 1.5 SDs below the mean.

FASD diagnostic outcomes by race: FASD diagnostic outcomes by race for WA and AK are presented in Figure 7. The prevalence of FASD diagnostic outcomes appeared largely comparable across the different races within each State.

Distribution of FASD diagnoses by year: The distribution of FASD diagnoses by year for WA and AK are presented in Figure 8. The distribution of FASD diagnoses remained relatively similar from year to year within each State despite the fact that the number of FASD clinics varied annually as did the clinicians providing the diagnostic services. AK observed a higher prevalence of PFAS and lower prevalence of ND/AE than WA. The cumulative proportion of patients with the most severe outcomes (FAS, PFAS and SE/AE) hovered around 60% annually in AK compared to 40% annually in WA.

Objective 3A: Guiding public health policy and legislation to support individuals with FASD

Data collected by the WA FASDPN was instrumental in helping guide public health policies to better meet the needs of individuals with FASD and their families. AK also implemented numerous public health policies over the decades that together, with the establishment of their FASD diagnostic clinics, helped meet the needs of individuals impacted by FASD. Below are a few examples of these policies and legislation. More comprehensive summaries are available from, the Alaska Mental Health Trust Authority and the Alaskan UAA College of Health [12,13,27].

Washington State:

- 1997: Expansion of the CDC-sponsored University of Washington FASD interdisciplinary diagnostic clinic into the Statewide network of clinics (FASDPN) through Substitute Senate Bill 5688 [11]. The WA FASDPN has been funded by the WA State Legislature for 30 consecutive years. The Senate Bill also established the WA FASD Interagency Workgroup ensuring coordination of FASD programs across the Department of Social & Health Services, Superintendent of Public Instruction, Department of Corrections and Department of Health. Senate Bill 5688 required the core clinic at the University

of Washington to collect data from all FASDPN network clinics and share an annual report with the above-named State departments summarizing the demand for diagnostic services, the ability to meet the demand and the PAE and FASD profiles of the patients served. These outcomes are also shared in aggregate, open-access form via our Tableau interactive dashboards [28].

- 1997-2009: Establishment of a Statewide evidence-based FASD prevention program (Parent-Child Assistance Program), evidence-based FASD intervention program (Families Moving Forward) and caregiver advocacy program (FASD Focus NW) [33-35].
- 2001: WA State law requiring warning signs from the Liquor Control Board at all points-of-purchase for alcohol warning against the possible danger of birth defects which may be caused by consumption of alcohol during pregnancy Washington Administrative Code 314-11-060 [36].
- 2014: Comprehensive report to the WA State Legislature on achievements, current challenges and recommended solutions to screen, diagnose, treat and prevent FASD [27].
- 2015: Acceptance of FASD as a qualifying condition for developmental disability assistance [37].
- 2022: Elimination of the use of IQ scores when determining eligibility for developmental disability assistance. WA Second Substitute House Bill 2008 [38].
- 2023: An act relating to expanding prevention services, diagnoses, treatment, and support for prenatal substance exposure including prenatal alcohol exposure. WA Second Substitute House Bill 1168 [39].

Alaska State:

- 1999: Alaska Senator Ted Stevens, Chairman of the Senate Appropriations Committee added $29 million into the federal budget to target FASD in Alaska for five years. A massive diagnostic effort began in 2000. The State created FASD diagnostic teams- from Sitka to Barrow, Fairbanks to Bethel to diagnose children with FASD. Seventeen were funded [14].
- 2001: Alaska Statute requiring bars, liquor stores and restaurants to display 11-by-14-inch signs that drinking while pregnant can lead to birth defects [40].
- 2012: The Alaska State Legislature though Senate Bill 151 made an FASD diagnosis a mitigating circumstance to be considered in sentencing for felony level criminal offenses through [41].
- 2012: The Alaska State Legislature permanently recognized September 9 as FASD Awareness Day in Alaska through Senate Bill 127. September 9 is recognized worldwide as FASD Awareness Day [42].
- 2018: Alaska FASD Strategic Plan 2017-2022. Governor's Council on Disabilities and Special Education (January 29, 2018). Included in the report is a detailed history of FASD efforts in Alaska from the 1970s through 2022 [14].
- 2020: Alaska FASD Diagnostic Team Data Analysis, Policy and Prevention Recommendations prepared for the Alaska Mental Health Trust Authority [12].

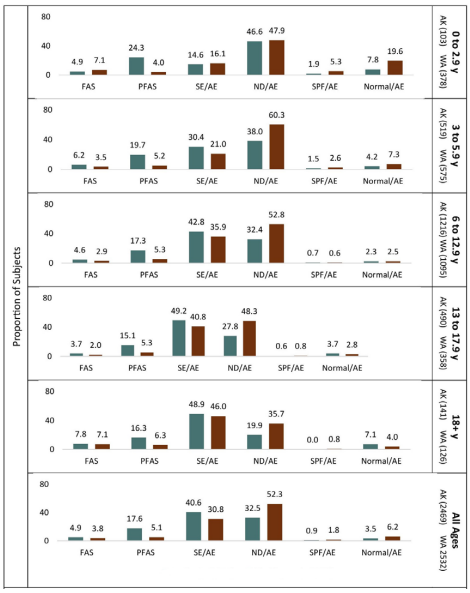

Figure 6: Alaska (AK) and Washington (WA) Fetal Alcohol Spectrum Disorder (FASD) diagnostic profiles by age group. The proportion of patients with Fetal Alcohol Spectrum (FAS) appears clinically comparable between AK and WA across all age groups. **Note:** (■) Alaska (n=2,469), (■) Washington (n=2,532). AK documented a higher proportion of PFAS (15% to 24%) across all age groups relative to WA (4% to 6%). Both States documented a higher proportion of Neurobehavioral Disorder (ND)/ Alcohol-Exposed (AE) than Static Encephalopathy /Alcohol-Exposed (SE)/AE among young patients and a higher proportion of SE/AE than ND/AE among older patients. This would be exp ected since patients under 8 years of age are too young to assess higher order brain functions like memory, executive function and language that have not yet matured.

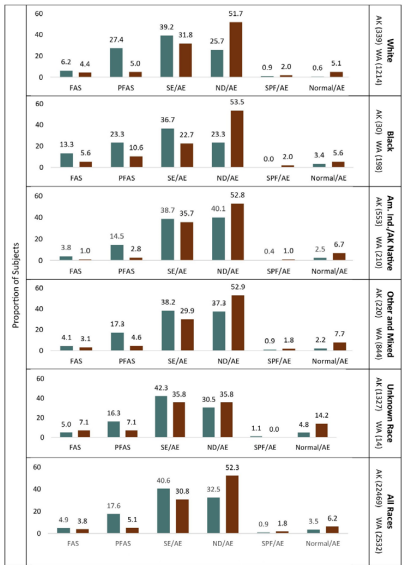

Figure 7: Alaska (AK) and Washington (WA) Fetal Alcohol Spectrum Disorder (FASD) diagnostic outcomes by race. The prevalence of FASD diagnostic outcomes appears comparable across all races within each State. **Note:** ( ) Alaska (n=2,469), ( ) Washington (n=2,532).

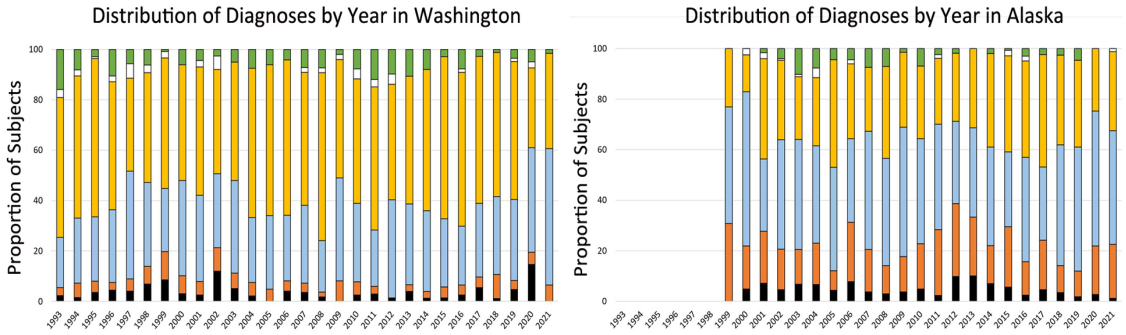

Figure 8: Distribution of Fetal Alcohol Spectrum Disorder (FASD) diagnoses by year of diagnosis in Washington and Alaska. The distribution of Fetal Alcohol Spectrum Disorder (FASD) diagnoses remained relatively similar from year to year within each State despite the fact the number of FASD clinics varied annually over the decades as did the clinicians providing the diagnostic services. Washington (n=2,532); Alaska (n=2,469). **Note:** ( ) Fetal Alcohol Spectrum (FAS), ( ) Partial Fetal Alcohol Spectrum (PFAS), ( ) Static Encephalopathy (SE)/ Alcohol-Exposed (AE), ( ) Neurobehavioral Disorder (ND)/AE), ( ) Sentinel Findings ( ) Normal/AE.

Objective 3B: Tracking successful prevention efforts

Washington State: To assess the effectiveness of fetal alcohol syndrome prevention efforts, one must be able to estimate accurately the prevalence of fetal alcohol syndrome over time in population-based samples. With the establishment of the WA FASDPN clinics, the development of the FAS Facial Photographic Analysis Software, the creation of the FASD 4-Digit Diagnostic Code, the establishment of the Foster Care Fetal Alcohol Syndrome Screening Program, and the collection of PRAMS data on maternal use of alcohol during pregnancy, the tools, methods and infrastructure for assessing the effectiveness of fetal alcohol syndrome primary prevention efforts in Washington State were in place [7,17-19,43,44]. A cross-sectional study was conducted in 2004 to determine whether the prevalence of fetal alcohol syndrome among children in a foster care population, born between 1993 and 1998, decreased with the documented decrease in prevalence of maternal use of

alcohol during pregnancy from 1993 and 1998 in Washington State documented through PRAMS [45]. The prevalence of maternal drinking during pregnancy in Washington State declined significantly ($p<0.001$) from 1993 to 1998 as did the prevalence of fetal alcohol syndrome among foster children born 1993-98 ($p<0.03$). These observations support the likelihood that FAS prevention efforts in Washington State were working successfully. Fundamental to WA State's success in creating and implementing FASD screening, diagnostic, intervention and prevention tools and programs over the decades is the ongoing support received from the State Legislature. In April 2023, the Governor of WA signed House Bill 1168, an act relating to providing prevention services, diagnoses, treatment and support for prenatal substance exposure [39]. This bill compliments and expands Senate Bill 5688, enacted in 1995 supporting efforts directed at the early identification of and intervention into the problems associated with fetal alcohol exposure through the creation of the Fetal Alcohol Syndrome Diagnostic and Prevention Network [11].

Alaska State: In a 2009 CDC-sponsored study, medical record abstractions were completed for all potential FAS cases reported to the Alaska Birth Defects Registry for children who were at least 6 years of age (birth years 1996-2002) [46]. Data from these abstractions was linked to birth certificates to determine FAS prevalence estimates. From 1996 to 2002, Alaska experienced a 32% decrease in FAS birth prevalence from 19.9 to 13.5 per 10,000 live births ($p=0.05$). Decline in the overall FAS prevalence was limited entirely to Alaska Native children who experienced a 49% decline from 63.1 to 32.4 per 10,000 live births ($p=0.003$). The prevalence among non-Native children increased 64% from 3.7 to 6.1 per 10,000 live births ($p=0.18$). The observed decline occurred in association with several prevention activities: development and sustainability of a network of community-based FASD Diagnostic Teams; development of university-level FASD curricula and Statewide training programs for educators and providers; a Statewide multi-media public awareness campaign; and increased substance use screening in primary care settings. The temporal association of declining FAS prevalence with prevention activities suggests that the interventions played a role.

DISCUSSION

WA and AK have demonstrated the feasibility of implementing the 4-Digit Code and the value of establishing longstanding, Statewide, interdisciplinary FASD diagnostic clinical networks. FASD diagnostic clinics and the databases derived from them serve as the foundation for FASD screening, diagnosis, intervention, training, research, public health policy and prevention [2,3,7-9,12,13,15,16,26-28,30,34,37,39,44-46,48,49,52-54]. Ongoing legislative support, centralized data collection, and use of an evidence-based FASD diagnostic system with online training continue to be key to the ongoing success of these two networks [7,15]. Interdisciplinary FASD diagnostic clinics using the 4-Digit Code have been established worldwide. Their FASD diagnostic profiles are compared and contrasted on our Tableau interactive dashboards [28]. Although AK and WA have maintained Statewide FASD diagnostic clinics for 20-30 years respectively, establishing and maintaining interdisciplinary FASD diagnostic teams are not without challenges. Briefly, challenges include geographic reach, training and turnover of professionals on FASD diagnostic teams, stigma related to those who consume alcohol during pregnancy and their offspring, funding, and community education/readiness. Utilizing telemedicine platforms like zoom proved indispensable during the COVID pandemic for remotely connecting clinicians and patients with the core interdisciplinary teams when in-person attendance was not possible. These platforms continue to be useful to address some of the challenges faced in rural communities. Having access to self-paced online diagnostic training programs like the FASD 4-Digit Code Online Course greatly facilitated training of new clinical team members [15].

To enhance interest and education related to FASD the University of Alaska College of Health in Anchorage established a 3-credit elective asynchronous course in 2021 for allied health and related professional students entitled Interdisciplinary Approaches to Fetal Alcohol Spectrum Disorders (FASD): Best Practices in Alaska [49]. For comprehensive reviews of WA and AK FASD diagnostic and prevention efforts, challenges, accomplishments and programmatic recommendations, please see the 2014 comprehensive report to the WA State Legislature on achievements, current challenges and recommended solutions to screen, diagnose, treat and prevent FASD prepared by the WA FASD Interagency Work Group , the 2020 Alaska FASD Diagnostic Team Data Analysis, Policy & Prevention Recommendations and the 2021 Alaska FASD Data Systems Development: Gaps, Opportunities & Recommendations prepared for the Alaska Mental Health Trust Authority [12,13,27].

CONCLUSION

WA and AK have demonstrated the feasibility and value of establishing statewide interdisciplinary FASD diagnostic clinical networks using the FASD 4-Digit-Code. Legislative support, centralized data collection, and use of a single, evidence-based FASD diagnostic system with online training have been key to the long-term, ongoing success of these two diagnostic networks. FASD diagnostic outcomes were similar across the 2,469 Alaskan and 2,532 Washington patients diagnosed over 20 and 30 years respectively. Alcohol use reported by pregnant women in WA and AK, as documented by the CDC PRAMS and BRFSS population-based surveillance systems, followed similar annual trajectories from 1991-2020.

Primary prevention of FASD remains the ultimate goal. To assess the effectiveness of FAS prevention efforts, one must be able to accurately estimate the prevalence of FAS over time in population-based samples. With the establishment of the WA FASDPN clinics, the development of the FAS Facial Photographic Analysis Software, the creation of the FASD 4-Digit Diagnostic Code, the establishment of the Foster Care Fetal Alcohol Syndrome Screening Program and the collection of PRAMS data on maternal use of alcohol during pregnancy, the tools, methods and infrastructure for assessing the effectiveness of FAS primary prevention efforts in Washington State were in place [7,17-19,27,33,43,44]. As early as the 19 90s, WA documented significant decreases in the prevalence of FAS and PAE. AK also documented a significant decline in the birth prevalence of FAS in the 1990s using medical record review of all cases reported to the Alaska Birth Defects Registry. The decline in FAS occurred in association with the establishment of their FASD diagnostic clinics, statewide training of educators and clinicians and public awareness campaigns.

Establishing and maintaining FASD diagnostic and prevention networks are not without challenges. The benefits to families impacted by FASD, however, far outweigh the challenges.

ACKNOWLEDGEMENTS

The creation of the WA and AK Statewide clinical datasets would not have been possible without the extensive clinical efforts and support of the interdisciplinary diagnostic teams and community health/social service agencies in WA and AK over the decades. Special thanks are extended to the patients and their families for their benevolent contributions to these public health efforts to help all families impacted by FASD.

Abstract

Background: Narrative discourse, or storytelling, is used in daily conversation and requires higher-level language and social communication skills that are not always captured by standardised assessments of language. Many autistic individuals and individuals with fetal alcohol spectrum disorders (FASD) have difficulties with both social communication and language skills, and narrative discourse analysis offers an ecologically relevant approach to assessing those challenges.

Aims: This study investigated narrative discourse in individuals with autism and FASD, as well as an age- and sex-matched comparison group.

Methods and Procedures: Narratives from 45 adolescents and adults, 11 with autism, 11 with FASD and 23 age- and sex-matched comparison participants were elicited using a wordless storybook. They were then transcribed orthographically, formatted to the Systematic Analyses of Language Transcript (SALT) convention and scored based on the SALT Narrative Scoring Scheme (NSS), a standardised language analysis protocol. In addition to the NSS total score, which assesses the overall structure and cohesion of the narratives produced, local and global measures of language ability were also employed. The local language measures included the number of mental state and temporal relation terms produced, while the global language measures included mean length of utterance, total different words, total words, total utterances, rate of speech, the number of mazes (e.g., repetitions, 'um', 'uh' or self-corrections) per total word and the NSS total score.

Outcomes and Results: Using the SALT *Language Sample Analysis* tool, our results revealed that on global language measures, group differences were found on rate of speech, number of mazes per total words and the description of conflict/resolution in the narratives produced. The autism group produced significantly more mazes per total word and scored higher on the NSS conflict/resolution category score compared to the FASD and comparison groups. Both the autism and FASD groups spoke at a lower rate than the comparison group. On local language measures of narrative production, all groups were comparable, on average.

Conclusions and Implications: While many aspects of narrative discourse in the autism and FASD groups were similar to each other and to the comparison group, we observed group differences on global measures of narrative production and significant individual variability within groups, suggesting that narrative abilities considered at an individual level may provide important clinical information for intervention planning. Future research should also consider additional variables that influence narrative discourse, such as motivation, distractibility or decision-making of individual participants.

KEYWORDS
autism, FASD, language ability, narrative ability, narrative storytelling

What this paper adds

What is already known on the subject

- Narrative discourse, or storytelling, is used in daily conversational interactions and reveals higher-level language skills that may not be well captured by standardised assessments of language. Many autistic individuals and individuals with fetal alcohol spectrum disorders (FASD) show difficulty with pragmatic and expressive language skills.

What this paper adds to existing knowledge

- We found that many aspects of the narratives produced by the adolescents/young adults in the autism and FASD groups were comparable to each other and to the neurotypical group. However, the groups differed on three global measures of narrative production: rate of speech, number of mazes per total words and the description of conflict/resolution in the narratives produced. Also, significant variability was observed within groups, suggesting that narrative abilities should be considered at an individual level as opposed to their clinical groups.

What are the potential or actual clinical implications of this work?

- This study showed that narrative discourse is an appropriate task that can be added to routine clinical assessments of language abilities in autistic adolescents/young adults as well as those with FASD or typical development and has the potential to reveal higher-level, real-world language skills. An important clinical implication of this study is that narrative language abilities should be considered at an individual level and individual-tailored interventions based on ability level due to the variability observed across individuals.

INTRODUCTION

Narrative discourse, or storytelling, is a form of communication aimed at constructing a shared experience between the storyteller and listeners. As such, it is important for making social-emotional connections with others, for sharing personal perspectives and interests, and for building a common ground of shared knowledge in a

social network. Successfully constructing these shared experiences requires speakers to have adequate language and social communication skills. As a result, narrative discourse is often challenging for neurodiverse individuals who have impairment in social communication and language, such as those with autism (e.g., Barnes & Baron-Cohen, 2012; Colle et al., 2008; Losh & Gordon, 2014) and fetal alcohol spectrum disorders (FASD; Coggins et al., 2007; Ganthous et al., 2017).

Autism is characterised by persistent deficits in social communication functioning accompanied by restricted, repetitive patterns of behaviour, interests or activities (American Psychiatric Association, 2013) and language impairment affects up to 63% of autistic individuals (Levy et al., 2010). It is estimated that 1 in 100 people around the world are diagnosed with autism with variability across sociodemographic groups (Zeidan et al., 2022). In the United States, the prevalence is estimated to be 1 in 36 children (Maenner et al., 2023).

Fetal Alcohol Syndrome (FAS) is a permanent birth defect caused by exposure to the teratogen ethyl alcohol during pregnancy. FAS is characterised by significant central nervous system (CNS) abnormalities, growth deficiency and a unique cluster of three minor facial anomalies—small eyes, thin upper lip and a flat philtrum (Astley, 2004). Most children impaired by prenatal alcohol exposure will not receive a diagnosis of FAS (Astley, 2010) and will instead receive a diagnosis of one of a variety of FASD diagnoses with FAS representing the most severe end of this spectrum. If the degree of CNS dysfunction is used to characterise FASD diagnoses, the term 'Static Encephalopathy, Alcohol Exposed (SE/AE)',—can be used to indicate a significant CNS dysfunction in the context of prenatal alcohol exposure, and the term 'Neurobehavioural Disorder, Alcohol Exposed (NB/AE)'—to indicate a mild-to-moderate CNS dysfunction in the context of prenatal alcohol exposure (Astley, 2004; see also Cook et al., 2016; Hoyme et al., 2016 for examples of other diagnostic nomenclature designed to capture the range of disorders falling under the umbrella of FASD). According to Lange et al.' meta-analysis of 24 unique studies (2017), approximately 8 in 1000 children and youth in the general population worldwide have FASD. In the United States, an estimated 1%–5% of the population have FASD (Center for Disease Control and Prevention, 2023). Past studies of FASD have shown difficulty with both expressive and receptive language skills (Aragón et al., 2008; McGee et al., 2009). Indeed, language impairment is one of the more commonly reported outcomes in FASD. For example, Hemingway et al. (2019) found that among 402 individuals with FASD 6 years of age and older, more than three-quarters of individuals with more severe FASD diagnoses (FAS and static encephalopathy) and a quarter of individuals with milder diagnoses (neurobehavioural disorder) presented with significant impairment in language. Many individuals with FASD also struggle with social communication and interpersonal communication (Coggins et al., 2003; Terband et al., 2018; Thorne & Coggins, 2016).

Social communication is typically measured through two approaches: standardised assessment of language use for social purposes (e.g., Test of Pragmatic Language; Phelps-Terasaki & Phelps-Gunn, 2007) and parent/caregiver report. However, prior studies have identified limitations with these assessment methods such as difficulty in using standardised testing for children with autism due to lack of motivation (Koegel et al., 1997) or the presence of bias in caregivers' reports of the child's language (Tomasello & Mervis, 1994). Thus, narrative discourse offers an ecologically valid method of assessing real-world language skills and social communication in autistic individuals (e.g., Levinson et al., 2020) and individuals with FASD (e.g., Proven et al., 2014; Thorne, 2017).

Narrative abilities in autistic individuals

Past studies of language abilities in autistic individuals show that the use of natural language samples provides additional information beyond standardised language assessments (Barokova & Tager-Flusberg, 2020; Charman, 2004; King & Palikara, 2018; Manolitsi & Botting, 2011; Peristeri et al., 2017; Tager-Flusberg et al., 2009). For instance, Manolisi and Botting (2011) found that although autistic children did not show expressive language deficits on standardised tests, narrative assessment revealed difficulty with storytelling and referencing. King and Palikara (2018) further note that despite the fact that many autistic adolescents may score within the average range on standardised assessments, difficulty with higher-level language skills may not be revealed by these assessments. Similarly, as standardised testing often misses important differences that are evident in naturalistic settings, Lee et al. (2018) found the use of computational linguistics in analysing narrative skills to be effective in distinguishing adolescents and adults with autism from comparison participants without autism.

In past studies of narrative discourse, autistic individuals were found to produce shorter and less complex sentences and stories (Banney et al., 2015; Eigsti et al., 2007; King et al., 2014; Tager-Flusberg & Sullivan, 1995), score lower on local language measures by

producing fewer personal pronouns, temporal expressions, referential expressions (Colle et al., 2008; King et al., 2014; Novogrodsky, 2013), mental states and causal statements (Siller et al., 2014; Tager-Flusberg & Sullivan, 1995). Some autistic individuals were also found to produce stories that were biased toward local details (Barnes & Baron-Cohen, 2012). For example, during a narrative task describing a film, autistic participants were more likely to describe the details in a visual scene, such as a computer in the background instead of the overall setting such as a hospital or an office building, as was typically described by the control group (Barnes & Baron-Cohen, 2012). These global details are needed to capture the 'big picture' of the story, which provides meaningful answers to each story element. Thus, autistic individuals may provide details about the setting or characters but may leave out significant information that helps a listener glean meaning from the information (Barnes & Baron-Cohen, 2012).

However, there are still many aspects of narrative abilities in autistic individuals that are not well understood due to inconsistent findings in past literature. Past research has mostly focused on autistic children and adolescents with fewer studies conducted in adults (e.g., Colle et al., 2008; Geelhand et al., 2020; McCabe et al., 2013). Furthermore, many past studies on narrative discourse have included heterogeneous samples, including autistic individuals across a wide range of age, intellectual and/or language abilities. There have been several reports that when groups are matched on age and cognitive abilities, fewer differences between narratives produced by autistic individuals and neurotypical comparisons are observed (e.g., Colle et al., 2008; Diehl et al., 2006; Losh & Capps, 2003; Losh & Gordon, 2014; Tager-Flusberg & Sullivan, 1995). Moreover, while some past literature reports shorter and less complex narratives (Banney et al., 2015; Tager-Flusberg, 1995), other studies find that the narratives produced by autistic individuals are comparable to comparison participants (Losh & Capps, 2003; McCabe et al., 2013; Sah & Torng, 2015). Similarly, while some past studies report that narratives produced by autistic individuals have fewer cohesive devices (Hilvert et al., 2016), others found minimal to no differences in cohesion compared to a matched control group (Kauschke et al., 2016). Colle et al. (2008) found that pragmatic skills in highly verbal autistic adults did not differ from age-, sex- and IQ-matched comparison groups; however, a narrative discourse task revealed specific challenges in autistic individuals such as using fewer personal pronouns, temporal expressions and referential expressions. Many of these previous studies; however, had small sample sizes and differences in how the study participants were matched to the autistic group, which further complicates the picture (Harvey et al., 2023).

Narrative abilities in individuals with fetal alcohol spectrum disorders

Although there are comparatively more studies on narrative discourse in autistic individuals, several studies have similarly explored the utility of narrative discourse as a language assessment method in individuals with FASD (e.g., Thorne, 2017; Thorne et al., 2007; Vega-Rodríguez et al., 2020). Thorne et al. (2007) analysed stories produced by children 8–11 years of age with FASD for semantic elaboration and reference strategy and found that the rate of ambiguous nominal reference was a marker that distinguished children with FASD from age-matched children without FASD. This finding indicated that errors in referential cohesion, which refers to the failure to introduce and maintain references in an organised way that allows the listener to recognise references and follow the story, may be harder for neurodiverse individuals. In addition to referential cohesion, a study by Ganthous et al. (2017) found difficulties with both global and local measures of narratives, including managing structural elements of the story as well as the ability to use diverse vocabulary, to produce appropriately complex sentences. Difficulty avoiding grammatical errors during narrative production may also be common in FASD (Thorne, 2017).

Present study

Since prior studies have noted difficulties in language and social communication for both individuals with FASD and autism (Bishop et al., 2007; Stevens et al., 2013), the approach taken in the current study is to compare the narrative discourse of adolescents and adults across the two groups, as well as an age- and sex-matched comparison group, to better understand the relationship between narrative discourse and language ability across these three groups. With the limited number of studies available, there is a need for more research on narrative discourse in individuals with FASD. Moreover, while there are numerous studies demonstrating difficulty producing cohesive narratives in autistic children, fewer have included adolescents or adults (Beaumont & Newcombe, 2006; Colle et al., 2008; Geelhand et al., 2020). Thus, the specific goal of the present study is to characterise the similarities and differences in the narrative discourse between adolescents and adults from autism, FASD, and neurotypical groups.

We adopted the *Systemic Analysis of Language Transcript* (SALT) convention for the narrative analysis (Miller & Iglesias, 2020) and the Narrative Scoring Scheme (NSS). The NSS total score is meant to serve as an overall assessment of an individual's ability to produce a structurally sound and coherent narrative with a scoring rubric of

seven categories: introduction, character development, mental states, referencing, conflict/resolution, cohesion and conclusion (see Methods section for further details). The SALT software and language analysis approach standardises the process of transcribing and analysing language samples, allowing for comparison to past studies. Besides the NSS total score, SALT includes two categories of measures: local and global. The local aspect of a narrative demonstrates the speaker's ability to integrate and form cohesive connections at the utterance level (within and across sentences) while the global aspects of a narrative demonstrate the speaker's general facility with language across the length of the narrative. Following SALT conventions, the local measures employed in this study include the use of temporal relation and mental state words. The global measures include the mean length of utterance, semantic measures of the number of used word roots, length of narrative (total words), the total number of utterances produced, rate of speech, mazes per total words as well the NSS total score for each story (Miller & Iglesias, 2020). All variables were measured using SALT's built-in tool—*Language Sample Analysis*, that provided a quick and accessible process for transcribing, coding and analysing the language samples. With detailed protocols, minimal coding and utilising computer analyses, SALT standardised the process of analysing language samples, thus giving consistent and reliable measures of narrative language (see Miller et al., 2015).

The overarching question addressed in this study is whether there are differences in the local and global structure of narratives produced by participants in the autism, FASD and comparison groups. Using a matched pairs research design in combination with random and opportunity sampling techniques to recruit age- and sex-matched comparison participants to the autism and FASD group, we asked the following questions:

Question 1: Are there group differences between local structure variables? To address this question, we quantified the number of temporal relations and mental states produced and compared them across autism, FASD, and comparison groups. Based on findings from prior studies, we hypothesised that participants with autism and FASD would perform worse on the local measures in comparison to the group. We further hypothesised that the FASD group would score higher on the local measures than the autism group.

Question 2. Are there group differences between global structure variables? To address this question, we quantified the global features, including mean length of utterance, total different words, total words, total utterances, rate of speech, number of mazes (e.g., repetitions, 'um', 'uh' or self-corrections) per total words and NSS total score and compared across autism, FASD and comparison groups. Despite the inconsistent findings from the literature, based on studies that reported comparable narrative ability of global structures, we hypothesised that participants with autism and FASD would perform similarly on all measures to the neurotypical comparison group.

Question 3. What is the relationship between local and global features of narratives produced? To address this question, we assessed the relationship between each local and global feature.

Question 4. What is the relationship between global features? To address this question, we assessed the relationship between each global feature.

METHODS

Participants

Forty-six individuals participated in the study from three groups: individuals with autism ($n = 12$), individuals with FASD ($n = 11$) and a comparison group ($n = 23$) that were age- and sex- matched to autism and FASD groups (see Table 1 for breakdown of demographic information by groups). Data from one autistic participant was not usable due to poor audio recording quality, resulting in 11 autistic participants being included in the narrative analysis.

Autism group

Twelve participants diagnosed with autism were recruited from a larger longitudinal study of preschool and early school age development conducted at a large university. The original cohort consisted of 72 autistic children initially recruited between 3 and 4 years of age via advertisements in the local community including parent groups, hospital clinics, the University of Washington Autism Center and the University of Washington Infant and Child

TABLE 1 Sample demographic information of autism, FASD and comparison groups.

	Autism	FASD	Comparison

Abbreviation: FASD, fetal alcohol spectrum disorders.

Subject Pool (see Dawson et al., 2004 for more details). Diagnoses of autism, according to criteria from the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV; American Psychiatric Association, 1994), were made at 3 years of age by a licensed clinical psychologist or supervised graduate student using: (1) the Autism Diagnostic Interview-Revised (Lord et al., 1994), (2) the Autism Diagnostic Observation Schedule-Generic (ADOS-G; Lord et al., 2000), (3) medical and family history, (4) cognitive test scores and (5) clinical observation and judgement (see Dawson et al., 2004; Emmons et al., 2021 for further details). These participants were evaluated again at 6, 9 and 13–15 years of age. Specific inclusion criteria for this present study included passing an audiometric screening for clinically normal hearing thresholds, being able to speak in three-word phrases, IQ > 80 and having no other health or developmental concerns. Normal hearing is an important criterion since autistic individuals have a higher incidence of hearing loss (e.g., Rosenhall et al., 1999; Szymanski et al., 2012), which could also affect language abilities. Forty-six participants from the original cohort were re-contacted and invited to participate in this current study. The remaining 26 were not contacted because they had been randomly recruited for another study. Of the 46 participants contacted, four had moved out of state, two were not interested in participating, one could not be scheduled, 25 did not respond to phone calls or emails and two did not meet our eligibility criteria of being able to speak in three-word phrases. Twelve autistic participants from the original cohort were enrolled in this study and tested at ages 21–23 years of age (see Table 1 for sample demographic information).

FASD group

Eleven participants diagnosed with FASD were recruited from the Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network, a database of individuals who have received assessments for FASD. Prenatal alcohol exposure was confirmed through (1) direct observation of drinking, (2) lab tests (blood alcohol) during pregnancy or delivery or (3) full face of FAS. During routine clinic visits, participants were provided with information about the current research study and given the option to participate, if interested. All participants were diagnosed using the FASD 4-Digit Diagnostic Code, which is an interdisciplinary approach to diagnose the full spectrum of outcomes guided by the magnitude of expression of the four features of FAS: growth deficiency, FAS facial phenotype, CNS structural/functional abnormalities and prenatal alcohol exposure (Astley, 2004; see McLaughlin et al., 2019 for more details). There are four diagnoses that fall under the umbrella of FASD: FAS, Partial FAS (PFAS), SE/AE, ND/AE. No participants in the FASD group received an ADOS autism classification. As with

the autism group, inclusion criteria for the FASD group included passing an audiometric screening for clinically normal hearing thresholds, being able to speak in three-word phrases, IQ > 80 and having no other health or developmental concerns. Ten of 11 FASD participants were adolescents and adults between the ages of 13 and 23; however, one 47-year-old female was also included in the study. The FASD group included two individuals with FAS, one with SE/AE and eight with ND/AE.

Comparison group

The comparison group consisted of 23 participants, who were recruited through flyers distributed around the university and the greater Seattle community. For each participant in the autism and FASD group, one age- and sex-matched participant was recruited as a pair-matched comparison participant. Age matching in comparison participants was ±1 year with one exception: a 47-year-old participant in the FASD group was matched to a 45-year-old comparison individual. Participants were also matched on sex to reflect the higher incidence of males with a diagnosis of ASD (Maenner et al., 2023). Comparison group participants all reported no history of cognitive, developmental or other health concerns. Two participants in the comparison group had a diagnosis of attention-deficit/hyperactivity disorder (ADHD) but were included because there were individuals with ADHD in both the autism and FASD groups. No participants in the comparison groups received an ADOS autism classification.

Procedure

The following measures were obtained over the course of several visits and as part of a larger study that included additional neurophysiological and behavioural measures. Written informed consent was obtained from all participants or their legally authorized representative for participants under 16 years of age. All methods were performed in accordance with protocols reviewed and approved by the Institutional Review Board at the University of Washington where the research was conducted. Participants were provided with monetary compensation for their time.

ADOS-2

The ADOS-2 (Lord et al., 2012), a measure of autism symptom severity, was administered to all participants at the time of testing to confirm autistic status in all participant groups. All participants in the autism group received an ADOS classification of autism. No participants in the comparison or FASD groups received an ADOS autism classification.

WASI-II

The Wechsler Abbreviated Scale of Intelligence—Second Edition (WASI-II; Wechsler, 2011), a measure of intellectual ability, was administered to all participants. Four subtests: Block Design, Vocabulary, Matrix Reasoning and Similarities, were administered to compute the WASI-II Full Scale Intelligence Quotient-4 for each participant and provide an overall estimate of intellectual functioning. The Verbal Composite Index score was computed from the Vocabulary and Similarities subtests and the Perceptual Reasoning Index scores were computed from the Block Design and Matrix Reasoning subtests (see Table 2 for score breakdown).

Auditory screening

To ensure clinically normal hearing thresholds in all participants, each participant was required to pass an audiometric screen (≤20 dB hearing level at octave frequencies between 500 and 8000 Hz), a distortion product otoacoustic emission screen, and an auditory brainstem response screen.

Elicitation of narratives

The 24-page wordless book, *Frog, Where Are You?* (Mayer, 1969), was used to elicit narrative language samples. This story has been used in previous research with both children and adults (Colle et al., 2008) and does not require any prior descriptions or specific prompts from the examiner. This wordless picture book requires the narrator to connect and organise different actions from the protagonists and events into a coherent story, providing a measure of temporal expressions. Because the story does not provide verbal cues, the participants have the freedom to explore the characters' inner states by taking the perspective of the characters and communicating them to the listener. The story is about a young boy and his dog in search of his lost pet frog. The protagonists' search involves numerous events and encounters with secondary characters. Throughout the story, the two characters engage with these secondary characters in developing the story to finally find the lost pet frog.

Each participant was assessed individually, and each narration was audio recorded for transcription and

TABLE 2 Sample characteristics: WASI-II score, story length by autism, FASD and comparison groups.

		Autism	FASD	Comparison
WASI-II FSIQ-4	*M*	102.36	97.00	119.91
	SD	(14.33)	(19.89)	(6.30)
WASI-II VCI	*M*	98.27	98.70	116.05
	SD	(23.44)	(19.56)	(8.25)

analysis. Participants were presented with a copy of the wordless book *Frog, Where Are You*? A divider was placed between the examiner and the participant so that the examiner was unable to see the pictures in the book while the participant was telling the story. The examiner instructed the participants to review the pictures in the book to become more familiar with the story and then they were asked to use the pictures as a visual prompt to tell the best story that they could. After the participant looked through the book, the examiner confirmed that they were ready and had them turn back to the first page of the book to start recording the story. The participant went through each page of the book and told the story without any prompts provided. The examiner did not intervene during the narration. However, when necessary, the examiner was permitted to provide a verbal prompt to help the participant get started (e.g., 'I will help you get started, once upon a time there was . . . ') or encourage the participant throughout the storytelling (e.g., 'What happened next?'). This procedure ensured that the participants did not memorise the story and emphasised the storytellers' ability to anticipate the listener's informational needs. After the participants finished telling the story, the examiner stopped the recording and praised the participants for their storytelling skills.

Transcription of narratives

Narratives were transcribed orthographically and formatted according to SALT conventions. Transcripts were segmented into *Communication units* (C-units). A C-unit is an independent clause with its modifiers, which includes one main clause with all subordinate clauses attached to it (Miller & Iglesias, 2020). As subordinate clauses depend on the main clause to make sense, they cannot be separated from the main clause, whereas the main clause can stand alone and can be segmented into C-units. Mazes, such as filled pauses, repetitions and revisions, along with unintelligible utterances, and irrelevant comments were marked and included in the transcription. Using SALT software (Miller & Iglesias, 2020), the transcribed narratives, including the C-units and marked mazes, were later used to analyse structural language properties of the transcription including mean length of utterance, total utterances, total different word roots, total words, rate of speech, mazes (e.g., word repetitions or 'um', 'uh') per total words and the overall NSS total score. Details of the transcription can be found on the SALT Training Website (Salt Software, n.d.).

Coding of narratives

The transcribed narratives were entered into the SALT software (Miller & Iglesias, 2020), which aids the process of analysing words, morphemes, utterances and discourse, and were used to code and analyse structural language properties. Codes from SALT was used to calculate the mean length of utterance, total utterances, total different word roots, total words, rate of speech, mazes (e.g., word repetitions or 'um', 'uh') per total words and the overall NSS total score. Additional codes were created to measure the use of mental state and temporal relation words. Two coders were trained on transcription and SALT coding, including the NSS total score and the identification of mental state and temporal relation words using two separate training stories. They were required to achieve over 80% agreement for both transcription and coding with a third experienced coder on the training stories before moving on to the actual data set.

Temporal Relations. The total number of temporal expression terms, excluding mazes, were counted to assess if participants with autism and FASD could organise events in sequential order. Temporal relation terms included temporal adverbs and conjunctions such as 'last night', 'yesterday', 'now' and 'meanwhile'.

Mental States. The total number of mental state terms, excluding mazes, were counted, which included the emotional state of a character in the story (e.g., 'The boy

is *angry* at the dog') and any reference to a mental state, including emphasising the character to explore their inner thoughts, beliefs, intentions (e.g., 'The boy *thought* the frog ran away').

NSS Score. Each of the narrative stories was then coded using the NSS total score as described in the SALT Training Website (n.d.). The NSS total score assesses the individual's ability to produce a structurally sound and coherent narrative. The scoring guideline included many features of story grammar including cohesiveness, connection of story events, consideration for characters' thoughts and behaviours and referencing. Each story was graded on a rubric of seven categories with a grading scale of 0–5: introduction, character development, mental states, referencing, conflict/resolution, cohesion and conclusion. Categories that could not be scored received a score of zero or N/A. Scores of zero were given for the target speaker errors (e.g., not following the protocols or telling the wrong story), and a mark of non-applicable (N/A) was given for the examiner errors (e.g., interference with the speaker's story or recording issues). For each section, a score of 1 indicated minimal/immature performance, a score of 3 indicated emerging skills and the highest score of 5 indicated proficient characteristics. Scores of 2 and 4 were undefined and given based on the examiner's judgment with justification. The scores for each section were then combined to give a total narrative score with the highest possible score of 35. For more details on scoring and guidance using the NSS, see the SALT training website (n.d.).

Interrater agreement

To ensure the reliability of the data, a systematic process of transcription and scoring was designed to prepare all narratives from recorded sourced files by two researchers. The secondary researcher was not informed of the group identity or diagnosis of the narrator. Interrater reliability was calculated for all measures with 93% agreement on words and 89% agreement on C-units in terms of transcription and 96% agreement on all categories of the NSS total score. Percent agreement on words and C-units was calculated based on the number of differences in terms of the numbers of words and C-units. Percent agreement on the NSS total score was determined for each of the seven category scores independently. In each category, the score had to be within ±1 point for the primary and secondary coders to be considered in agreement. The percent agreement between the primary and secondary coder was high across categories; introduction: 93%, character development: 98%, mental states: 96%, referencing: 91%, conflict/resolution: 100%, cohesion: 100% and conclusion: 96%. Since a high percent agreement was achieved, the scores determined by the secondary coder were used to avoid the first coder's biases, who is an author on the manuscript.

Statistical analysis

Pair matching was conducted during the recruitment of the comparison group participants to achieve a balance in age and sex between the study groups. A two-tailed Fisher's exact test revealed a reasonably balanced gender profile across groups ($p = 0.53$; see Table 1 for more details). A Kruskal–Willis test, used due to unequal variance between the groups, revealed no significant difference in the age distribution across groups ($c^2 = 2.29$, $df = 2$, $p = 0.32$; see Table 1 for more details). Thus, this pair matching was not maintained in the statistical analyses because preliminary analyses conducted detected no significant group differences in age or gender.

All analyses were conducted using the same sample size ($N = 46$; autism, $n = 11$; FASD, $n = 11$; comparison, $n = 23$. To test the main hypothesis of whether there were differences in the local and global structure of narratives produced, a one-way analysis of variance (ANOVA) was used to test for statistical differences between the means across all the groups. To assess the relationship between local and global variables, Pearson correlation coefficient (Pearson's r) was used to measure the strength of the linear relationship between the number of temporal relation words produced as well as between mental state words produced and other global measures. Finally, Pearson's r was also used to investigate the relationship between different global measures of the narratives.

RESULTS

Local measures across groups

To address our first research question, Table 3 shows the means and standard deviations for the two measures of local abilities, temporal relation words and mental state words. A one-way ANOVA revealed no statistically significant group differences in the number of mental state words produced (Figure 1b; one-way ANOVA, $F(2,42) = 0.54$, $p = 0.59$, $\eta^2 = 0.02$) or temporal relation words produced (Figure 1a; one-way ANOVA, $F(2,42) = 1.85$, $p = 0.17$, $\eta^2 = 0.08$).

Global measures across groups

Table 4 presents the means and standard deviations for five measures of global abilities including total words produced, rate of speech, number of mazes produced per total words, number of different words produced, mean

TABLE 3 Local measures raw scores: Means, SDs, and one-way ANOVA comparisons between autism, FASD and comparison groups.

length of utterances in words, total utterances produced and the NSS total score. A one-way ANOVA comparing each of the global measures in the autism, FASD and comparison groups revealed significant differences in the rate of speech and mazes per total words but no significant group differences in total words produced, number of different words produced, mean length of utterance or NSS total score. Of the seven categories that contribute to the

NSS total score, significant group differences were also observed for conflict/resolution,

Rate of speech. The comparison group spoke with a faster rate of speech, measured by the number of words spoken per minute, compared to the autism and FASD groups (Figure 2b). A one-way ANOVA revealed a significant difference across groups in the number of words spoken per minute (one-way ANOVA, $F(2, 42) = 15.35$, $p < 0.001$, $\eta^2 = 0.42$). Post-hoc comparisons using independent sample *t*-tests with Bonferroni correction revealed a lower rate of speech in the autism ($M = 128.90$, $SD = 23.07$) and FASD ($M = 115.19$, $SD = 28.24$) groups compared to the comparison group ($M = 159.04$, $SD = 20.43$). However, no significant difference was observed between the autism and FASD groups. Notably, four of the individuals with autism and four from the FASD group (one with FAS) spoke at a rate more than 2 SD slower than the mean of the comparison group (See Figure 2b).

Number of mazes per total words. The number of mazes produced per total words showed that the autism group produced more mazes (e.g., repetition, 'um', 'uh') compared to the FASD and comparison groups (see Figure 2c). A one-way ANOVA revealed a significant group difference in the number of mazes per total words (one-way ANOVA, $F(2,42) = 8.82$, $p < 0.001$, $\eta^2 = 0.30$). Post-hoc comparisons were conducted using independent sample *t*-tests with Bonferroni correction, which revealed a significantly higher number of mazes produced per total words in the autism group ($M = 0.12$, $SD = 0.08$) compared to the comparison group ($M = 0.04$, $SD = 0.03$) and to the FASD group ($M = 0.06$, $SD = 0.05$). However, no significant group difference was detected between the FASD and comparison groups. Notably, the autism group had a much wider variability in the maze words per total words and the mean from the autism group on this measure was more than 2 SD higher than the mean of the comparison group (See Figure 2c).

NSS conflict/resolution. To generate the NSS total score, an estimate of the overall score of whether the story is structurally sound and coherent, each story was graded on a rubric of seven categories. The NSS category score for conflict/resolution showed that the autism group scored higher compared to the FASD and comparison groups (Figure 2h). A one-way ANOVA revealed a significant group difference in the score of conflict/resolution (one-way ANOVA, $F(2,42) = 3.68$, $p = 0.03$, $\eta^2 = 0.15$). Post-hoc comparisons were conducted using independent sample *t*-tests with Bonferroni correction, which revealed a significantly higher score for conflict/resolution in the autism group ($M = 4.09$, $SD = 1.38$) compared to the comparison group ($M = 3.00$, $SD = 0.85$). However, no significant group difference was observed between the autism and FASD groups ($M = 3.09$, $SD = 1.38$) or between the FASD and comparison groups. Notably, six from the autism group and three from the FASD group received the highest possible score on this measure (i.e., a score of 5), where only one individual from the comparison group performed as well (See Figure 2h).

Relationships between local measures and global measures

To investigate the relationship between local and global measures of the narratives, Pearson correlation coefficient (Pearson's r) was used to measure the strength of the linear relationship between the number of temporal relation words produced as well as between mental state words produced and other global measures (see Table 5). This revealed a positive correlation between the NSS total score and the number of temporal relation words (Pearson's r, $r(43) = 0.38$, $p = 0.01$) and between NSS category conflict/resolution and the number of temporal relation words (Pearson's r, $r(43) = 0.49$, $p < 0.001$). The higher the overall NSS score or NSS conflict/resolution, the greater the number of temporal relation words observed. A positive correlation between NSS total score and the mental state words as well as NSS category conflict/resolution was also detected (NSS total score, Pearson's r, $r(43) = 0.63$, $p < 0.001$; NSS conflict/resolution, Pearson's r, $r(43) = 0.47$, $p < 0.001$). The higher the overall NSS score and its conflict/resolution category, the more mental state words are observed.

Relationships within global measures

To investigate the relationship between different global measures of the narratives, Pearson correlation coefficient (Pearson's r) was also used (see Table 6). A strong correlation between the number of total words produced and the number of mazes produced per total words (Pearson's r, $r(43) = 0.33$, $p = 0.03$) was observed, which indicates a higher number of mazes was observed for longer narratives. The rate of speech was also positively correlated with mean length of the utterances (Pearson's r, $r(43) = 0.36$, $p = 0.01$), which suggests that the longer the length of the utterances, the faster the rate of speech. Additionally, a strong correlation between NSS category conflict/resolution and a few other global measures were also observed, including total words with mazes (Pearson's r, $r(43) = 0.80$, $p < 0.001$), total different words (Pearson's r, $r(43) = 0.79$, $p < 0.001$), mean length of utterances (Pearson's r, $r(43) = 0.35$, $p = 0.02$), total utterances produced (Pearson's r, $r(43)$

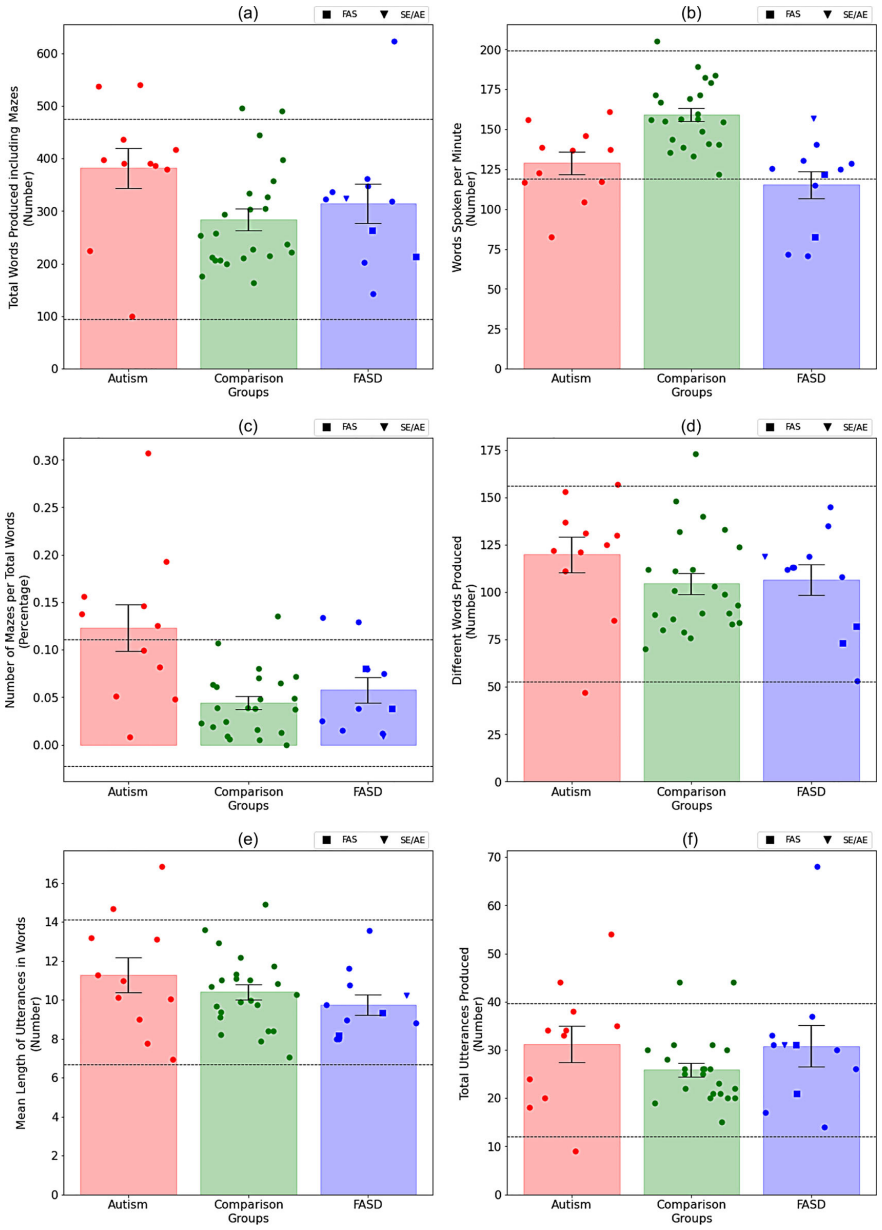

FIGURE 2 Global measures: total words produced (a), words spoken per minute (b), number of mazes per total words (c), different words produced (d), mean length of utterances in words (e), total utterances produced (f), Narrative Scoring Scheme (NSS) total score (g) and NSS conflict/resolution as a function of participant group (h). $= 0.63$, $p < 0.001$) and NSS total score (Pearson's r, $r(43) = 0.81$, $p < 0.001$).

DISCUSSION

In this study, we elicited narratives using a wordless picture book to investigate narrative discourse abilities in a sample of adolescent and adults with autism, FASD and an age- and sex-matched comparison group. We evaluated both local and global language features of the narratives produced and group differences were observed on three global measures: the number of mazes per total words produced, rate of speech, as well as the conflict/resolution category score that contributed to the NSS total score. Participants in the autism group produced significantly more mazes per total words compared to the FASD and comparison groups, and both the autism and FASD groups spoke at a lower rate of speech compared to the comparison group (i.e., talked slower). Participants in the autism group also scored significantly higher than the FASD and comparison group on the NSS category score for conflict/resolution. No significant group differences were found on local measures, including the number of temporal relation and mental state words produced. While our findings revealed that at the group level, many aspects of global narrative production, including the total number of words including mazes, number of different words, total number of utterances, mean length of utterances, the NSS total score in the autism and FASD groups were comparable to the comparison group, there was notable variability within each group.

The control of local and global aspects of language contributes to successful social communication and narrative discourse as the speakers are required to consider a listener's perspective to construct a cohesive narrative as they organise the story. Our results addressed the broad question: are there differences in the local and global structure

TABLE 6 Correlations between global measures.

of narratives produced by participants from the autism, FASD and comparison groups? Each of these findings is discussed in more details later.

Local measures

Temporal relations

At group level, there was no significant difference observed in the number of temporal relation words produced by autism, FASD and comparison groups. This finding is in contrast with Colle et al. (2008), who did find a difference between the autism and comparison groups. Additionally, we observed a positive correlation between the NSS total score as well as the NSS category conflict/resolution score and the number of temporal relation words, indicating that the more temporal relation words produced, the more coherent the story and the better the conflict and resolution. A positive correlation between the number of total words (including mazes) and the number of temporal relation words was also observed, which indicates that the number of temporal words produced was proportional to the length of the story itself but may not necessarily tell us about how participants maintained and used temporal references. Given the strong relationship between the number of temporal relation words produced and the NSS total score, the use of temporal relation words may have helped the storytellers produce a more coherent story. Thus, this finding suggests that the number of temporal relation words produced may be a good predictor for the storyteller's overall ability to produce a coherent narrative.

Mental states

Our results also did not show any significant differences at group level between the autism, FASD and comparison groups in the production of mental state words. This, however, was not what we predicted. These findings were consistent with some of the results from the narrative discourse of autistic individuals in both adults (Beaumont & Newcombe, 2006; Colle et al., 2008; Suh et al., 2014) and children (Tager-Flusberg & Sullivan, 1995). However, although Tager-Flusberg and Sullivan (1995) showed that autistic children produced a similar quantity of emotional and mental state words, they noted that autistic children were more likely to use expressions with a limited understanding of intentions and internal states of the character and less likely to take into consideration the point of view of the listener. Similarly, Beaumont and Newcombe (2006) found no differences in the number of mental state words produced, but adults with autism were less likely to provide an explanation as to why a character was thinking or feeling in a particular way compared to comparison participants. In short, these children were able to label emotions but did not fully understand the role of the mental state expressions that they used. This finding suggests that although autistic individuals may produce the same number of mental state words as the comparison group, they may show difficulty in comprehension that is not captured by the measures employed in this study.

Nevertheless, a strong correlation between the overall score of NSS as well as its category conflict/resolution and the number of mental state words produced was observed, which indicates that the use of mental state words may help aid in the production of a coherent story.

Global measures

The results showed significant group differences between autism, FASD and comparison participants on the number of mazes per total words, rate of speech and the NSS category score for conflict/resolution. The finding that autistic

individuals produced narratives with greater number of mazes per total words compared to FASD and comparison groups is consistent with past studies that found excessive production of mazes in autistic individuals (Lake et al., 2011; Suh et al., 2014). The slower rate of speech in both autism and FASD compared to the comparison group is also consistent with past studies that found a relationship between low processing speed and communication symptoms in autistic individuals (Haigh et al., 2018; Hedvall et al., 2013; Oliveras-Rentas et al., 2012) and individuals with FASD (Burden et al., 2005; Olson et al., 1998).

Additionally, higher scores on the NSS category score for conflict/resolution of the narratives observed in the autism group revealed the individuals' ability to clearly state all these critical details that help advance the plot of the story (Miller & Iglesias, 2020). These findings are not consistent with past studies that found children with autism produced globally impoverished stories compared to their comparison participants, including a lower score on NSS overall and conflict/resolution specifically (King et al., 2014; King & Palikara, 2018). In our study, participants in the autism group received higher scores compared to the FASD and comparison groups, contrary to our initial expectations.

On other aspects of the global features, the results showed that the autism and FASD groups were comparable to each other as well as the comparison group, including the length of narrative, mean length of utterances, total utterances, total different words produced and the NSS total score. The results on the number of total words produced including mazes are consistent with past studies that found a comparable length of narrative between autism and comparison group (Banney et al., 2015; Colle et al., 2008; King et al., 2014; Suh et al., 2014; Tager-Flusberg & Sullivan, 1995). The results on other measures are consistent with Reindal et al. (2021) as well as Colle et al. (2008)'s findings that autistic children had comparable structural language skills to neurotypical children such as choice of vocabulary. However, since pragmatic language difficulty was found to be more prevalent in autistic children compared to neurotypical children and is an essential component of social communication, pragmatic language skill should be examined in relation to the structural components of narrative discourse.

A particular strength of this study is the multi-group approach, which enabled us to compare the narrative discourse in individuals with autism and FASD. Such examination increases the generalisability of findings to the broader population of adults evaluated for autism and FASD since the literature on narrative discourse in FASD is still limited.

A limitation of this study is that only group-level analyses were conducted due to the small sample size. While our findings suggest strong narrative abilities for the participants in the autism and FASD groups on average in our participant sample, there was also significant variability across individuals. Such heterogeneous results suggest that language abilities need to be considered at the individual level as opposed to the diagnostic category and that our observed results may not generalise to all individuals with autism and FASD. Importantly, individual data with normative reference lines for ±2 SD of the comparison group are presented in Figures 1 and 2 so that one could consider what magnitude of contrast would be clinically meaningful for each subject across diagnostic categories, in addition to what was statistically significant at group level. For the NSS total score and the NSS Conflict/Resolution score, normative ranges were also included in Figure 2 (see figure caption for further details).

In this current study, since we expected heterogeneity in language and intellectual ability in both autism and FASD groups, we measured both verbal and non-verbal intellectual abilities using the WASI—Second Edition (see Table 2). Given the widely distributed performance in both local and global levels of narrative language production, future studies should recruit larger participant numbers and also assess their participants based on their groups' distinctive characteristics or co-occurring conditions such as shape bias in individuals with autism (Abdelaziz et al., 2018) or attention deficit in individuals with autism (Baixauli et al., 2017) and FASD (Nanson & Hiscock, 1990; Rasmussen et al., 2010). Additional variables that influence narrative discourse, such as motivation, distractibility and decision making of individual participants should also be considered.

An additional limitation of this study is that only one storytelling task was obtained, which may not reflect how each individual would perform across different settings in daily social communication situations. It is important to note that although there are aspects of narrative discourse that the participants in this sample did not show difficulty with on this particular task, they may show difficulty with other higher-level language measures. Moreover, the findings reported in this study may not generalise to other individuals with autism and FASD or even other types of narratives within the same participant. Additional tasks and analyses involving narrative discourse would provide useful comparisons between these two groups. Lastly, when context is used to support other structural components of language (e.g., providing temporal relation terms to make a smoother transition between parts of a story or using non-linguistic signals to communicate; Barokova & Tager-Flusberg, 2020), more than just spoken language is used to deliver stories. As such, future studies of narrative discourse in individuals with FASD and autism should be extended to all components of language,

including but not limited to, expressive or pragmatic language skills.

A further limitation of the study is that the majority of the FASD cases were at the moderate end of the spectrum (eight with ND/AE) while only three were at the severe end (two with FAS, one with SE/AE). If the study sample contained only those with FAS/PFAS or SE/AE, we may have identified more significant contrasts. Nonetheless, given the limited number of past studies on the narrative discourse of adolescents and adults with FASD and their shared characteristics with autism (Kippin et al., 2022; Stevens et al., 2013; Terband et al., 2018), this present investigation of narrative discourse will contribute to what we know about the language abilities of individuals with FASD. This study suggests that many aspects of the narrative discourse of individuals with autism and FASD in our particular sample are comparable to the neurotypical comparison participants and each other when considered at the group level. This includes both local and global features. With the comparatively large body of research available in autistic individuals, the results highlighting the similarities between autism and other neurodiverse populations like FASD could lead to more research that is focused on the representations of autistic characteristics in other neurological conditions (e.g., Stevens et al., 2013), and specifically its potential influence on the development of language skills.

Ultimately, the results of this study could aid in the development of clinical tools to best assess language abilities across populations. This understanding could also lead to the development of language support systems that further help individuals advance their language skills and gain self-confidence in daily social communication (Nanson & Hiscock, 1990). Taken together, this current study provided evidence that narrative assessment is an appropriate tool that can be included in routine clinical assessments of language that may reveal important aspects of higher-level language skills required in everyday real-world conversational interactions.

Early identification

ABSTRACT

Background: Prenatal alcohol exposure (PAE) can disrupt children's neurodevelopment and exert lasting influences on overall child well-being and family functioning. A comprehensive exploration of developmental outcomes in infants/toddlers with PAE seen for a diagnosis on the fetal alcohol spectrum can inform early identification and intervention.
Aims: To describe the prevalence and patterns of neurodevelopment, sensory processing, and emotional and behavioral functioning in a clinical sample of infants/toddlers with PAE.
Methods: In this retrospective analysis, clinical data from 125 infants/toddlers with PAE, aged 2–42 months, assessed at the University of Washington Fetal Alcohol Syndrome Diagnostic and Prevention Network clinic were analyzed.
Results: Seventy-four to 87% of infants/toddlers demonstrated delayed development in one or more domains of the Bayley Scales of Infant and Toddler Development (n = 125). Adverse developmental outcomes were significantly correlated with PAE and/or postnatal risk factors. All 93 infants/toddlers with a complete Infant/Toddler Sensory Profile obtained definite difference scores in at least one quadrant/section. Over half of infant/toddlers with a completed Child Behavior Checklist/1½– 5 had total problem scores in the borderline or clinical range.
Conclusions: Findings suggest that several domains of child functioning may be vulnerable to the teratogenic impact of PAE, and that these delays are evident in the first years of life. Early screening, ongoing monitoring and comprehensive assessment is needed to facilitate earlier identification and guide clinical intervention.

What this paper adds?

Prenatal alcohol exposure (PAE) appears to be under-recognized by early childhood practitioners. Challenges related to effective

screening processes, as well as difficulties detecting early delays or problems in the absence of physical features, may be inhibiting the early identification and intervention of infants/toddlers with PAE. Intervening early can buffer against the developmental vulnerability and postnatal adversity associated with PAE and optimize child and family outcomes in the long term. A comprehensive exploration of developmental, sensory processing and behavioral outcomes in young children seen in a Fetal Alcohol Spectrum Disorder (FASD) diagnostic clinic for individuals with PAE can inform early identification and intervention practices.

Clinically significant developmental delays were highly prevalent in this sample of infants/toddlers with PAE. These adverse developmental outcomes were significantly correlated with PAE and/or postnatal risk factors. Atypical sensory processing behaviors in at least one area were reported for every infant/toddler in the clinical sample. Over half of infants/toddlers presented with emotional and behavior problems outside of the normal range. Present findings, considered with similar studies reported in the literature, suggest that most domains of child functioning are vulnerable to the teratogenic impact of PAE and that these delays are evident in the first years of life. Findings reinforce the value of early screening, ongoing monitoring, and comprehensive assessment to facilitate earlier identification and to provide opportunities for infants/toddlers with PAE and their caregivers to benefit more fully from early supports and intervention.

1. Introduction

A wide range of adverse neurodevelopmental, sensory, and behavioral outcomes have been documented among children with prenatal alcohol exposure (PAE) (Astley, 2010; Astley et al., 2009; Carr et al., 2010; Subramoney et al., 2018). Fetal alcohol spectrum disorders (FASD), an umbrella term representing the full range of physical, cognitive, and behavioral impairments caused by PAE, are estimated to occur in at least 1% of children and youth in the general population (Popova et al., 2019; Roozen et al., 2016). Children with PAE and FASD are a clinically heterogenous group, who may experience brain-based challenges across multiple domains including cognition, language, executive function, motor, self-regulation, and adaptive behavior functioning (Astley, 2010; Mattson et al., 2019). Although earlier diagnosis provides opportunities for children to benefit more fully from intervention and is predictive of more positive life outcomes in this population (Streissguth et al., 2004), PAE appears to be under-recognized by early childhood practitioners. In fact, many referrals for FASD diagnosis are not initiated until a child reaches school age (Olson et al., 2007), well beyond the time for early intervention. Challenges related to effective screening processes for maternal alcohol use history, as well as difficulties detecting early signs of delays or problems in the absence of physical features, may be inhibiting the early identification and intervention of infants/toddlers with PAE (Clarren & Astley, 1998; Olson et al., 2007; Watson et al., 2011).

Understanding the early neurodevelopmental effects among infants/toddlers with PAE is necessary to facilitate early diagnosis and intervention, a top priority in the field of FASD (SAMSHA, 2014). Decades of research has documented the developmental outcomes of infants/toddlers with PAE, frequently relying on global, standardized measures such as the Bayley Scales of Infant Development (Bayley, 1993; 2006; for a review of literature see (Garrison et al., 2019; Subramoney et al., 2018). Many of these earlier studies used the Bayley-II (Bayley, 1993), for example, which provides a general indication of functioning when it combines cognitive, expressive, and receptive language outcomes into one index (i.e., Mental Developmental Index) and gross and fine motor development into a second index (i.e., Pyschomotor Developmental Index). Given that young children with PAE show considerable individual variability in development (Astley, 2010; Astley et al., 2009), more useful information may be generated from a developmental profile that examines outcomes across distinct scales. Other global measures of infant/toddler development, including newer versions of the Bayley (Bayley et al. (2019); Bayley (2006), are comprised of distinct domains and/or subdomains, which broadens the scope of the assessment. Furthermore, assessment of infant/toddlers' functioning in each of the five core developmental domains (i.e., cognitive, language, motor, social-emotional and adaptive functioning), for the purpose of identifying suspected delays and determining early intervention eligibility, is consistent with federal (Yell et al., 2006) and professional early childhood (Zeanah et al., 2016) standards.

Impairments in self-regulation have been frequently observed in young children (birth to 8 years) with PAE (Astley, 2010; Reid & Petrenko, 2018) and as such, have been recognized as a core symptom in the FASD 4-Digit Code diagnostic criteria for "Neurobehavioral Disorder/Alcohol-Exposed and the proposed DSM-5 diagnostic criteria for "neurobehavioral disorder associated with PAE (ND-PAE)" (Kable et al., 2016). Self-regulation is defined as the ability to manage internal sensory, emotional, and behavioral states (Wells et al., 2012). These are the skills that allow children to regulate and respond to sensory input, pay attention, practice self-control, and manage strong emotions in an adaptive and age-typical manner. Sensory processing refers to an individual's capacity to detect, modulate, interpret, and respond to everyday sensations (Dunn, 2007; Miller et al., 2007). As such, information about early regulatory skills, which may be reflected in sensory processing behaviors and emotional and behavioral functioning, helps to broaden the picture of overall child development.

Documenting self-regulatory difficulties is important both for understanding the variable developmental performance of infants/toddlers with PAE and for guiding intervention. Caregiver rating scales and questionnaires have frequently been used to assess sensory processing differences and emotional/behavioral problems in the early childhood period (Astley, 2004, 2010; Coles et al., 2015; Fjeldsted & Xue, 2019; Molteno et al., 2014). Findings from a recent comparative analysis demonstrate the usefulness of caregiver-reported assessments for identifying behavioral deficits in infants with PAE, including those with light/moderate PAE (Bakhireva et al., 2018). However, for children older than three, researchers suggest that both caregiver-reported observations/ratings and performance-based measures of neurodevelopment be included to establish a comprehensive profile of FASD (Astley & Clarren, 2000; Lange et al., 2017). Taken together, findings underscore the importance of collecting relevant information from multiple sources to accurately identify developmental and behavioral problems across a continuum of infants/toddlers at risk for FASD (Astley, 2013).

This study aimed to explore the prevalence of neurodevelopmental delay, atypical sensory processing, and emotional and behavioral problems in a clinical sample of infants/toddlers with confirmed PAE to assist early childhood practitioners in identifying

early delays or problems that may arise from PAE. Given that alcohol is a neurobehavioral teratogen and children with PAE often experience high levels of co-occurring postnatal risks, outcomes were also explored in relation to PAE and selected demographic and environmental factors (Hemingway et al., 2020). The following research questions were asked:

1. What is the prevalence of neurodevelopmental delay in five core developmental domains (i.e., cognitive, language, motor, social-emotional and adaptive behavior)?
2. What is the prevalence of atypical sensory processing behaviors among infants/toddlers with PAE?
3. What is the prevalence of emotional and behavioral problems among infants/toddlers with PAE?
4. Are these adverse outcomes positively correlated with PAE and/or other postnatal risk factors? Does the prevalence of adverse outcomes differ by gender and age?

2. Methods

2.1. Research design

This study is a retrospective exploratory analysis of clinical data obtained from 125 infant/toddlers, ages 2–42 months, who received an interdisciplinary FASD diagnostic evaluation at the University of Washington Fetal Alcohol Syndrome Diagnostic and Prevention Network (FASDPN) clinic between 2009 and 2019. Children were referred to the clinic if they had a confirmed prenatal alcohol exposure history, at any level. Referral to the FASDPN does not require evidence of developmental delay. Data used for this study were collected with University of Washington Human Subjects Division oversight and approval and caregiver consent at the time of diagnosis.

The clinic has provided FASD diagnostic evaluations for individuals of all ages with PAE since 1993 and is one of the few clinics nationally that diagnose children under the age of three. The FASDPN database currently contains over 2000 fields of data (exposures and outcomes) on approximately 3000 patients (newborn to adult) with PAE. All patients in the FASDPN database received an FASD diagnostic evaluation by an interdisciplinary team (medical doctor, occupational therapist, psychologist, and speech language pathologist) using the FASD *4-Digit Diagnostic Code* (Astley, 2004, 2013). The 4 digits of the code reflect the magnitude of expression of the 4 key diagnostic features of FASD in the following order: (1) growth deficiency, (2) FAS facial features, (3) central nervous system (CNS) structural, neurological and/or functional abnormality, and (4) prenatal alcohol exposure. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FASD feature and 4 reflecting strong

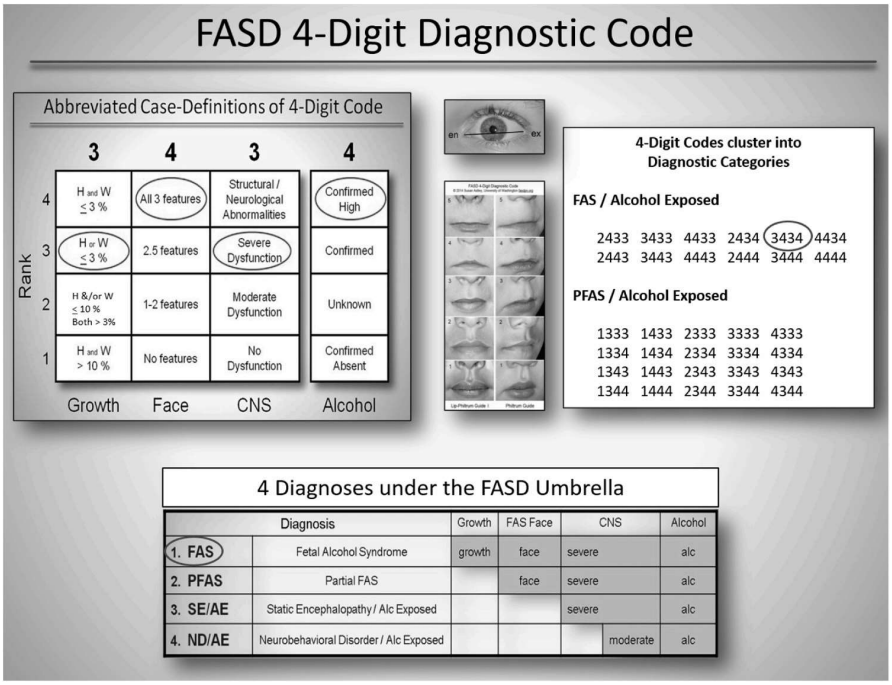

Fig. 1. Abbreviated case-definitions of the FASD 4-Digit Code (Astley, 2004, 2013). The 4-Digit Code 3434 is one of 12 Codes that fall under the diagnostic category FAS. The 4-Digit Code produces four diagnostic subgroups under the umbrella of FASD: FAS, PFAS, SE/AE and ND/AE. Abbreviations: Alc alcohol; CNS central nervous system; h height; w weight; % percentile.

"classic" presence of the FASD feature. Each Likert rank is specifically case defined (Fig. 1). There are 102 4-Digit codes that fall broadly under the umbrella of FASD. These codes cluster into four clinically meaningful FASD diagnostic subcategories (Astley, 2004): Fetal Alcohol Syndrome (FAS) (diagnostic categories A, B); Partial FAS (PFAS) (diagnostic category C); Static Encephalopathy/Alcohol Exposed (SE/AE) (diagnostic categories E, F) and Neurobehavioral Disorder/Alcohol Exposed (ND/AE) (diagnostic categories G, H). Not all individuals with PAE present with adverse outcomes that meet criteria for FASD. The FASD 4-Digit Code classifies these individuals as follows: "Sentinel Physical Findings/Alcohol-Exposed" (SPF/AE) (diagnostic category I; individuals with PAE who present with growth and/or facial abnormalities, but normal CNS outcomes) and "No Physical Findings or CNS Abnormalities/Alcohol-Exposed" (Normal/AE) (diagnostic category J). See Fig. 1. The FASD 4-Digit Code also ranks the magnitude other prenatal risks (e.g., other teratogens, illicit drugs, tobacco, poor prenatal care, family genetics) and postnatal risks (e.g., neglect, trauma, multiple home placements).

2.2. Participants

Data from children who met the following inclusion criteria were used in this study: 1) age 1 month to 3.5 years at the time of their FASD diagnostic evaluation; 2) received one of the following diagnoses FAS, PFAS, SE/AE and ND/AE, SPF/AE, Normal/AE reflecting the full continuum of outcomes observed among individuals with PAE using the FASD 4 Digit Diagnostic code; 3) had complete data on a minimum of two domains from the Bayley Scales of Infant and Toddler Development, third edition (Bayley-III; Bayley, 2006); and D) were of any race, ethnicity, or gender. The upper age range of the inclusion criteria was based on the age range of the Bayley Scales of Infant Development.

2.3. Measures and methods of data collection

The data used for this study were collected by an interdisciplinary diagnostic team using the FASD 4-Digit Code (Astley, 2004). While a core set of assessments are used during the diagnostic clinic visit, the final battery of assessments administered to each infant/toddler are based on clinician judgement. Therefore, data may be limited by clinically warranted situations and decisions where testing was not appropriate or not completed (e.g., child had a recent comprehensive assessment from another provider, or child was unable to attend to items, or child became irritable, upset or tired). Thus, complete data for outcomes on the Bayley-III from this clinical sample vary based on factors such as age, presenting developmental concern(s), and child's ability to complete the assessment. Standardized parent questionnaires were completed by the primary caregiver prior to the scheduled diagnostic clinic date. Time, effort, or other demands placed on a caregiver may have resulted in some caregiver-report measures not being fully completed.

2.3.1. Child and family demographics

Information about child demographics, birth and medical history, growth, prenatal and postnatal experiences was collected during the intake process and caregiver interview at the time of diagnosis.

2.3.2. Assessment of infant/toddler development across five domains

Infants/toddlers were clinically assessed by the occupational therapist using the Bayley-III, a widely used, standardized developmental assessment for infants/toddlers, 1–42 months of age. The Bayley-III has five domains (i.e., Cognitive, Language, Motor, Social-Emotional, and Adaptive Behavior) that are presented as standard scores (mean = 100, *SD* = 15). Each of the five domains has 1–10 subdomains that are presented as scaled scores (mean = 10, *SD* = 3). Three of the domain scales are performance-based measures (i.e., Cognitive, Language, and Motor) and two scales are caregiver-report measures (i.e., Social-Emotional and Adaptive Behavior). For this study, domain and subdomain scores were collapsed into the following categories: domain scores: typical development (standard scores $\geq$ 86, scores ≥ -0.9 *SD*), at-risk development (78–85, scores between -1.0 and -1.4 *SD*), and delayed development ($\leq$ 77, scores ≤ -1.5 *SD*); subdomain scores: typical development (scaled scores $\geq$ 8, scores ≥ -0.9 *SD*), at-risk development (6–7, scores between -1.0 and -1.4 SD), and delayed development ($\leq$ 5, scores ≤ -1.5 SD). These categories were created to reflect current eligibility criteria for early intervention services in the state of WA. The Bayley-III is reported to have high internal consistency demonstrated by Cronbach's alphas, ranging from .91 to .93 for domain scores and .86 to .91 for scaled scores (Albers & Grieve, 2007).

2.3.3. Assessment of sensory processing

The Infant Toddler Sensory Profile (ITSP; 7–36 months; (Dunn, 2002) is a 48-item caregiver-report questionnaire designed to measure sensory processing abilities in children ages 7–36 months. Caregivers rate the frequency of their child's daily behavior on a scale from "*almost always"* (score of 1) to *"almost never"* (score of 5). Sensory processing was evaluated across five sections (i.e., auditory, visual, tactile, vestibular, and oral sensory processing). Infants/toddlers also received a score on their behavioral responses to sensation within four quadrants: low registration (i.e., fails to notice and respond to sensory input), sensation seeking (i.e., derives pleasure from and seeks out sensory experiences), sensory sensitivity (i.e., notice sensory input easily, tends to be reactive) and sensation avoiding (i.e., notices sensory input easily, tends to withdraw quickly). The ITSP categorizes the raw scores as typical performance (scores at or between plus 1.0 *SD and minus 1.0 SD*), probable differences (scores within -1.1 to -1.9 SDs or $+1.0$ to $+1.9$ SDs) and definite difference (scores at or below -2 SDs or at or above $+2$ SDs). The ITSP is reported to have excellent test-retest reliability ($\alpha = .86$) for domain/section scores and adequate ($\alpha = .74$) for quadrant scores (Eeles et al., 2013). Validity was established in several studies (Dunn, 2002; Dunn & Daniels, 2002; Eeles et al., 2013).

2.3.4. Assessment of emotional and behavioral problems

The Child Behavior Checklist for ages 1½– 5 years (CBCL; (Achenbach & Rescorla, 2000) is a widely used instrument used to identify a range of behavioral and emotional problems in young children. Completed by the primary caregiver, the CBCL contains 100 items, rated as 0 = not true, 1 = sometimes true, and 2 = very true or often true, based on the preceding 2 months. The CBCL yields scores on three summary scales (Internalizing, Externalizing, and Total Problems), seven syndromes (Emotionally Reactive, Anxious/Depressed, Somatic Complaints, Withdrawn, Sleep Problems, Attention Problems, and Aggressive Behavior), and five DSM-oriented scales (Affective, Anxiety, Pervasive Developmental, Attention Deficit/ Hyperactive and Oppositional Defiant Problems). Summary scale *t*-scores are categorized as normal range (*t*-scores < 60), borderline clinical range (*t*-scores 60 to 63), and clinical range (*t*-scores ≥ 64). Syndrome and DSM-oriented *t*-scores are categorized as normal range (*t*-scores ≤ 64), borderline clinical range (*t*-scores 65 to 69), and clinical range (*t*-scores ≥ 70). This measure is reported to have high levels of internal consistency (α = 0.97) and good test–retest reliability (mean *r of.85* across all scales) (Rescorla, 2005).

2.3.5. Diagnostic outcome data

FASD 4-Digit Code Diagnoses. FAS; PFAS; SE/AE; ND/AE; Sentinel Physical Findings/AE; No Physical or CNS Abnormalities/AE. See full description above (Astley, 2004) and case definitions for the following diagnostic features (Fig. 1).

Growth Deficiency. 'Growth Rank': 1 = none; 2 = mild; 3 = moderate; 4 = severe. This variable yields the first digit in the FASD 4-Digit Diagnostic Code and documents the magnitude of prenatal and/or postnatal growth deficiency (Astley, 2004).

FAS Facial Phenotype. 'Face Rank': 1 = absent; 2 = mild; 3 = moderate; 4 = severe. This variable represents the second digit in the FASD 4-Digit Diagnostic Code and documents the magnitude of expression of FAS facial phenotype defined by short palpebral fissure lengths, a smooth philtrum, and a thin upper lip using the FAS Facial Photographic Analysis Software (Astley, 2004; Astley, 2016).

CNS Likelihood of Structural Abnormality. 'CNS Rank': 1 =unlikely; 2 =possible; 3 =probable;4 =definite. This variable yields the third digit in the FASD 4-Digit Diagnostic Code. These four ranks document the increasing likelihood of CNS structural abnormality. Alcohol is a teratogen that interferes with the structural development of the fetal brain. This, in turn, can lead to abnormal function. The greater the dysfunction, the higher the probability of CNS structural abnormality (Astley et al., 2009; Astley et al., 2009; Astley, 2013). The first three CNS Ranks document the severity of CNS dysfunction (Rank 1-no dysfunction; Rank 2- mild-to-moderate dysfunction; Rank 3-severe dysfunction). CNS Ranks 1–3 are based on brain function (executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention, and activity level) assessed by an interdisciplinary team using standardized psychometric tools. CNS Rank 4 documents the presence of direct evidence of CNS structural and/or neurological abnormalities (e.g., microcephaly, structural brain abnormalities, a seizure disorder of prenatal origin, or other hard neurological signs).

Prenatal Alcohol Exposure. 'Alcohol Rank': 1 = confirmed absence of exposure; 2 = unknown exposure; 3 = confirmed exposure; level unknown or low to moderate; 4 = confirmed exposure; level high). Alcohol exposure is the fourth digit in the FASD 4-Digit Diagnostic Code, which is ranked according to the quantity, timing, frequency, and certainty of exposure during pregnancy. A confirmed prenatal alcohol exposure at any level is required for a diagnostic evaluation in the FASDPN clinic. The clinic intake form (New Patient Information Form (Astley, 2004)) requests the following exposure information before and during pregnancy: average and maximum number of drinks per drinking occasion, average number of drinking days per week, trimesters of exposure and source of information. The primary sources of information are past and present medical and social service records. Roughly half of patients with confirmed prenatal alcohol exposure report quantity, frequency and duration of exposure. (see appendix 2 from Astley, 2004, 2013).

2.4. Other risk factors

Other Prenatal Risks. Rank: 1 = no risk; 2 = unknown risk; 3 = some risk; 4 = high risk (Astley, 2004). Other prenatal risk factors documented in the FASDPN clinical database include, but are not limited to poor prenatal care, pregnancy complications, prematurity, presence of other syndromes/genetic abnormalities, and prenatal exposure to other substances (e.g., medications, tobacco, illicit drugs, and/or other teratogens). The 4-Digit Code ranks the magnitude of these other prenatal risks in a single composite measure labeled "Other Prenatal Risks Rank." Rank 4 is assigned when there is exposure to another teratogen (e.g., Dilantin) or when another syndrome or genetic condition is present (e.g., Down syndrome, Fragile X, etc.). Rank 3 is assigned to all other prenatal risks. The clinic intake form requests the patient to report these other prenatal risk factors when known. The ranking is determined by available records and caregiver or other report on intake forms and/or clinical interview (Astley, 2004).

Other Postnatal Risks. Rank: 1 = no risk; 2 = unknown risk; 3 = some risk; and 4 = high risk (Astley, 2004). Postnatal risk factors documented in the FASDPN database include, but are not limited to perinatal complications, number of home placements, physical and/or sexual abuse, neglect, and trauma. The 4-Digit Code ranks the magnitude of these other postnatal risks in a single composite measure labeled "Other Postnatal Risks Rank". Rank 4 is used to note severe postnatal circumstances that have been shown to have a significant adverse effect on development in most instances. Examples include physical or sexual abuse, multiple home placements, and severe neglect. Rank 3 is used to note conditions akin to those in Rank 4, but the circumstances are less severe. The clinic intake form requests the patient to report these other postnatal risk factors when known.

3. Data analysis

Data analyses were completed using SPSS 27.0 (IBM Corp., New York). Descriptive statistics (e.g., means, standard deviations, proportions) were used to summarize the sociodemographic and clinical profiles of the study sample and to describe children's scores

Table 1
Demographic and clinical profiles of infants/toddlers with Bayley-III, ITSP, and CBCL assessments.

on measures of neurodevelopment, sensory processing, and emotional and behavioral problems (Research Questions 1–3). Associations between Bayley-III, ITSP and CBCL outcomes and selected child demographics and exposures (age, gender, PAE and postnatal risk factors) were examined using chi-squared tests (χ^2), *t*-tests or one-way analysis of variance (ANOVA), as appropriate (Research Question 4). Results having an alpha level of $p \leq .05$ (two-tailed) were considered statistically significant. No adjustments were made for multiple comparisons due to the exploratory nature of this study; thus, significant findings should be interpreted accordingly.

With regard to missing data, any subject with complete data on two or more Bayley-III domains and the entire CBCL were included in the analyses. For the ITSP, any subjects with missing data on more than one-third of items in any one quadrant/section were excluded. On the rare occurrences (n = 8) when less than a third of items were missing, the average of the child's remaining scores was calculated and rounded to the nearest whole number. This value replaced the missing score(s) in that quadrant/section.

4. Results

4.1. Demographic and clinical outcomes

Records from 125 infants/toddlers with PAE met the inclusion/exclusion criteria for this study. All 125 had a Bayley-III administered. Sixty-one (49%) infants/toddlers had all five domains on the Bayley-III completed; 27 (22%) had 4 domains; 31 (25%) had 3

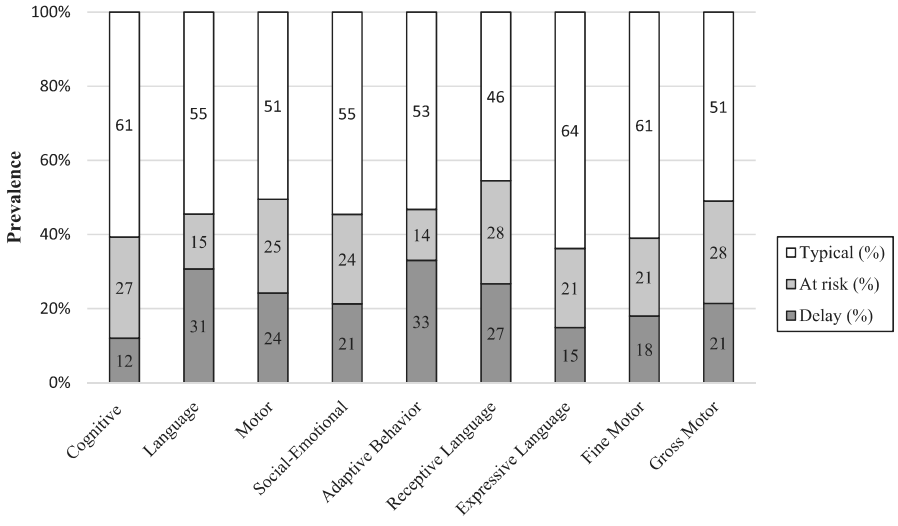

Fig. 2. Proportion of 125 infants/toddlers with typical, at-risk, and delayed development across the five Bayley-III domains: typical (standard scores ≥ 86, scores ≥ −0.9 *SD*); at-risk (78–85, scores between −1.0 and −1.4 *SD*); delayed (≤ 77, scores ≤ −1.5 *SD*) and proportion of infants/toddlers with typical, at-risk, or delayed development in the Bayley-III Language and Motor subdomains. Receptive language: n = 90, expressive language: n = 94, fine motor: n = 100, and gross motor: n = 98. Typical (scores ≥ −0.9 *SD*). At-risk (scores between −1.0 and −1.4 *SD*). Delayed (scores ≤ −1.5 *SD*).

domains; and 6 (5%) had 2 domains. ITSP outcomes were available for 93 of the 125 infant/toddlers and CBCL outcomes were available on 67 infant/toddlers. The full sample of 125 ranged in age from 0.28 to 3.5 years (mean = 1.9 years), was 51% female and 46% white (Table 1). Diagnostic outcomes spanned the full continuum of FASD, with a majority of these young children receiving a diagnosis of ND/AE (60%). An overwhelming majority of our sample (90–98%) had documented exposure to prenatal and/or postnatal risks, in addition to their PAE. At the time of the assessment, 34% percent of infants/toddlers were living with their birth mother or father. The demographic and clinical profiles of the current study sample were largely representative of the entire birth to 3.5-year population evaluated in the FASDPN clinic ($n = 468$) from which they were drawn. The demographic and clinical profiles of infants/toddlers with Bayley-III, ITSP, and CBCL assessments were comparable to one another.

4.2. Research Question 1: Developmental performance on the Bayley-III

Bayley-III outcomes are presented in Figs. 2 and 3. The proportion of infants/toddlers that presented with delayed development (≤ -1.5 *SDs*) within each of the five domains ranged from Cognitive (12%), Social-Emotional (21%), Motor (24%), Language (31%), and Adaptive Behavior (33%). Within the Language and Adaptive Behavior domains, the most prevalent delays were observed in Receptive Language (27%) and Adaptive Behavior's Self Care (44%).

Of the 61 infants/toddlers with complete data across all five domains, 53 (87%) had one or more domains or subdomains with a developmental delay. Of the 125 infants/toddlers with two or more domains assessed using the Bayley-III, 93 (74%) had one or more domains or subdomains with a developmental delay. Since not all domains were assessed, 74% serves as a minimal estimate.

4.3. Research question 2: Sensory processing performance on the ITSP

Ninety-three infants/toddlers ranging in age from 7–36 months had a completed ITSP. Compared to the larger group of 125 children with Bayley-III assessments, this subgroup had no infants/toddlers diagnosed with FAS. The distribution of Bayley-III domain scores by classification category (typical, at-risk, delayed) in this subgroup was, however, very similar to the distribution of Bayley-III domain scores in the full group of 125 infants/toddlers. This would suggest the subgroup of 93 was likely reasonably representative of the full study group of 125.

Within each quadrant and section of the ITSP, roughly half of the infant/toddlers presented with outcomes in the probable or definite difference range (Fig. 4), with two exceptions (i.e., sensory seeking and visual processing). The most prevalent atypical patterns observed were Low Registration (reflecting a high threshold for sensory input and use of passive strategies to respond) and Auditory Processing (reflecting an inadequate ability to modulate sounds representing over or under responsiveness). Of the 93 infants/toddlers who completed the ITSP, all were rated with a definite difference in at least one quadrant/section of the ITSP.

4.4. Research question 3: Emotional and behavioral functioning on the CBCL

Sixty-seven infants/toddlers ranging in age from 18–42 months had a completed CBCL assessment. Compared to the larger group of

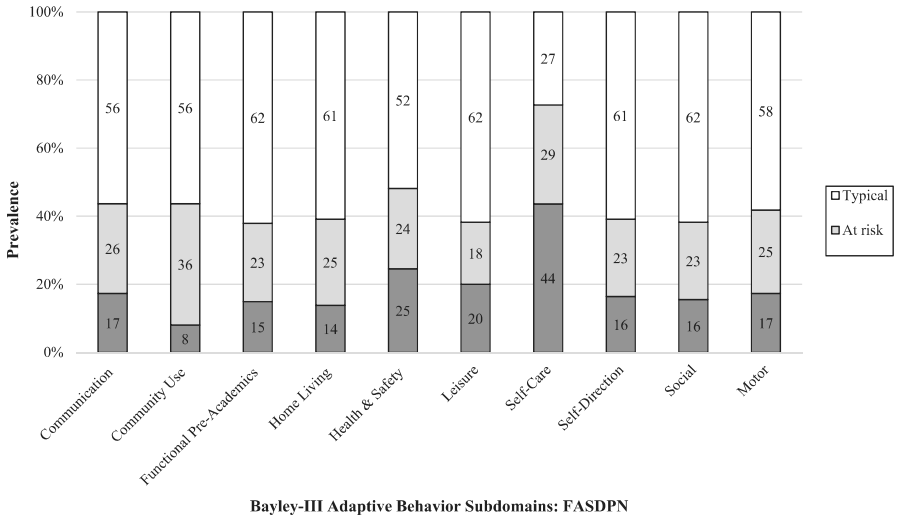

Fig. 3. Proportion of infants/toddlers with typical, at-risk, or delayed development in the Bayley-III Adaptive Behavior subdomains. Communication: n = 110, community use: n = 87, functional pre-academics: n = 87, home living: n = 87, health & safety: n = 110, leisure: n = 110, self-care: n = 110, self-direction: n = 110, social: n = 110, and motor: n = 110. Typical (scores ≥ -0.9 *SD*). At-risk (scores between -1.0 and -1.4 *SD*). Delayed (scores ≤ -1.5 *SD*).

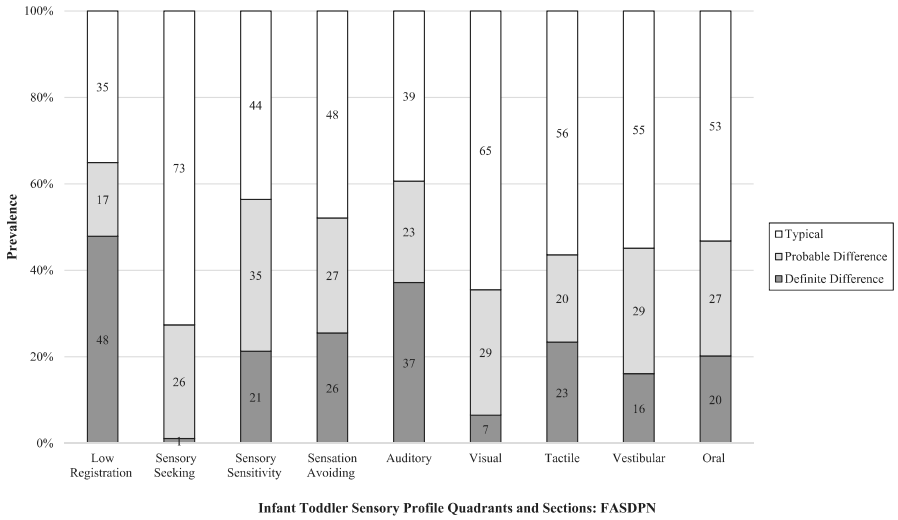

Fig. 4. Proportion of 93 infants/toddlers with typical performance, probable difference, or definite difference across the four ITSP quadrants (low registration, sensory seeking, sensory sensitivity, sensory avoiding) and five section (auditory, visual, tactile, vestibular, and oral sensory processing). Typical performance (scores at or between plus 1.0 *SD and minus 1.0 SD*), probable difference (scores within −1.1 to −1.9 SDs or within +1.0 to + 1.9 SDs), and definite difference (scores at or below −2 SDs or at or above +2 SDs).

125 infants/toddlers, this subgroup had no children diagnosed with FAS and only one child with PFAS. The distribution of Bayley-III domain scores by classification category (typical, at-risk, delayed) in this subgroup was comparable to the full group of 125 infants/toddlers.

Approximately half of the infants/toddlers presented in the borderline or clinical range on the Internalizing, Externalizing and/or Total problem scales (Fig. 5). Attention Problems had the highest prevalence of elevated scores on the Syndrome scales (37%) and Pervasive Developmental Problems had the highest prevalence of elevated scores on the DSM-Oriented Scales (42%; Fig. 5). Of the 67

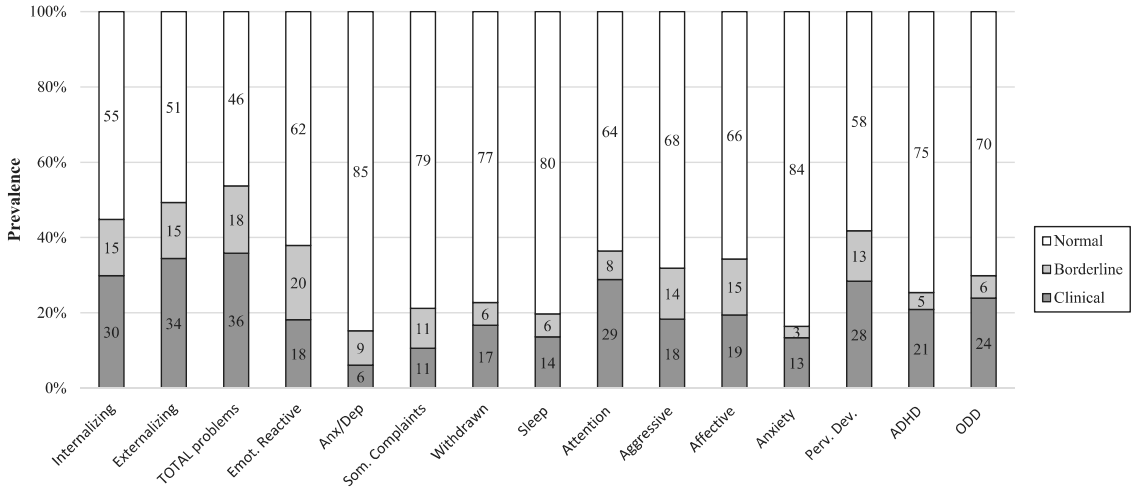

Fig. 5. Proportion of 67 infants/toddlers with scores in the normal, borderline clinical and clinical range across three Summary Scales (Internalizing, Externalizing and Total problems), seven Syndrome Scales (Emotionally Reactive, Anxious/Depressed, Somatic Complaints, Withdrawn, Sleep, Attention, and Aggressive problems) and five DSM-Oriented Scales (Affective, Anxiety, Pervasive Developmental, Attention Deficit Hyperactivity, and Oppositional Defiant problems) of the CBCL. Summary *t*-scores are categorized as Normal (*t*-scores < 60), Borderline (*t*-scores 60 *to* 63) and Clinical (*t*-scores ≥ 64). Syndrome and DSM-Oriented Scale *t*-scores are categorized as Normal (*t*-scores ≤ 64), Borderline (*t*-scores 65 *to* 69), and Clinical (*t*-scores ≥ 70).

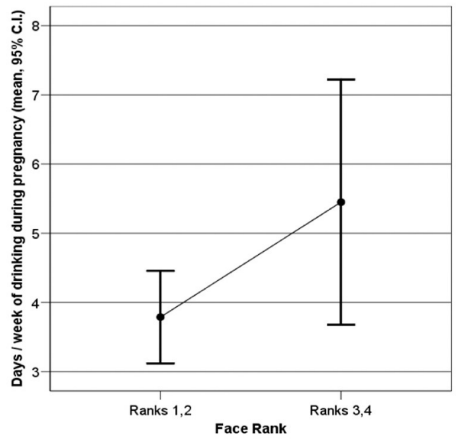
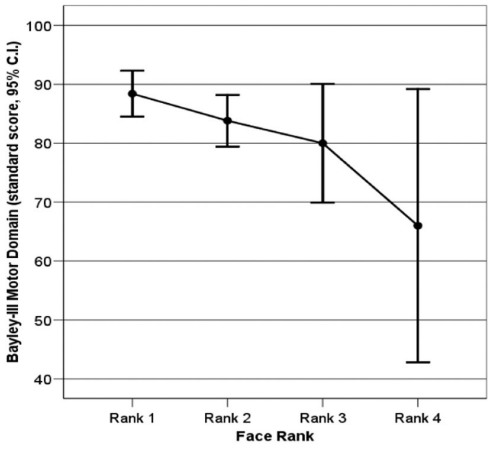
A.



B.



C

(caption on next page)

Fig. 6. Mean scores across all Bayley-III domains and subdomains (with the exception of Adaptive Behavior) decreased with increasing PAE. Using the Motor domain as an example: A. The mean Bayley-III Motor score decreased with increasing number of days/week of drinking during pregnancy ($t = 0.9$, $p = 0.36$). Only 60 infants/toddlers had days/week of exposure reported, limiting the statistical power to identify significant outcomes. B. Face Rank is a proxy measure for PAE and was available on all 125 infants/toddlers. Infants/toddlers with Face Ranks 3 and 4 had significantly higher days/week of PAE than infants/toddlers with Face Ranks 1 and 2 ($t = -2.0$, $p = .05$). C. Using Face Rank as a proxy measure for PAE, mean Bayley-III Motor scores decreased significantly with increasing Face Rank (ANOVA F linear term 14.3, $p = .000$). Mean scores across all Bayley-II domains decreased with increasing PAE.

infant/toddlers with CBCL data, 29 (43%) scored in the clinical range on the Internalizing, Externalizing and/or Total Problem scales.

4.5. Outcomes spanning all three measures

Two additional exploratory analyses were conducted to document the proportion of infants/toddlers who presented with a clinically significant delay (≤ -1.5 *SDs*) in one or more areas of the Bayley-III, ITSP and CBCL. Of the 31 infants/toddlers with full data across all three assessments, 30 (97%) presented with a clinically significant delay in at least one area of the Bayley-III, ITSP and/or CBCL, while 17 (55%) presented with a clinically significant delay across all three assessments. For the entire sample of 125 infants/toddlers (including those with complete and incomplete data), 124 (99%) presented with a clinically significant delay in at least one area of the Bayley-III, ITSP and/or CBCL.

4.6. Research Question 4: Associations between independent variables (PAE, other postnatal risk factors, gender and age) and dependent variables (Bayley-III, ITSP, CBCL)

Mean scores across all Bayley-III domains and subdomains (with the exception of the Adaptive Behavior domain) were lower (although not significantly lower) among those infants with 5–7 days/week of PAE compared to those with 1–4 days/week of PAE (Fig. 6A). Decades of analyses conducted with FASDPN data has shown that the greater the number of days/week of drinking during pregnancy (i.e., 5–7 days/week versus 1–4 days/week), the more severe the FAS Facial Rank (Astley, 2010, 2013). Only 62 infants had days/week PAE reported, limiting the statistical power to identify significant associations. Previous research has confirmed the FAS Facial Rank serves as an accurate proxy measure of PAE. Data from the first 1400 patients diagnosed at the WA FASDPN document the more severe the 4-Digit FAS facial phenotype (Facial Ranks 1–4), the greater the number of days/week of drinking during pregnancy (significant linear trend, F=10.7, $p = 0.001$) (see Figure 10 from Astley, 2013). Since this same association was observed in the current study (Fig. 6B), the FAS facial rank was used as a proxy for PAE in the current study. Unlike the limited number of infants/toddlers with days/week of PAE reported, all 125 infants/toddlers had a Facial Rank. All Bayley-III domain and subdomain scores (with the exception of Adaptive Behavior) decreased significantly with increasing severity of the FAS facial phenotype (as demonstrated in Fig. 6C for the Motor domain). Domain standard scores decreased roughly 10–20 points from Face Rank 1 to Face Rank 4. Subdomain

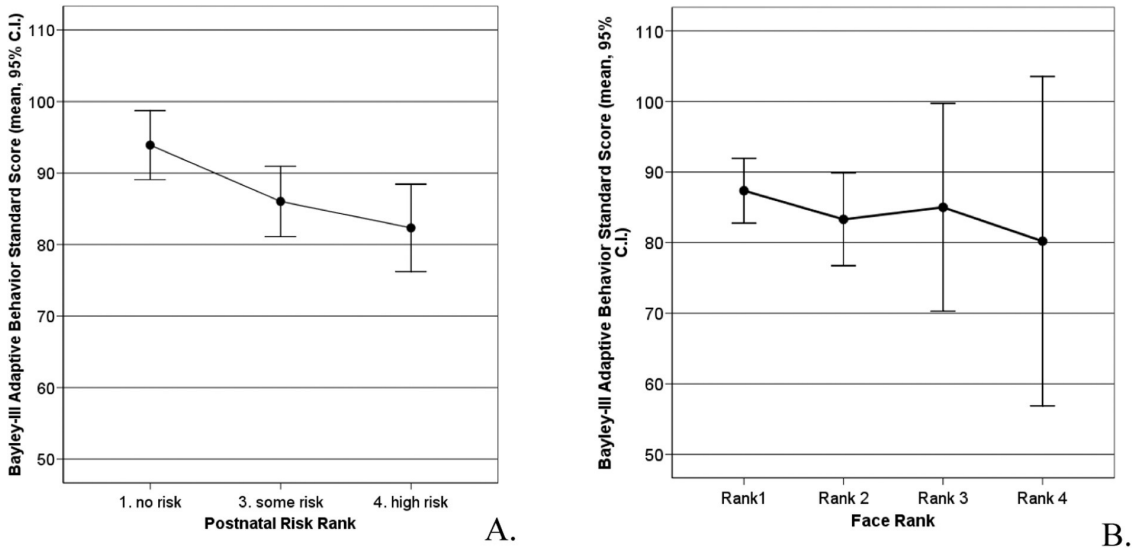


Fig. 7. Impairment in Adaptive Behavior appeared to be more strongly associated with postnatal risk factors than PAE. A. The mean Bayley-III Adaptive Behavior standard score decreased approaching statistical significance with increasing severity of the postnatal risk rank (Linear Term: $F = 1.7$, $p = 0.067$). B. The mean Bayley-III Adaptive Behavior standard score did not decrease linearly with Face Rank (a proxy measure for PAE) (Linear Term: $F = 0.6$, $p = 0.46$).

scaled scores decreased roughly 2–4 points from Face Rank 1 to Face Rank 4. Fig. 7.

The magnitude of postnatal risk was also explored with outcomes across the Bayley-III domains. Interestingly, the mean scores in the Adaptive Behavior domain decreased with increasing levels of postnatal risk, and approached significance (ANOVA: $F = 3.4$, $p = .067$). This is in contrast to mean scores in the other developmental domains whereby scores decreased relative to PAE, but not for the postnatal risk rank. The number of home placements, as a proxy measure of postnatal risk, were also explored relative to Bayley-III outcomes. Mean Cognitive and Expressive Language scores were significantly inversely correlated with the number of home placements ($r = -.18$, $p = .049$ and $r = -.21$, $p = .041$, respectively).

To explore developmental competencies across the early intervention years, two age categories were created (2–23 months and 24–42 months). Limited sample sizes precluded the use of four age categories (i.e., one for each year of life). Delays in the Language and Motor domains were significantly more prevalent (45% vs 10%, $X^2 = 12.8$, $p = .002$% and 35% vs 11%, $X^2 = 8.3$, $p = .016$ respectively) among the younger age group (2–23 months) than the older age group (24–42 months). Conversely, Social-Emotional delays were significantly more prevalent among the older age group relative to the younger group (28% vs 15%, $X^2 = 6.0$, $p = .049$). Mean Language domain scores (89, *SD* 13.9) were significantly higher among females than males (83.2, *SD* 13.3) ($t = -2.0$, $p = .048$).

Limited sample sizes precluded in-depth analyses of three ITSP quadrants/sections because they were divided into multiple age categories (i.e., Sensation Seeking, Tactile and Oral Sensory processing). However, for those remaining quadrants/sections without multiple age categories (i.e., Low Registration, Sensory Sensitivity, Sensation Avoiding, Auditory, Visual and Vestibular processing), no significant associations were found for age, gender, PAE, postnatal risk, and number of home placements.

The prevalence of emotional and behavioral problems did not vary significantly by age, gender, PAE, or number of home placements. However, scores on the Withdrawn and Oppositional Defiant Problems scales were positively correlated with increasing level of postnatal risk rank ($r = .25$, $p = .048$ and $r = .28$, $p = .024$ respectively).

5. Discussion

This research is notable as it is the first paper to describe a wide range of developmental, sensory, and behavioral outcomes in a very young sample of children with confirmed PAE from a specialty clinic for individuals with PAE. Of the 31 infants/toddlers with full data across all three assessments, 30 (97%) presented with a clinically significant delay in one or more areas of the Bayley-III, ITSP and/or CBCL, while 17 (55%) presented with one or more clinically significant delays in each of the three assessments. For the entire sample of 125 infants/toddlers (including those with complete and incomplete data), 124 (99%) presented with a clinically significant delay in one or more areas of the Bayley-III, ITSP and/or CBCL. These findings highlight the substantial diversity and prevalence of challenges experienced by infants/toddlers with PAE during the early intervention period.

5.1. Developmental outcomes and implications

Within each of the five Bayley-III domains, roughly half the infant/toddler study population had at-risk or delayed development. The prevalence of delayed development was lowest in the Cognitive (12%) and Motor (24%) domains, higher in the Language domain (31%) and highest in the Adaptive Behavior domain (33%). This pattern of delayed development was remarkably comparable to the pattern observed among the first 1400 patients with PAE (infant to adult) evaluated in the FASDPN clinic through 2005 (Astley, 2010) and among the 2283 patients with PAE evaluated at the FASDPN through 2020 (infant to adult) presented on the FASDPN Tableau Dashboard (Hemingway, 2022a). While the pattern of developmental delay (from least prevalent to most prevalent) is comparable between this infant/toddler study sample and our predominantly older childhood/adult FASD clinical population, the prevalence of severe impairment (2 or more SDs below the mean) in each domain is roughly two-fold greater in the older childhood/adult population (cognition 24%, motor 25%, language 39%, adaptive behavior 59%) (Hemingway, 2022a). Given that older children and adults have more mature neuropsychological function and can be assessed with more sophisticated neuropsychological instruments, one might expect to detect a higher prevalence of impairment when using these more sensitive instruments (Clarren et al., 2000). These findings provide evidence that a global developmental measure, such as the Bayley-III, may be useful for identifying early indicators of delay among infants/toddlers with PAE. Early identification leads to early intervention. A future longitudinal study is planned to assess whether the Bayley-III predicts which individual infant/toddlers go on to present with cognitive, language, motor, social emotional and/or adaptive behavior impairments later in childhood.

In this clinical sample of infants/toddlers, significant correlations were observed between PAE and developmental delay. Findings demonstrated that Bayley-III domain and subdomain scores (with the exception of Adaptive Behavior) decreased significantly with increasing levels of PAE, which further supports known trends on the gradient effect of alcohol on severity of outcomes (Astley, 2013; Carr et al., 2010; Subramoney et al., 2018). Individuals with PAE typically present with a multitude of other prenatal and postnatal risk factors that likely contribute, at least in part, to their adverse outcomes. Hemingway et al. (2020) reported other prenatal and postnatal risk factors were 3 to 7-fold more prevalent in the FASDPN clinical population than in the general population. Ninety percent of this infant/toddler population presented with adverse prenatal and postnatal risks. Significant correlations were observed between postnatal risks including multiple home placements and adaptive behavior, cognition, and expressive language delays. Similar to literature showing associations between early adverse experiences and poorer functioning in the general population (Garner & Shonkoff, 2012; van der Kolk, 2003), and among individuals with PAE (Coggins et al., 2007; Hemingway et al., 2020; Price et al., 2017; Streissguth et al., 2004), our analyses revealed a significant correlation between other postnatal risks and adaptive behavior delays. This suggests that the postnatal environment may have an impact on these developing behaviors, warranting further research since

adaptive behaviors are a lifelong disability and because there continue to be ongoing questions about the impact of biological vs environmental risks in this complex population of children.

5.2. Sensory processing outcomes and implications

Atypical sensory processing behaviors were observed in a large proportion of infants/toddlers. Based on our work with older children with PAE (Jirikowic et al., 2020; McLaughlin et al., 2019), the sensory processing patterns most impacted were low registration (65%) and auditory processing (61%). In general, infants/toddlers in this study had a high threshold for sensory input (e.g., does not notice stimuli easily) and used passive strategies to regulate (e.g., remains in situations that are uncomfortable rather than controlling for the amount and type of input). Infants/toddlers also showed a decreased capacity to modulate sound, as evidenced by ratings of over-responsiveness or under-responsiveness to auditory input. Definite differences in low registration and auditory processing were similarly reported in a clinic-referred sample of infants/toddlers with PAE, with even more severe impacts in those diagnosed with FASD (Fjeldsted & Xue, 2019). Current findings were consistent with those using FASDPN clinical data (Jirikowic et al., 2020; McLaughlin et al., 2019), showing that preschool and school-age children with FASD had the highest proportions of definite differences in Auditory Filtering and Under-responsive/Sensation Seeking domains using the Short Sensory Profile (SSP; McIntosh et al., 1999). Although an exact comparison cannot be made between ITSP and SSP domain categories, findings suggest that a caregiver-reported measure of sensory processing, such as the ITSP, may be useful for identifying sensory processing differences among infants/toddlers with PAE. Importantly, a child's ability to engage and participate successfully in everyday life, including forming healthy attachment relationships, is closely tied to their sensory processing abilities (Dunn, 2007). When early intervention providers and families have a working knowledge of sensory processing, they can reframe their understanding of their child's behavior and develop appropriate intervention strategies.

5.3. Emotional and behavioral functioning outcomes and implications

Atypical emotional and behavioral problems on the CBCL were observed in a large proportion of infants/toddlers. Results are consistent with prior research demonstrating that problem behaviors co-occur in older children with FASD (Astley, 2010; Astley et al., 2009; Franklin et al., 2008; Jirikowic et al., 2008). Notably, the prevalence of Total Problem scores in the clinical range for the older children (5–10 years of age) (86%; Franklin et al., 2008) and 79% among 997 children 6–18 years of age from the FASDPN clinic (Hemingway, 2022b) were much higher in comparison to the current sample of infants/toddlers (birth to3.5 years of age) with PAE (36%). The prevalence of Attention Problems in the clinical range (61% among 730 children 6–18 years of age from the FASDPN clinic (Hemingway, 2022b) was 3-fold greater than the prevalence (21%) among the infant/toddlers in the current study. A future longitudinal study, with larger numbers and a comparison group, would add significantly to the literature on the trajectory of emotional and behavioral outcomes in young children with PAE and the protective and risk factors associated with these outcomes.

5.4. Limitations

This study had a number of potential limitations. First, because this was a retrospective chart review using diagnostic clinical data, our results are limited by the clinical data available. Missing data due to a flexible clinical assessment protocol and some incomplete caregiver-report measures contributed to uneven datasets for each infant/toddler, thus limiting the analysis of outcomes at the individual level. Future studies, with a larger prospective sample and assessments spanning similar age ranges, could examine neurodevelopmental profiles in relation to sensory processing differences and problem behavior. Additionally, further research could examine how factors such as attachment relationships, family engagement or early intervention impact infant/toddlers' emerging, and declining competencies. Second, this was a clinic-referred sample and might not represent all infants/toddlers with PAE. It is important to note that the FASDPN clinic does not require patients to present with a concern or delay in order to receive an FASD evaluation; they only need to have a confirmed PAE at any level. For this reason, our study sample may more closely resemble the broader population of infants/toddlers with PAE compared with other clinic-referred samples. Third, the ITSP, CBCL and Adaptive Behavior components of the Bayley-III are standardized measures based on caregiver report, which are inherently susceptible to reporting bias. Nevertheless, researchers working towards the earlier identification of children with PAE (Astley, 2010; Bakhireva et al., 2018), and children with autism spectrum disorders (Zwaigenbaum & Maguire, 2019), advocate for the use of caregiver-reported assessment to identify early appearing problems in development and behavior. One additional limiting factor to consider is the potential for cohort effects, given that data from this sample of infants/toddlers were collected over a 10-year time span (2009–2019). No annual temporal trends were observed from 2009 to 2019 across any of the following study population characteristics: number of infant/toddlers diagnosed, gender, race, FASD diagnostic outcome or level/rank of prenatal alcohol exposure.

6. Conclusion

An overwhelming majority of infants/toddlers with PAE in this sample presented with clinically significant delays in development, sensory processing and/or emotional and behavioral functioning. Present findings, considered with similar studies reported in the literature, suggest that most domains of child functioning are vulnerable to the teratogenic impact of PAE and that these delays are evident in the first years of life. Findings reinforce the value of early screening, ongoing monitoring, and comprehensive assessment to facilitate earlier identification and to provide opportunities for infants/toddlers with PAE and their caregivers to benefit more fully

from early supports and intervention.

What is FASD?

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. FAS is characterized by growth deficiency, permanent brain damage, and unique facial features. Not all children exposed to alcohol during gestation are born with FAS. Many are born with the same severity of brain damage, but do not have the facial features that permit a diagnosis of FAS. These children need the same social, educational, and healthcare services as children with FAS and far outnumber children with FAS. The full spectrum of damage caused by prenatal alcohol exposure is called Fetal Alcohol Spectrum Disorders (FASD). For every child with FAS, there are 10 with FASD.

What is the Fiscal Impact of FASD on Washington State?

- It costs WA an estimated 2 million dollars in lifetime social and health care services for every child born with FASD.
- It costs Medicaid 9 time more to cover the medical expenditures for a child with FAS than for a child without FAS.
- Preventing FASD in just one child will pay for over 5 years of the FASDPN operating costs.
- Prevention starts with diagnosis. Women at highest risk for producing children with FASD are women who have already given birth to a child with FASD. The FASDPN clinic identifies over 100 high-risk women annually through the diagnosis of their children.
- It costs Washington State 30 times more to raise a child with FASD than to prevent FASD in a child.
- Published empirical data confirms FASD prevention efforts are working in WA State and FASD diagnoses lead to effective intervention.

VII. FASD Facts

- FASD is 100% preventable. The FASDPN has empirical evidence documenting it is successfully preventing FASD in WA.
- FASD is the leading known cause of intellectual disabilities.
- An estimated 870 children are born with FASD in WA each year (1% of all births).
  An estimated 70,000 individuals with FASD of all ages currently live in WA State.
- FASD is not just a health care issue. Its primary impact is on schools, foster/ adoptive care, the justice system, and mental health services.
- Less than 10% of adults with FASD live independently or remain employed.

What is the WA FAS Diagnostic and Prevention Network (FASDPN)?

- The University of Washington FASD diagnostic clinic opened in 1993. It has been providing FASD diagnostic services for 31 years.
- The clinic expanded into the statewide WA FASDPN in 1995 through RCW 70.96A.500 and is the first program of its kind in the nation.
- The WA FASDPN has included up to 6 Satellite clinics led by the Core diagnostic/research/training site in at the University of Washington. See our interactive data Tableau Dashboards
- The WA State FASDPN is recognized as a national/international model for FASD diagnosis and prevention demonstrating an invaluable partnership between academic research and public health through interagency collaboration (WA FASD Interagency Workgroup).
- Our Mission is FASD prevention through FASD screening, diagnosis, intervention, research, and training.

What does the FASDPN do for children, families, and health care professionals in WA? (2014 FASD State Recommendations)

Diagnostic Program

- The FASDPN provides 100% of the interdisciplinary FASD diagnostic evaluations in WA State. The FASDPN is currently funded to conduct 70 diagnostic evaluations annually. The demand for FASD diagnostic evaluations exceeds the State's current capacity to provide timely FASD diagnostic evaluations. The average wait time for a family seeking an evaluation is 2 to 12 months.
- The FASDPN provides accurate diagnoses and comprehensive care plans for individuals under 22 years of age with prenatal alcohol exposure. Patient satisfaction is high. 92% of families report they received help from us they could not receive elsewhere. 89% report the FASD diagnosis afforded them access to interventions that met their needs. 99% would recommend our diagnostic services to other families in similar need.
- We developed the evidence-based FASD 4-Digit Code Diagnostic System and FAS Facial Recognition Software that is used worldwide.

Training Program

- We provide FASD training to 1000s of community health care, educational, correctional, and social service students and providers statewide.

Screening Program

- We used our FAS Facial Recognition Software to screen all children entering King County Foster Care for FAS for 10 years. The prevalence of FAS in King County foster care is 10 times higher (1/100) than in the general population (1/1000). Early accurate diagnosis is confirmed to reduce secondary disabilities like school failure, job loss, and trouble with the law.

Intervention Services

- Patients/families report tremendous access to and benefit from interventions recommended by the FASDPN clinics. FASDPN published research confirmed early diagnosis and a stable, nurturing home environment led to significantly reduced brain dysfunction. The FASDPN has attracted millions of dollars in free assessment (e.g., MRIs, neuropsychological exams) and intervention services (e.g., 9-month in-home intervention) for hundreds of WA children through the FASDPN research program. Family advocacy is provided by FASD Focus NW.org .

Primary Prevention Program

- We identify women at highest risk to give birth to children damaged by prenatal alcohol, namely the birth mothers of children diagnosed with FASD at our FASDPN clinics. We provide the women with referrals to appropriate community-based programs including the Parent-Child Assistance Program to help them reduce their use of alcohol during pregnancy and practice effective family planning.
- Published evidence supports WA FASD prevention efforts are working! A significant reduction in maternal drinking during pregnancy correlated with a significant reduction in the number of children being born with FAS in WA State.

Research Program

- The FASDPN has attracted millions of research dollars to WA State to support free neuropsychological evaluations, MRIs, and 9-month, in-home intervention services for children and families impacted by FASD (Families Moving Forward).

Executive Summary

The mission of the Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network (FASDPN) since its inception in 1993 is primary and secondary prevention of fetal alcohol spectrum disorders (FASD) through screening, diagnosis, intervention, research, and training/education. Primary prevention refers to prevention of FASD births. Secondary prevention refers to prevention of secondary disabilities among individuals exposed to and damaged by prenatal alcohol exposure. The FASDPN's innovation and utility have been nationally and internationally recognized and replicated. A summary of our accomplishments to date is presented in our Legislative Fact Sheet above and detailed in full below.

Washington is one of very few states that has significantly reduced the prevalence of drinking among pregnant women through primary prevention efforts such as those conducted by the FASDPN and the WA State Parent-Child Assistance Program (P-CAP). Women in Washington State reported a significant decrease in their consumption of alcohol during pregnancy from 7.8 percent in 1993 to 3.9 percent in 1998, exceeding the Health People 2010 National Goal of 6% (Washington State DOH, May 2002). This significant decline in the prevalence of maternal drinking during pregnancy corresponded to a significant decline in the prevalence of FAS among foster children born between 1993 to 1998. These observations strongly support that FAS prevention efforts in Washington State were working (Astley, 2004). A comprehensive summary of WA State efforts to prevent FASD from 1968-2004 are posted on the WA FASD website in a document entitled FASD: WA State History.

It is paramount that WA State sustain its successful efforts to reduce the incidence of FASD. Unfortunately, the most recent CDC Pregnancy Risk Assessment Monitoring System (PRAMS) data for WA documents a small, but steady increase in maternal reporting of drinking during pregnancy, in contrast to the steady decline observed in the early 1990s (Astley Hemingway et al., 2023). Preliminary data documents this increase in drinking is associated with an increase in prevalence of FAS in foster care among children born after 1998. To reverse this trend, the WA FAS Interagency Workgroup intensified its efforts on FASD identification, prevention, intervention, and policy as outlined in House Bill 2737. The WA FAS Interagency Workgroup, chaired by Susan Astley Hemingway, PhD, submitted a comprehensive report entitled "Recommendations from the WA FASD IAWG" to the State Legislature in December 2014 to describe the impact of FASD on WA State; identify evidence-based practices for early screening, diagnosis, prevention, and intervention; and recommend policy changes. In 2024 the WA State Legislature approved House Bill 1168 to once again expand diagnostic services and increase availability of intervention.

2024 marks the 32nd year of operation for the University of Washington FASDPN core clinical/research/training clinic and the 29th year of legislative support for the expansion of the UW clinic into a statewide network of FASD clinics (FASDPN). We are gratified with our successes in the last three decades and are appreciative of the continued support we receive from the Washington State Legislature and Division of Behavioral Health and Recovery. This annual report summarizes our activities and progress through June 30, 2024. Essentially all tasks that were proposed to be completed by this date are completed; all work planned to be ongoing at this time is ongoing. The remainder of this report provides further detail on the background and establishment of the FASDPN and our accomplishments to date.

Full Report

I. What is Fetal Alcohol Spectrum Disorder (FASD)?

FASD is an umbrella term used to describe the spectrum of adverse outcomes that can occur in an individual whose mother drank alcohol during pregnancy. These outcomes may include physical and neuropsychological abnormalities with lifelong implications. The term FASD was not intended for use as a clinical diagnosis. Rather, the spectrum of diagnoses that fall under the umbrella of FASD include FAS, Static Encephalopathy/Alcohol-Exposed, and Neurodevelopmental Disorder/Alcohol-Exposed. FAS is a permanent birth defect syndrome characterized by growth deficiency, a unique cluster of minor facial anomalies and structural, neurological and/or functional brain abnormalities. FAS was first discovered by Christy Ulleland, MD at the University of Washington in 1972 (Ulleland et al., 1972). The term FAS was first coined in the medical literature in 1973 by University of Washington professors Kenneth Jones MD and David Smith MD (Jones & Smith, 1973). FASD is the leading known cause of intellectual disability and is 100% preventable. The incidence of FAS is estimated to be 1 to 3 per 1,000 live births in the general population, similar to the incidence of down syndrome (Abel & Sokol, 1987). The prevalence of FAS in King County foster care is 10 times greater than in the general population or approximately 1 out of every 100 children (Astley, et al., 2002). In Washington State an estimated 200 infants are born with full FAS each year. Not all infants exposed to and damaged by prenatal alcohol exposure have FAS. Many infants damaged by prenatal alcohol exposure have brain damage that can be as severe as the damage seen in infants with FAS, but do not have the physical anomalies (growth deficiency and/or facial anomalies) that permit a diagnosis of FAS. The medical, educational, and social service needs of these individuals with Static Encephalopathy/Alcohol Exposed and Neurodevelopmental Disorder/Alcohol Exposed are no different than those with FAS (Jirikowic et al, 2010). In Washington State, an estimated 870 children are born with FASD each year (1% of births) and approximately 70,000 individuals with FASD of all ages currently live in Washington State. Early diagnosis, intervention and a stable, nurturing home environment with intervention and accommodations helps reduce the prevalence of secondary disabilities such as school failure, unemployment, and trouble with the law. This was confirmed in a publication (Astley, 2010) summarizing the outcome of the first 1,400 patients diagnosed at the FASDPN clinics. Despite heavy prenatal alcohol exposure, 9.3% of patients evaluated in the clinic present with normal growth and development. The two features that significantly differentiated this small group of children from the much larger group of children that presented with significant cognitive/behavioral impairments was an early diagnosis and a stable, nurturing home environment.

II. Establishment of and Funding History for the FAS Diagnostic and Prevention Network (FASDPN)

Fetal Alcohol Spectrum Disorder (FASD) has been identified as an important health issue. The 1994 Washington State Public Health Improvement Plan identified maternal substance abuse during pregnancy and the resulting alcohol related birth defects as an important public health issue. The March of Dimes Western Washington Chapter Needs Assessment (1992) community Delphi survey found the communities' top concern was perinatal substance abuse and its resultant problems. The Washington State 1995 MCH Title X Block Grant identified substance use/abuse during pregnancy and its resultant negative outcomes as an area of focus for 1995. In 1992, Congress mandated the CDC to lead national efforts in FASD prevention. In response to the mandate, the CDC released an Request of Proposals that would fund 5 clinical research teams nationwide to empirically assess proposed methods for FASD prevention. The University of Washington was one of the five recipients of the CDC funding. The UW proposed to identify and intervene with women at highest risk for bearing

children with FAS/D by opening the first ever interdisciplinary FASD diagnostic clinic. Women at highest risk for bearing children with FAS/D are women who have already given birth to a child with FAS/D.

Back in 1992, FASD was not easily assigned to any specific medical specialty or governmental agency for overall leadership. Psychiatrists are primarily interested in problems of substance abuse, obstetricians are primarily interested in pregnancy risk reduction, pediatricians and pediatric subspecialties like genetics, dysmorphology, neurology, and developmental disabilities are primarily interested in the diagnosis and management of affected children (it is unclear who has specialty concern for affected adults). All of these groups express interest and some expertise in dealing with a portion of the FASD management problem, but no specialty is positioned to assume responsibility for the whole. Similarly, in government, the challenges faced by these affected individuals requires the involvement of schools, social service agencies, alcohol treatment agencies, the criminal justice system, vocational rehabilitation, developmental disabilities, health agencies, etc. All of these agencies have an important role to play in helping affected patients, but no single agency is in a position to organize and direct services across recognized divisional and departmental boundaries.

Providing diagnostic and intervention services to both mother and child through a FASD Diagnostic Clinic not only benefits the mother and child but has the potential of being a very cost-effective approach to FASD primary prevention (Astley et al., 2000a). Based on the results of the study published by Astley et al., (2000a), one out of every three patients evaluated in the FASDPN clinics is diagnosed with FAS or Static Encephalopathy/Alcohol Exposed. The birth mothers of one out of every three of these children can be directly contacted. Half of the birth mothers directly contacted will still be at risk for producing more children damaged by prenatal alcohol exposure. Thus one out of every 18 children evaluated in the FASDPN clinics has a birth mother who can be found and is at risk for giving birth to more children damaged by prenatal alcohol exposure. The cost to society to raise a child with FAS was estimated to be $1,000,000 in the 1980s (Abel and Sokol, 1987). A diagnostic evaluation for a child through a FASDPN clinic cost approximately $1,200 in 2007 (Astley et al., 2007a). Providing effective intervention to the highest risk birth mothers through the Parent-Child Assistance Program cost an estimated $3,800 per year per woman over three years in 1999 (Grant *et al*., 1999). One out of every 10 children evaluated in the FASDPN clinic is diagnosed with full FAS. If, on average, 18 children must be diagnosed to identify and intervene with one high-risk mother, the approximate cost to find and provide effective intervention services to the birth mother would be $33,000 ($21,600 to diagnose 18 children and $11,400 to provide three years of advocacy services to the mother through the P-CAP program). Thus, the cost of raising a child with FAS would be roughly 30 times the cost of preventing FAS in the child. The benefit to the mothers, their children, and society would be immeasurable.

Establishment of the FASDPN: In 1992 the University of Washington entered into a 5-year Cooperative Agreement with the CDC to conduct a FAS primary prevention study that focused on identifying and profiling the needs of women at high risk for giving birth to children with FAS. To identify the women, the CDC provided funds to establish an interdisciplinary FASD Diagnostic Clinic at the Institute on Human Development and Disability at the University of Washington (UW). This was the first ever interdisciplinary FASD diagnostic clinic in the world. The purpose of the clinic was to identify high-risk women through the diagnosis of their affected children. Although the UW clinic had the capacity to see 160 patients per year, the demand for diagnostic services far exceeded its capacity. In 1995, two additional FASD diagnostic clinics, led by the UW FASD clinic, were established in Federal Way and Everett through support from the Western Washington March of Dimes Birth Defects Foundation (Fig. 1). In 1996, the WA State Legislature through Senate Bill 5688

went one step further and expanded the single UW FASD clinic into a statewide network of six Satellite clinics led by the core clinical/research/training site at the University of Washington. In 2019, a 7th FASDPN site was established in King/Snohomish Counties: the Wonderland Hope Rising FASD diagnostic clinic.

The six Satellite FASDPN clinics were established in Spokane, Yakima, Whitman, Pierce, South King and Snohomish Counties (listed below). The University of Washington core staff provided FASD diagnostic training. A diagnostic manual "Diagnostic Guide for FAS and Related Conditions" (Astley & Clarren 1997, 1999; Astley Hemingway 2004, 2024), standardized diagnostic forms, and neuropsychological and motor-sensory assessment batteries were created to assure consistency and accuracy of diagnosis across all FASDPN sites. A comprehensive set of educational materials was also distributed. All sites were networked via interactive video teleconferencing and a centralized database was established.

Figure 1. Locations of FASDPN clinics between 1993-2024.

A. Core FASDPN Clinical/Research/Training Site:
   1. University of Washington, Institute on Human Development and Disability, Seattle. Susan J. (Astley) Hemingway, Ph.D. Director (1993 to present).

B. Six contracted Satellite FASDPN Sites:
   1. Pierce County: Mary Bridge Children's Hospital, Tacoma (1996-1999).
   2. South King County: Federal Way Public Health Clinic, Federal Way (1995-2004).
   3. Whitman County: Wilson Psychological Services, Pullman. (1997-2007).
   4. Spokane County: Sacred Heart Hospital, Spokane. (1997-2010).
   5. Yakima County: Children's Village, Yakima. (1997-2017).
   6. Snohomish County: Providence Medical Center, Everett. (1995-2017).

C. One noncontracted Satellite FASDPN site opened in 2019.
   1.King County: Wonderland Developmental Center, Hope Rising, Bothell (2019-present).

Overall, the six contracted Satellite FASDPN sites were maintained for an impressive number of years with four of the six open for 16 to 21 years. The primary reason for closure was insufficient funds.

Funding History for the Satellite Clinics: The six Satellite FASDPN clinics were community based and community owned since their inception in 1996. Each Satellite clinic typically conducted 1 or 2 diagnoses per month. Up until 2008, the Satellite clinics never received funding support through the FASDPN-DASA contract. The Satellite FASDPN clinics were supported through a variety of

mechanisms including: in-kind service from local professionals, in-kind space from local medical/public health facilities, fee for service (billing Medicaid and/or private insurance), cost shifting (the psychologist, speech language pathologist, and occupational therapist in a clinic are often 'on loan' one day per month from the local school district); and funds from local philanthropic agencies (e.g., March of Dimes, United Way). The Satellite clinics demonstrated the cost of conducting a single diagnostic evaluation in 2008 was approximately $3,500 in Washington State. This cost included administrative costs and professional fees and was commensurate with the cost of an evaluation in a typical neurodevelopmental clinic. Only a small portion of the cost could be billed to and collected from Medicaid and/or private insurance. Securing the remaining funds continued to be the number one challenge for these regional clinics. Many states have replicated the WA State FASDPN model and have encountered similar funding challenges. Alaska established 12 FASD Diagnostic Clinics in 1998. In a report prepared by the Alaska Mental Health Trust Authority, the average cost of a FASD diagnostic evaluation in Alaska in 2001 was $4,821. Like WA, Alaska demonstrated only $1,076 (22%) could be billed to and collected from Medicaid and/or private insurance. Recognizing that Medicaid and/or insurance alone would not cover the full cost of a diagnosis, Alaska established a FASD Diagnostic Services Provider Agreement in 2005. Qualified Alaska FASD diagnostic clinics received a Provider Agreement payment of $3,000 per diagnostic evaluation to cover the costs not covered by Medicaid/insurance. The Alaska Agreement was shared with the Washington State Legislature in Jan 2008. In 2008, the WA Legislature approved $100,000 to cover the cost of 50 FASD diagnostic evaluations conducted by four FASDPN Satellite clinics (Yakima, Pullman, Spokane, and Everett). These funds helped sustain these 4 clinics for a few more years, but by 2017, all four closed due to insufficient funds. The cost of $2,000 per diagnostic evaluation is reflective of costs 15-20 years ago. The current cost of an FASD diagnostic evaluation in 2024 in WA is roughly $6,500. By 2017, most of the FASDPN Satellite clinics closed due to insufficient funds. In 2024, the Legislature approved WA Second Substitute House Bill 1168 to re-establish FASD diagnostic and intervention services statewide. Establishing FASD diagnostic clinics statewide would provide more equitable access to diagnostic services and shorten the wait time for a diagnostic evaluation.

III. Interagency Collaboration and Personnel

Interagency Collaboration: From 1997 through 2014, the FASDPN met with representatives from NOFAS-WA, FASFRI, FADU, P-CAP, OSPI, MAA, CA, ITEIP, JRA, DOC, DOH, DSHS, DCFS, MCH, and IHS quarterly through the FAS Interagency Work Group (FAS IAWG) as stipulated by Senate Bill 5688. These meetings facilitated the development and implementation of all components of the FASDPN program. FASDPN staff members have also participated as speakers for the annual FASD conferences held by the FAS IAWG in 1999, 2000, 2001, 2005. Starting in 2007, the FAS IAWG merged its annual FASD conference with the ongoing Co-Occurring Disorders Conference. The FASDPN created and maintains WA State's FASD website. In 2015, the focus of the FAS IAWG was House Bill 2737. The FAS IAWG submitted a report entitled "Recommendations from the Washington State Fetal Alcohol Spectrum Disorders (FASD) Interagency Work Group" to the Governor and Legislature in December 2014. As an example of the benefits of working collaboratively with State agencies, in March 2015 DDD posted Management Bulletin D15-012 that expanded eligibility from just FAS to the full spectrum of FASD. The more rigorous, evidence-based method of diagnosis (the FASD 4-Digit Code) paved the way for this expanded DDD eligibility.

Key personnel at the University of Washington FASDPN Core site during the 2023-2024 fiscal year are listed below. Those marked with an * have been with the FASDPN for 15-32 years.

*Susan J. Astley Hemingway, Ph.D. FASDPN Director, Professor of Epidemiology/Pediatrics

*Julie Bledsoe, M.D.	Professor and Pediatrician
*Julian Davies, M.D.	Professor and Pediatrician
*Allison Brooks, Ph.D.	Psychologist
*Erin Olson, PhD.	Professor and Psychologist
*John Thorne, Ph.D, SLP	Professor and Speech/Language Pathologist
Ryan Conley, M.S. SLP	Speech/Language Pathologist from Hope Rising Clinic
*Tracy Jirikowic, Ph.D., OTR/L	Professor of Rehabilitation Medicine and OT
Jennifer Nash, Ph.D. OTR/L	Occupational Therapist
Misty Pruner, Ph.D. OTR/L	Occupational Therapist
*Julie Gelo, B.S.	Family Advocate, Director FASD Focus NW
Sandra McIntire	Program Assistant
*Faye Louie, B.S.	Clinic Coordinator

IV. Mission of the FASDPN

The mission of the Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network (FASDPN) is primary and secondary prevention of fetal alcohol spectrum disorders (FASD) through screening, diagnosis, intervention, research, and training/education. The FASDPN has achieved each of these missions as outlined below.

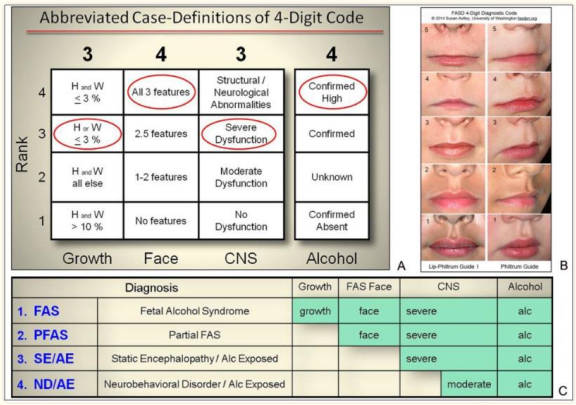
IV.A. Diagnosis

IV.A.1. FASD Diagnostic Model and Method

FASD Diagnostic Model: In 1993, the UW opened the first-ever interdisciplinary FASD diagnostic clinic sponsored by the Center for Disease Control (CDC) as a FASD primary prevention study. Data collected in the clinic was used to develop and validate the FASD 4-Digit Diagnostic Code in 1997 (Astley & Clarren, 1997, 2000). In 2024, the 4th edition of the 4-Digit Code was released (Astley Hemingway, 2024). The 4-Digit Code and interdisciplinary approach to diagnosis is used worldwide.

FASD is characterized by growth deficiency, a unique cluster of 3 minor facial anomalies and structural, neurological and/or functional abnormalities of the brain. Individuals with prenatal alcohol exposure present with a wide range of outcomes, most of which are not specific to (caused only by) prenatal alcohol exposure and often manifest differently across the lifespan. Professionals from multiple disciplines (medicine, psychology, speech-language pathology, occupational therapy) are needed to accurately assess and interpret the broad array of outcomes that define the diagnoses. The pattern and severity of outcome is dependent in part on the timing, frequency, and quantity of alcohol exposure (which is rarely known with any level of accuracy) and the fetus' genetic vulnerability to prenatal alcohol exposure (Astley et al., 2019a). The pattern and severity of outcome is also dependent on the other prenatal and postnatal risk factors that are prevalent among individuals with prenatal alcohol exposure (Astley, 2010; Astley et al., 2020). The FASDPN interdisciplinary team conducts an FASD diagnostic evaluation in one 4-hour evaluation. In preparation for the evaluation, all birth, medical, school and social service records are collected and reviewed. A summary of these records is presented to the team in the first half hour of the diagnostic evaluation. In the next 2 hours, the medical doctor conducts an interview with the caregiver(s) while the psychologist, speech-language pathologist and occupational therapist conduct standardized neuropsychological assessments on the patient. The team reconvenes for one hour and derives the FASD 4-Digit Code and composes a comprehensive intervention recommendation report. In the final half-hour of the evaluation the results are shared with the caregivers and a comprehensive medical summary report is submitted to the patient's medical records.

FASD Diagnostic Method: The FASDPN created the FASD 4-Digit Code in 1997 to guide interdisciplinary teams in the diagnosis of the full spectrum of FASD. A pictorial representation of the FASD 4-Digit Code is presented in Fig. 2). The four digits reflect the magnitude of expression of the four key diagnostic features of FASD in the following order: (1) growth deficiency, (2) the FAS facial phenotype, (3) brain structural, neurological and functional abnormalities, and (4) prenatal alcohol exposure. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic" presence of the FAS feature. Thus, the 4-Digit Code 4444 reflects the most severe expression of FAS (significant growth deficiency, all three FAS facial features, structural/neurological evidence of brain damage, and confirmed prenatal exposure to alcohol). At the opposite end of the scale is the 4-Digit Code 1111 reflecting normal growth, none of the three FAS facial features, no evidence of brain abnormalities, and confirmed absence of prenatal alcohol exposure. Every combination of 4-Digit Code has been observed among individuals with prenatal alcohol exposure evaluated in the WA State FAS Diagnostic & Prevention Network. The 4-Digit Code is fully validated (Astley, 2013) and serves as the cornerstone of a fully integrated and highly successful screening, diagnostic, prevention and surveillance program in Washington State (Astley et al., 2002; Astley, 2004a, 2013; Hemingway (Astley) et al., 2024).



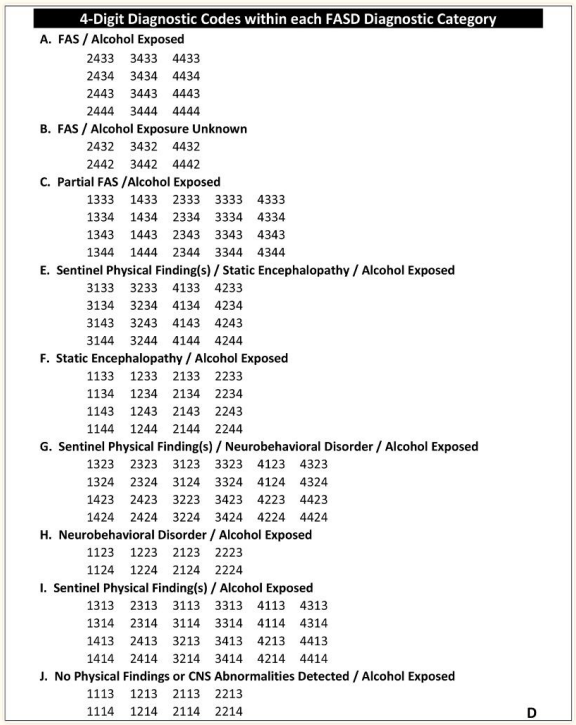


Figure 2. FASD 4-Digit Diagnostic Code.
A) Abbreviated case-definitions for the fetal alcohol spectrum disorder (FASD) 4-Digit Code (Astley, 2004). The 4-Digit Code 3434 is one of 12 4-Digit Codes that fall under the diagnostic category FAS. **B)** The Rank 4 FAS facial phenotype requires 3 features: 1) palpebral fissure lengths 2 or more standard deviations below the mean; 2) a smooth philtrum (Rank 4 or 5 on the University of Washington Lip-Philtrum Guide); and 3) a thin upper lip (Rank 4 or 5 on the University of Washington Lip-Philtrum Guide). **C and D)** The 4-Digit Code produces four diagnostic subgroups under the umbrella of FASD: FAS (Diagnostic Categories A, B), PFAS (Diagnostic Category C), SE/AE (Diagnostic Categories E, F), and ND/AE (Diagnostic Categories G, H). Abbreviations: CNS: central nervous system; H: height percentile; W: weight percentile. The 4-Digit Code was updated in 2024 (Astley Hemingway, 2024)

IV.A.2. FASD Diagnostic Outcomes and Patient Satisfaction

Of the 3,084 patients diagnosed in the FASDPN from 1993 through 2023, 3.3% received a diagnosis of FAS, 4.5% Patial FAS, 26.7% Static Encephalopathy/Alcohol-Exposed and 45.6% Neurodevelopmental Disorder/Alcohol-Exposed (Fig. 3A). The majority of patients were school-aged at the time of their diagnosis with 13.8% birth to 3 years of age and 5.3% 18 years and older (Fig. 3B). More detailed socio-demographics are provided in our profile of the first 1,400 patients diagnosed (Astley, 2010) and via our interactive Tableau Dashboards (e.g., Fig. 4) that are periodically updated. Seventy-eight percent of the patients seen in the FASDPN clinics were no longer in the care of their biological parents. The FASDPN provides accurate diagnoses and comprehensive care plans for individuals under 22 years of age with prenatal alcohol exposure. Ninety-four percent of families report they received medical/educational/social services in our clinics they could not find elsewhere. Ninety-nine percent would recommend the clinic to other families in similar need. Ninety-four percent of families report the intervention services we recommended met some to all their needs (Astley, 2014). A comprehensive profile of the first 1,400 patients evaluated in the WA FASDPN clinics was published in 2010 (Astley, 2010).

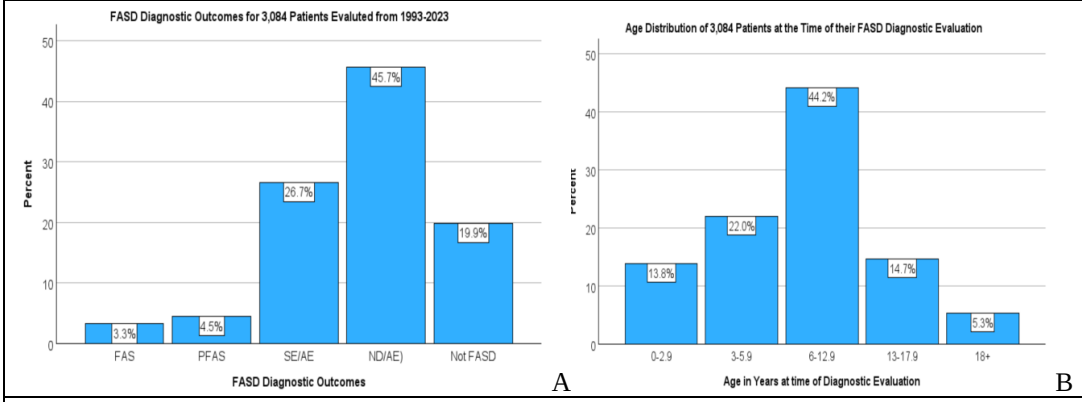

Figure 3. FASD diagnostic outcomes (A) and age distribution (B) of the 3,084 patients diagnosed at the FASDPN clinics from 1993-2023.

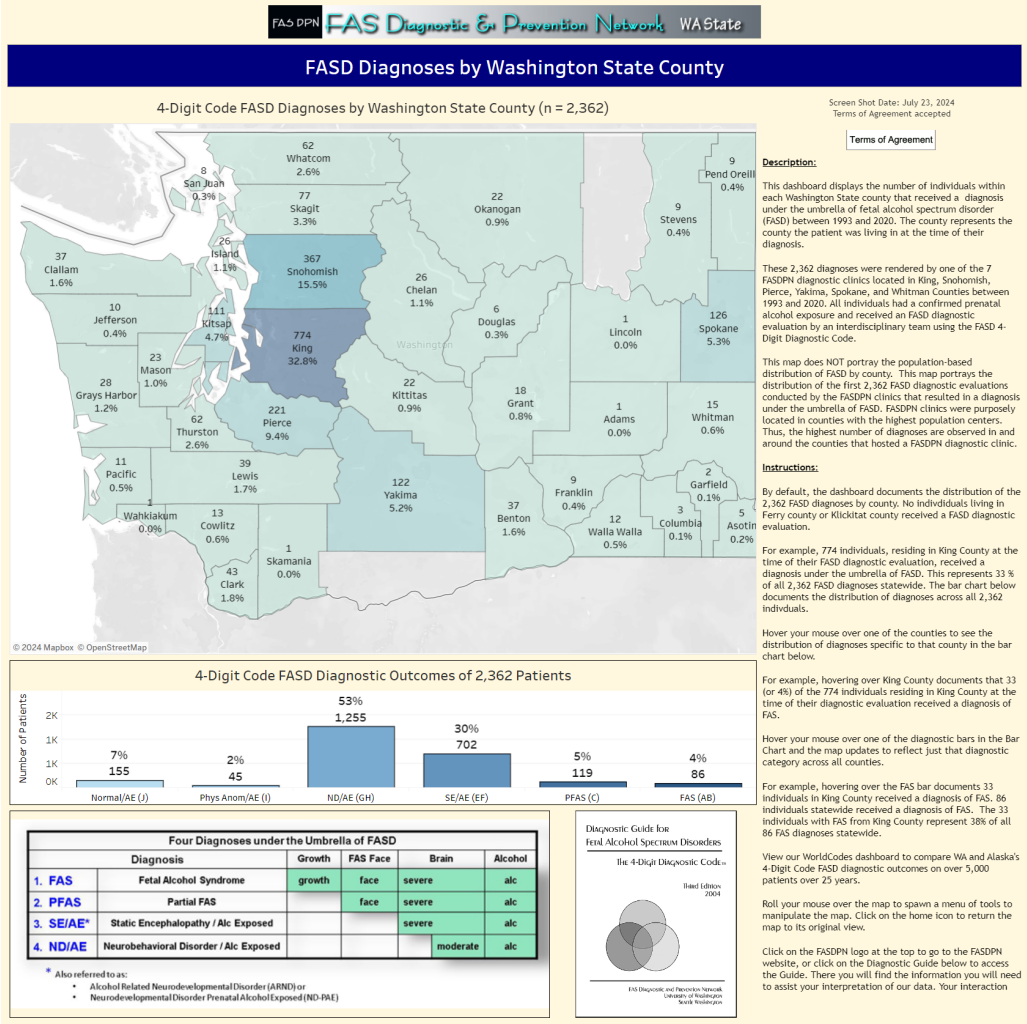

Figure 4. [FASDPN Interactive Tableau Dashboards](#). This interactive dashboard displays the number and percent of individuals receiving a diagnosis under the umbrella of FASD based on the Washington State County they resided in at the time of their FASD diagnostic evaluation. These evaluations were conducted on 2,362 patients between 1993 and 2021. This dashboard is updated periodically

IV.A.3. FASD Diagnostic Demand and Capacity over 30 years

The original University of Washington interdisciplinary FASD Diagnostic Clinic was funded by the CDC from 1993 – 1997 as part of a national FASD prevention study. The CDC-sponsored University of Washington FASD Clinic had the capacity to conduct 160 diagnostic evaluations per year. Patients often had to travel long distances to obtain these FASD diagnostic services in Seattle. In 1995, two additional FASD diagnostic clinics, led by the UW FASD clinic, were established in Federal Way and Everett through support from the Western Washington March of Dimes Birth Defects Foundation. In 1996, one year prior to the completion of the 5-year CDC FAS Prevention Study, funds were received

from WA DSHS, through Senate Bill 5688, to continue support of the University of Washington FASD Diagnostic Clinic and expand it into the Washington State FAS Diagnostic & Prevention Network (FASDPN) through the addition of six Satellite clinics statewide.

Since the opening of the first FASD Diagnostic Clinic at the University of Washington in 1993, the Washington State FASDPN has received 5,473 requests for diagnoses and diagnosed a total of 3,084 patients through 2023, (2,276 (74%) by the University of Washington Clinic and 808 (26%) by the six Satellite Clinics). On average, over the past three decades (1993-2023), the demand for FASD diagnostic evaluations in WA has been roughly twice the diagnostic capacity of the FASDPN clinics. Requests for evaluations are made by submitting a New Patient Information Form (NPIF) (white bars in Figs 4 and 5). An individual is eligible for a FASD diagnostic evaluation if they have a reported prenatal alcohol exposure at any level. Fig. 4 documents the number of NPIFs submitted and FASD diagnoses completed by the patients' county of residence from 1993-2023. The greatest number of requests were received from the largest population centers in WA and correlated with the location of FASDPN clinics over time (e.g., Seattle, Federal Way, Tacoma, Evertt, Pullman, Spokane and Yakima). Fig. 5 documents the number of NPIFs submitted and diagnoses completed annually from 1993-2023. The pattern of requests and diagnoses annually reflects a number of factors that varied across the decades. One important factor was how many clinics were open each year and where they were located. This is portrayed in Fig. 6. In 1993 and 1994, the Seattle clinic at the University of Washington was the first and only FASD diagnostic clinic open in the U.S. (black bars in Fig. 6). Understandably, there was a large backlog of individuals seeking diagnostic evaluations. From 1995 to 2017 additional FASDPN Satellite clinics were opened (depicted by colored bars in Fig. 6), resulting in increased diagnostic demand, capacity and geographic access. The Satellite clinics were community owned and operated and did not receive funding support from the State from 1996 to 2013. The dip in diagnostic activity that occurred in 2008-2009 was due to the national recession that closed the UW FASDPN clinic for 3 months in 2009 and forced the closure of most of the Satellite clinics. It was not until 2013 that the State Legislature allocated funds to help support the Satellite clinics. These funds allowed the Yakima and Evertt clinics to reopen until 2017. By 2018, the UW Core clinic was the only clinic open. The dip in diagnostic demand and capacity in 2019-2022 reflected the impact covid had on the population seeking diagnoses and the UW's ability to safely conduct diagnoses. The UW clinic was closed from March through June of 2020 due to the covid pandemic and reopened in April 2020 using a hybrid zoom/in-person model following covid safety protocols. By 2021 the UW FASDPN clinic was back up to full capacity (70 diagnoses per year). The black bars in Fig. 6 reflect the number of diagnostic evaluations conducted annually by the UW FASDPN core clinic. The number of diagnostic evaluations conducted by the UW FASDPN clinic has varied from 50-160 per year based on funding availability. In 2019, the Hope Rising Clinic in Bothell opened. They provide diagnostic evaluations and intervention for patients with prenatal substance exposure including prenatal alcohol exposure. They were trained to use the FASD 4-Digit Code but have never had a formal contract with HCA or the UW FASDPN, thus have not been in a position to share data with the FASDPN core clinic at the University of Washington.

In fiscal year 2023-24, the only FASDPN clinic open in WA State was at the University of Washington in Seattle. The UW FASDPN clinic was funded to conduct 70 diagnostic evaluations per year. With over 100 patients requesting evaluations, the wait time for some patients was over 1 year. With the closure of the FASDPN satellite clinics in Spokane, Yakima and Pullman by 2017, the number of requests for evaluations from families living in eastern WA decreased considerably, not because the need decreased, but because geographic access to diagnoses decreased. Families impacted by FASD would be better served if FASD diagnostic services were more geographically dispersed and wait times were reduced.

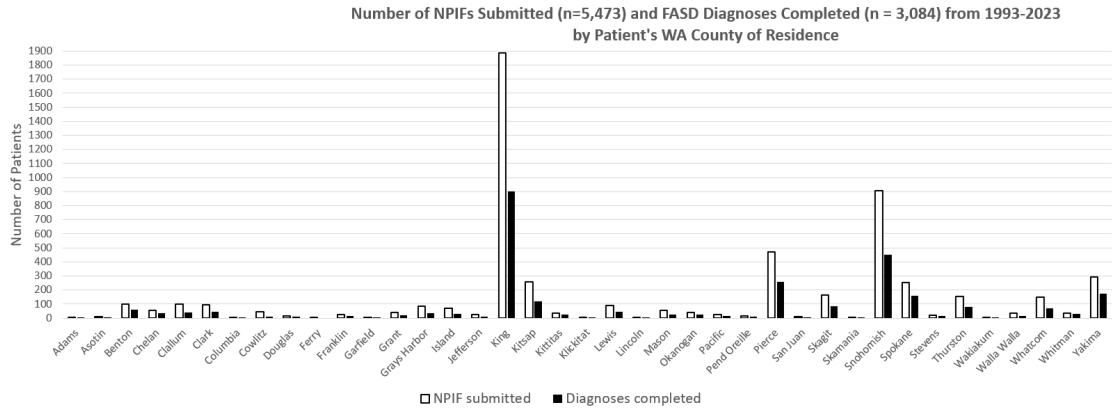

Figure 4. See interpretation of this figure in the text of Section IV.A.3 above.

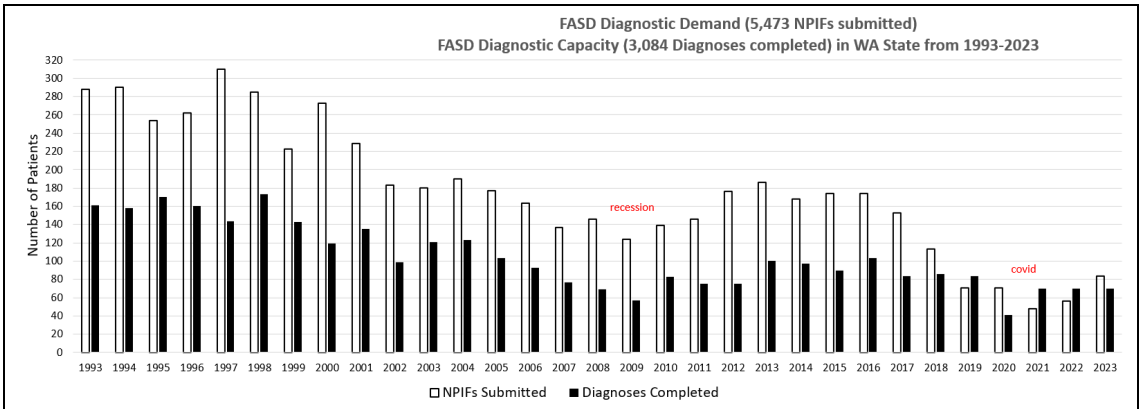

Figure 5. See interpretation of this figure in the text of Section IV.A.3 above.

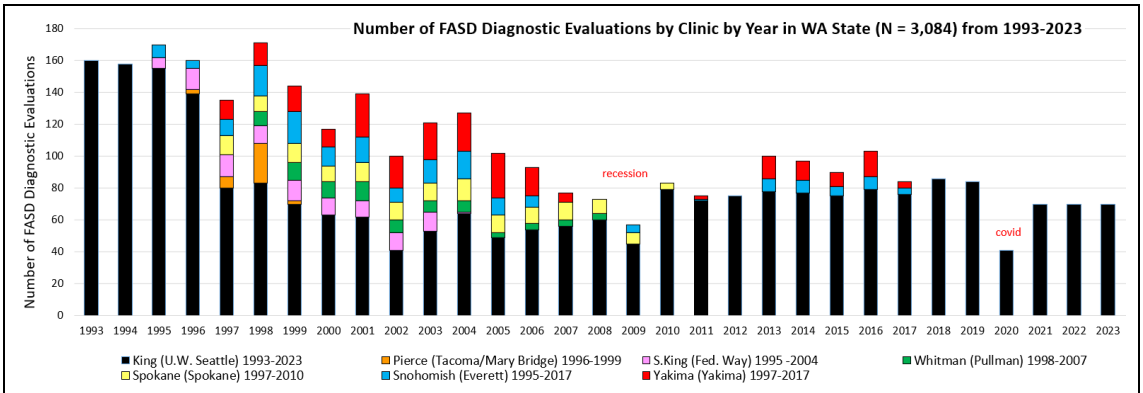

Figure 6. See interpretation of this figure in the text of Section IV.A.3 above.

IV.A.4. Creation and Distribution of FASD Diagnostic Tools and Training Materials

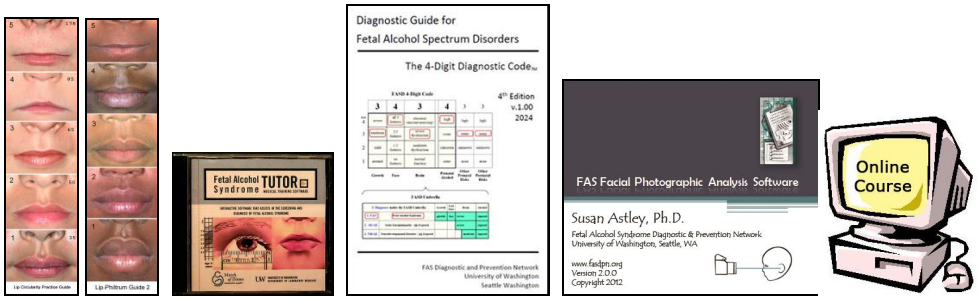

Figure 7. FASD 4-Digit Code diagnostic tools and online training course developed by the FASDPN.

The FASDPN has created and distributes FASD screening, diagnostic and prevention tools and training to a broad array of professionals worldwide (see Fig. 7 and list below). The development of these tools and training materials were supported in part by DSHS and outside contracts. These tools and training materials were developed to assure consistency and accuracy of diagnosis across all FASDPN sites. All are distributed worldwide free of charge.

1. FAS Facial Photographic Analysis Software, 1996, 2003, 2012, 2016.
2. Diagnostic Guide for FASD: The 4-Digit Diagnostic Code, 1st ed. 1997, 2nd ed. 1999, 3rd ed. 2004; 4th edition 2024.
3. FASDPN Clinical Manual, 1997, 1999, 2004
4. Community Development of a FASDPN, 1997, 1999, 2004.

Dr. Astley Hemingway created the FASD 4-Digit Diagnostic Code for use by interdisciplinary teams back in 1997. It has been updated in 1999, 2004 and 2024. It is a fully validated diagnostic system that is now used worldwide. Thousands of copies of the Guide have been distributed worldwide. Requests have been made to translate the Guide into Russian, German, French, Polish, and Spanish. In 2003, the *FAS Facial Photographic Analysis Software* was created by Dr. Astley Hemingway through funding support from the Washington Research Foundation and as of June, 2024, 3,858 copies of this software have been distributed worldwide. The software is used to screen and diagnose the facial features of FAS. The software was updated in 2012 and 2016 to incorporate new palpebral fissure length normal growth charts. A CD-ROM was developed in 1999 to accompany the FASD Diagnostic Guide. The CD-ROM trained medical professionals to screen and diagnose FASD. The National March of Dimes funded the development of the CD-ROM and has distributed over 3,000 copies nationwide. The National FASD Center for Excellence (2002) described the FASDPN method of diagnosis as a clearly advanced, highly developed approach to diagnosis and screening. Our interdisciplinary approach to diagnosis is regarded as Best Practice worldwide by SAMHSA (2014). In 2015, the American Academy of Pediatrics recognized the WA FASDPN as a national/international leader in FASD. As of February 2024, all diagnostic tools (4-Digit Code Diagnostic Guide (2024), FAS Facial Software (2016), Lip Philtrum Guides (2014) and the 4-Digit Code Online Course (2024) are distributed electronically, worldwide, free of charge.

Dr. Astley Hemingway developed a comprehensive manual entitled "*Diagnostic Guide for FAS and Related Conditions. The 4-Digit Code*" to ensure diagnostic accuracy and precision across all FASDPN clinics. This guide was written in response to the documented lack of accuracy and precision of FAS diagnosis nationwide (Cordero et. al., 1994, Stratton et. al., 1995). The Guide was printed by the University of Washington Publication Services in May 1997. It was distributed by the U.W. FASDPN Core site to all FASDPN personnel free of charge and was sold nationally and internationally at cost. A second edition of the Guide was printed in May 1999 to coincide with the release of the FAS-Tutor CD-ROM. This 2nd edition provides further instruction and clarity on the use of the 4-Digit Diagnostic Code for FAS. A comprehensive summary of the 2nd edition was published in the peer-reviewed medical journal *Alcohol & Alcoholism* in July 2000. A 3rd edition was released in 2004 by Dr. Astley: *Diagnostic Guide for Fetal Alcohol Spectrum Disorders: The 4-Digit Diagnostic Code*. A 4th edition was released in 2024 by Dr. (Astley) Hemingway. The latest edition is distributed worldwide, free of charge.

FASDPN clinical team members Heather Carmichael Olson, Ph.D., Sandra Clarren, Ph.D., Sharon Beck, M.Ed. and Tracy Jirikowic, M.O.T. finalized the '*Psychological Assessment and Treatment Planning Manual'* based on information gained from conducting comprehensive psychometric evaluations at the U.W. FASDPN Core site in 1998. This final edition was distributed to each of the FASDPN network sites during the FASDPN "Assessing Brain Dysfunction" training in May 1999.

Robin LaDue and Carolyn Hartness authored "Journey Through the Healing Circle", a series of CDs and illustrated workbooks narrated by Native American storyteller Loyd Red Crow Westerman, who uses animal stories to talk about children with FAS and the problems families face with these effects. Funded by the WA DSHS. The series showcases the UW FASDPN clinic and interdisciplinary approach to FASD diagnosis.

Funds were received from the National March of Dimes Birth Defects Foundation to create a compact disk to instruct physicians on how to screen and diagnose FAS using the tools and manuals developed by the FASDPN. This CD entitled *FAS-Tutor™* was created through a collaborative effort between Dr. Astley Hemingway at the U.W. FASDPN and Dr. Astion in the Department of Laboratory Medicine at the University of Washington. This CD was distributed nationwide by the National March of Dimes.

FASDPN clinical team members Sandra Clarren, Ph.D. (psychologist) and Tracy Jirikowic, Ph.D. (occupational therapist) created the "*Intervention Ideas Guide, 2000*" based on information gained from conducting comprehensive psychometric evaluations at the U.W. FASDPN Core site and the collective experiences of parents and professionals who have worked with or raised children with prenatal alcohol exposure. This reference guide was distributed to each of the FASDPN network sites during the FASDPN "Organic Brain Dysfunction and Prenatal Alcohol Exposure" Training, October 2000.

Susan Astley Hemingway Ph.D. worked with a software programmer to design and develop *FAS Facial Photographic Analysis Software* that allows clinicians and researchers to accurately and efficiently measure the magnitude of expression of the FAS facial phenotype from photographs for diagnosis and screening. This software was originally developed in 1996 with funding support from the Washington Research Foundation. In 2002 funds were received to develop a Windows-based, user-friendly version that is available for distribution to medical professionals. The software was updated in 2012 and 2016. This software was used to screen all children entering long term foster care in the King County Foster Care Passport Program. The results of this screening were published in the J. Pediatrics (Astley et. al., 2002). This software is distributed free of charge and used worldwide to screen and diagnose the facial features of FAS (Fig. 7).

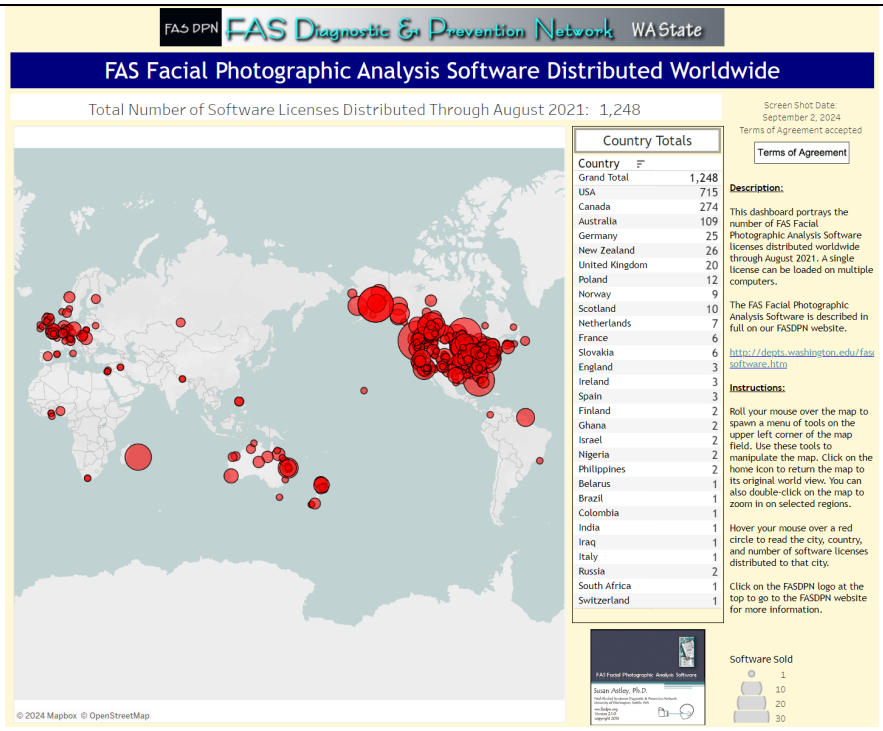

Figure 7. The FAS Facial Photographic Analysis Software has been distributed to thousands of clinicians and researchers in over 40 countries.

IV.B. FASDPN Training Programs

The U.W. FASDPN core site provides eight different FASD training programs targeted to families and professionals from WA State and around the world. Each is described below. Those marked by an asterisk are funded by this HCA contract.

1. **Training FASDPN Network Clinic Sites in Washington State***
   Over the years, there have been six FASDPN Satellite clinics in Snohomish, Pierce, South King, Yakima, Spokane and Whitman counties. In 2018, a 7th Network clinic "Hope Rising" (located in Bothell, King/Snohomish Counties) commenced training and opened in May 2019. Each Satellite clinic was locally owned and operated. Each received continuing education to stay abreast of the latest developments in diagnosis and prevention and to ensure diagnostic consistency across all sites. The continuing education is provided in two forms: 1) onsite consult on the diagnosis of patients evaluated at the Satellite clinics and 2) periodic one-day training sessions on key topics such as diagnosing organic brain damage. Each clinic sent the University of Washington the diagnostic files on all patients diagnosed. These files are reviewed for diagnostic accuracy. Feedback was provided to each clinic periodically throughout each year. A brief summary of selected one-day trainings is presented below.

   1998 FASDPN Clinic Coordinator Conference
   Six clinic coordinators attended a one-day training session. Topics included how to screen patient requests for clinic appointments, how to complete the FAS Diagnostic Evaluation Form, how to take properly aligned clinic photos, how to compose response letters to caregivers requesting appointments and how to bill for services.

   1999 Assessment of Brain Function
   The first annual one-day training session for Satellite clinics was held in Seattle. Sixteen professionals from the FASDPN Satellite clinics including psychologists, occupational therapists, speech language pathologists, and physicians attended. This session provided additional training on how to assess brain function in the FASDPN clinics. The 1999 edition of the FASDPN Psychometric Training Guide was distributed.

   2000 Organic Brain Dysfunction and Prenatal Alcohol Exposure
   The second annual one-day training session for Satellite clinics was held in Yakima, WA. Forty-six professionals from the FASDPN Satellite clinics including psychologists, occupational therapists, speech language pathologists and physicians attended. This session provided additional training on how to assess minimal brain dysfunction in the FASDPN clinics. he 2000 edition of the *Intervention Ideas Guide* was distributed.

   2002 Assessment of Brain Function
   The third annual one-day training session for Satellite clinics was held in Yakima WA in May, 2002. Fifty-two clinical team members from the FASDPN Satellite clinics attended. The FAS Facial Photographic Analysis Software was distributed to each clinic site.

   2004 Assessment of Brain Function
   The fourth annual one-day training session for Satellite clinics was held in Yakima WA in May 2004. Twenty nine clinical team members from the FASDPN Satellite clinics attended. The primary focus was review of the upcoming CDC FAS Diagnostic Guidelines and the 3rd edition of the Diagnostic Guide for FASD.

   2006 FASD Diagnosis and Intervention
   The fifth annual one-day training session for Satellite clinics was held in Yakima WA in May 2006. Fifty-seven clinical team members from the FASDPN Satellitel clinics attended. Preliminary outcomes of the following FASDPN research projects were presented:

MRI/MRS/fMRI study, Family Intervention study, Sensory Processing study, and the Social Communication Intervention Study.

2018 Diagnostic Team Training of the Wonderland Hope Rising FASDPN Network Clinic.
The Wonderland Developmental Center commenced training to become a FASDPN Network Clinic. Hope Rising opened their clinic in May, 2019.

2. **Training WA State Professionals at the U.W. FASDPN Clinic***
The University of Washington FASDPN core staff provides FASD training to community professionals throughout WA State A total of 5,739 professionals have been trained to date (Table 1). Trainees learn what FASD is and how it is diagnosed; who benefits from a FASD diagnostic evaluation; what services the FASDPN clinics provide and how to utilize them; and what their role is in the referral, diagnostic, and service provision process. These trainees have included the state social workers receiving professional development training through the UW Alliance for Child Welfare Excellence. The U.W. FASDPN clinic is open each week to visiting professionals who want to gain an understanding of our unique, comprehensive evaluative model. Trainees attend a 30-minute introductory lecture and observe the clinical team conduct FASD diagnostic evaluations on two patients. The clinic staff members are available throughout the day to guide the trainees and answer their questions. Included in our list of visitors was Washington State's First Lady Mrs. Mary Lowry, Ohio State's First Lady Mrs. Hope Taft, Dr. Faye Calhoun from the National Institute of Alcohol Abuse and Alcoholism, Dr. Sami Noursi, Director National FAS Center for Excellence and Jose Cordero, M.D., Director, CDC. The clinic hosts 150-250 professionals annually. The community professionals have expressed very high satisfaction with the training. Over 90% gave the training the highest possible score of 'excellent'.

In 2020 and 2021, trainings (and diagnostic evaluations) at the University of Washington clinic were interrupted by the COVID pandemic. The COVID pandemic closed the UW clinic from March through June 2020. The clinic re-opened July 2020. COVID safety policies at the UW Medical Center limited the number of trainees we were permitted to host in person in clinic. In addition, HIPAA policies prevented us from hosting trainees via Zoom. By July 2021 the UW Medical Center permitted trainees to attend both in person and via Zoom. In fiscal year July 2023-June 2024, the UW FASDPN held 35 clinics (2 patients per clinic) and trained 406 community professionals (in person and via Zoom). COVID safety policies continued to be followed.

Table 1. Total number of professionals trained by the University of Washington FASDPN Clinic.

Profession	N
Medical	1,454
Professional student	1,261
Psychologist, therapist, counselor, social worker	1,250
Administrator, coordinator, director	501
Educator, teacher	450
Alcohol treatment or chemical dependency counselor	152
Legal system	289
Other or not specified	436
TOTAL	5,793

3. **Off-site Training of Community-based Clinics or Institutions in WA State***
One-day didactic lectures on referral, diagnosis, and treatment planning of individuals with prenatal alcohol exposure are provided upon request to groups within WA State that provide services to high-risk populations and have requested training/diagnostic services in their

community. The number of trainings conducted to date are too numerous to list. Selected trainings are listed below. Webcasts of selected presentations are posted on the FASDPN website to increase access to training.

- Trained 30 JRA staff at Echo Glenn to address identification of and intervention with juveniles affected by prenatal alcohol exposure (1998).
- Provided diagnostic and primary prevention training and conducted special on-site diagnostic clinics for three WA State Native American tribes. (1997-1998).
- Trained JRA staff at Maple Lane School and DCFS foster care staff in King County on how to screen for FAS using facial photographs. (1998-ongoing).
- Conducted two lectures to DCFS, FCPP and DASA staff regarding outcomes of the FAS Screening in King County Foster Care (2002).
- Trained 200 members of the Skagit County FASD Juvenile Court Initiative including probation officers from the Skagit County Juvenile Court, officers from the courts of four tribal nations, staff from Youth and Family Services, ARIS and CHET (2005-06).
- FASDPN clinical members conduct 20-30 lectures annually to groups statewide requesting training/education on all aspects of FASD (family advocacy, adoption support, education, diagnosis, intervention, and prevention).
- The FASDPN clinical staff provided a half-day training of over 50 birth to three providers from the Experimental Education Unit at the University of Washington. Birth to three teachers from the Seattle Public Schools also attended. (2008).
- FASD: Focus on Executive Functioning Deficits. Hosted by NOFAS Washington State featuring speakers from the FASDPN. Aug 2010, Everett WA Target audience, families and professionals caring for individuals with FASD.
- FASD: From Discovery to Prevention in WA State. University of Washington Board of Regents. November 2011, Seattle WA.
- FASD: Focus on Intervention. Hosted by NOFAS Washington State featuring speakers from the FASDPN. March 2011, Everett WA Target audience, families and professionals caring for individuals with FASD.
- Institute on Human Development and Disability Core Seminar. FASD. Annually since October 2011, University of Washington. Target Audience: LEND Trainees, Birth to Three Trainees.
- Co-Occurring Disorders Conference. FASD: From Discovery to Prevention in WA State. Hosted by DSHS, DBHR, October 2011, Yakima, WA.
- FASD: Focus on Intervention. Hosted by NOFAS Washington State featuring speakers from the FASDPN, November 11, 2012, Everett WA. Target audience, families and professionals caring for individuals with FASD.
- FASD: Focus on Intervention. Hosted by NOFAS Washington State featuring speakers from the FASDPN, 2013, Everett WA. Target audience, families and professionals caring for individuals with FASD.
- Screening and referral of children with FASD. CHET Conference, April 2013, Seattle WA.
- Screening and referral of children with FASD. FCAP Conference, Sept 2013, Children's Home Society, Seattle WA.
- Developmental Medicine Teaching Rounds; FASD update presented by Dr. Astley Hemingway. October 2013, Seattle Children's Hospital.
- Advanced Practice in Primary Acute Care. FASD diagnosis, intervention and prevention. October 2013, Seattle WA.

- Astley Hemingway testimony on House Bill 2737 concerning fetal alcohol exposure. Invitation by Rep. Ruth Kagi, Chair Early Learning & Human Services Committee, Feb. 13, 2015. Olympia WA
- Webinar: Prevention of FASD, 2014, presented by Susan Astley Hemingway, sponsored by Association of Reproductive Health Professionals.
- Web-based "Talking with Patients about Alcohol Use During Pregnancy Clinical Minutes" 2016 sponsored by Association of Reproductive Health Professionals. Content contributed by Susan Astley Hemingway.
- Autism Clinic Rounds: FASD update presented by Dr. Astley Hemingway, October 2016, Seattle Children's Hospital.
- Demonstration of the FAS Facial Photographic Analysis Software developed by Dr. Astley Hemingway. 2016
- Developmental Medicine Teaching Rounds; FASD update presented by Dr. Astley Hemingway. March 2017, Seattle Children's Hospital.
- FASD from Discovery to Prevention; presented by Dr. Astley Hemingway to the Polish Institute of FASD. 2020
- Tacoma School psychologists: FASD training conducted by FASDPN psychologist Erin Olson PhD March 2022.
- WA-AK Neuropsychological Society: FASD training of 55 licensed psychologists in WA and AK by Dr. Astley Hemingway and Dr. Allison Brooks, April 2022.
- WA CHET: FASD training of 72 CHET personnel statewide by Dr. Hemingway, February 2023.
- Comparison of four international FASD diagnostic guidelines presented by Dr. Hemingway (keynote speaker) at the EUFASD international conference in September, 2024.
- Comparison of FASD diagnostic outcomes and PRAMS/BRFSS prenatal alcohol exposure histories over 20 and 30 years in AK and WA presented by Dr. Hemingway in February 2023 to the University of Alaska Anchorage CHD Project ECHO series (n = 55).
- Comparison of four international FASD diagnostic guidelines presented by Dr. Hemingway on April 13, 2024 at the International FASD conference held in Seattle WA (n = 98).
- Advancing justice for individuals with FASD across judicial systems by Dr. Julian Davies MD on April 11, 2024 at the International FASD conference held in Seattle WA (n = 250).

4. **Training of Washington State Students***
   University students from across WA State in medicine, nursing, speech and language, occupational therapy, education, dentistry and social work regularly attend clinic to observe how the interdisciplinary clinic manages this special population. A total of 1,261 students have attended clinic to date. Residents, fellows and interns from Pediatrics, Rehabilitation Medicine, and Psychology also rotate through the U.W. FASDPN clinic. Several students from Epidemiology, Speech and Hearing Sciences, Orthodontics, and Occupational Therapy and social work have earned their Master's and Doctorate degrees using the FASDPN database and patient population. One student won the nation's top student award for student research.

5. **Training for FAS Facial Screening and Diagnosis***
   The FASDPN provides training to medical and research personnel around the world on how to analyze facial photographs for screening and diagnosing the facial features of FAS. The FASDPN has worked with several hundred professionals to assess several thousand photographs. These professionals include staff from WA State Foster Care Passport Program, JRA, and the Skagit Juvenile Justice FASD Initiative. The FASDPN was contracted to provide FASD screening training for a multistate FAS Screening Program sponsored by SAMHSA from 2009-2012. In November 2011, the FASDPN participated in the NIH/CDC national meeting to formulate the

American Academy of Pediatrics endorsement of ARND. This work led to the inclusion of Neurodevelopmental Disorder-Prenatal Alcohol Exposed (ND-PAE) in the DSM-V in 2013.

6. **Training FASDPN Sites Outside Washington State**
The FASDPN conducts two-day training sessions on FAS screening, diagnosis, and prevention for clinical teams worldwide that would like to establish a FASDPN program in their community. These training sessions are held throughout the year. To date, over 255 teams worldwide have been trained. Our most intensive efforts in 2017-22 was focused on free training (enrollment in the FASD 4-Digit Code Online Course) for 50 clinicians in Slovakia and 47 clinicians in Poland. Trainees complete the FASD 4-Digit Code Online Course prior to their 2-day training in Seattle. In 2019, we trained a team from Poland and Dr. Astley Hemingway provided a keynote speech on International FASD Day (September 10, 2019) in Poland. The team in Poland established the Polish Institute of FASD in June 2020 and will serve as a center of excellence for FASD diagnosis using the FASD 4-Digit Diagnostic Code. Trainees in 2024 included clinicians from Israel, New Zealand, Mexico and the Netherlands. Over 1700 professionals from 40 countries have completed the FASD 4-Digit Code Online Course as displayed in the FASDPN Tableau Dashboard. The trainees spend the first day attending didactic lectures and receiving hands-on instruction in the specific screening and diagnostic techniques used by the FASDPN. The trainees spend the second day observing two interdisciplinary FASD diagnostic evaluations using the 4-Digit Code.

7. **Training via Video-teleconference, webinars and conferences**
The FASDPN provides FASD training to large, geographically dispersed audiences via video-teleconference, upon request. To date eight conferences/webinars have been held in 1999, 2000, 2004, 2009, 2010, 2011, 2012, 2013, 2014, 2017, 2018, 2022, and 2024 (Continuing Education for WA State nurses hosted by Children's Hospital and Regional Medical Center, FASD training via Alaska's ECHO program, training of medical and social service providers in Alberta and Ontario Canada, training FAS screeners nationwide hosted by SAMHSA, training of FASD interventionists nationwide hosted by the CDC, prevention webinar for healthcare professionals nationwide hosted by the Association of Reproductive Health Professionals). In 2017, three members of the FASDPN diagnostic team gave 5 FASD presentations at the 7th International Conference on "FASD Research: Results and Relevance; Integrating Research, Policy and Promising Practice Around the World" held in Vancouver BC. Hundreds of WA State professionals attended this conference. Three team members presented at the 2018 Adults with FASD International Conference in Vancouver BC and 7 team members presented at the 8th International Conference on FASD in Vancouver BC in 2019. Dr. Hemingway served as the keynote speaker at the 6th European Conference on FASD held in Norway in September 2022. Drs. Hemingway and Davies served as speakers at the 9th International Research Conference on Adolescents and Adults with FASD in April 2024 in Seattle WA.

8. **Answering Questions from Families***
The FASDPN staff answer several thousand questions annually from families and their care providers who call, send letters or leave questions on the FASDPN website (www.fasdpn.org).

IV.C. Screening and Surveillance

- A highly sensitive and specific, computerized FAS facial photographic screening/diagnostic tool was developed by the FASDPN in 1996 (Astley & Clarren, 1996). It was used to screen and

diagnose several thousand individuals. In 2003/2016, this photographic tool was upgraded to the FAS Facial Photographic Analysis Software by Dr. Astley Hemingway. Thousands of copies of the software have been distributed worldwide to date.

- A centralized, computer photographic analysis laboratory at the University of Washington FASDPN was established in 1998 and provides analysis of facial photographic data sets worldwide. Several thousand photographs have been analyzed to date. This service is supported on a self-sustaining revenue budget at the University of Washington.

- The FASDPN implemented computerized FAS photographic screening in two high-risk populations (foster care and juvenile justice) in 1999 in Washington State using the FAS Facial Photographic Analysis software developed by Dr. Astley Hemingway. All children/adolescents who screened positive (had the facial features of FAS) received a FAS diagnostic evaluation at a FASDPN Clinic. All children entering long term foster care in the King County Foster Care Passport Program were screened for FAS for 10 years with 98% participation. The prevalence of FAS in this foster care population was one out of every 100 children, or 10 to 15 times greater than the prevalence of FAS in the general population (1/1,000). The results of this screening were published in the Journal of Pediatrics (Astley, et al., 2002). Eight hundred and fifty adolescents in JRA were screened between 1999 and 2001. Several screened positive for FAS.

- The Washington State Birth Defects Surveillance System was an active surveillance system from 1986 to 1991. Since then, the system has been passive, relying on hospitals to report cases of children with birth defects. Currently, an enhancement project is in progress to develop a web-based, electronic reporting system to reduce the reporting burden to hospitals. The FASDPN reports all cases of FAS and Partial FAS to the State Birth Defects Surveillance Program annually.

- The FASDPN participated in the Skagit County FASD Juvenile Justice Initiative to establish methods to screen, diagnose, and intervene with youth entering the juvenile justice system. The project was one of five funded nationally by the SAMHSA FASD Center of Excellence. This national effort by SAMHSA to screen, diagnose, and prevent FASD was extended to 2012. SAMHSA utilized the screening and diagnostic tools and models established by the WA State FASDPN.

- The FASDPN participated in the National Children's Study to estimate the prevalence of FAS nationwide and in WA State. The photographic methodology established by the FASDPN to screen FAS in the King County Foster Care Passport Program was used.

- The FASDPN participated in the WA State Department of Corrections Adaptive Supports Program, Screening Offenders for Intellectual Disabilities, and Traumatic Brain Injury study. The FASDPN used the FAS Facial Photographic Analysis Software to screen facial photographs of study subjects for FAS (2013-2015).

- The FASDPN participated in the CDC-sponsored Danish Lifestyle During Pregnancy Study (2013-2019). The FASDPN analyzed 1,700 facial photographs for FAS using the FAS Facial Photographic Analysis Software. The study was published in 2019 (Kesmodel, Astley Hemingway et. al, 2019). The study documented low to moderate average alcohol consumption and isolated episodes of binge drinking in early pregnancy were associated with facial features

related to FAS in five-year-old children". The FASDPN hosted this Danish team to visit the UW FASDPN in May 2022.

IV.D. Prevention: Evidence of Success in WA State

Although FAS is entirely preventable, the factors associated with maternal alcohol use during pregnancy are complex and resistant to change. Maximizing primary prevention efforts will require targeting limited prevention resources to women at highest risk for producing children damaged by prenatal alcohol exposure. One of the highest-risk, identifiable populations are women who have already given birth to a child with FAS or given birth to a child with prenatal alcohol exposure and CNS dysfunction. A five-year Cooperative Agreement between the University of Washington and the CDC (Astley & Clarren, Co-Principal Investigators) demonstrated that these women can be identified and located through the diagnosis of their children in the Washington State FASDPN. Eighty mothers who currently live in Washington State and have given birth to a child with FAS were identified and extensively interviewed by members of the U.W. FAS Clinic team. The purpose of the interview was to generate a comprehensive profile of these women and identify factors that enhanced and hindered their ability to achieve sobriety or practice effective family planning. This baseline data was collected to develop an effective primary prevention program within the FASDPN. The results of this study were summarized in a 300-page final report to the CDC entitled "*Primary Prevention of Fetal Alcohol Syndrome: Targeting Women at High Risk through the FAS Diagnostic and Prevention Network 1992-97*". This report was submitted to DASA in 1998 and is posted on the FASDPN website. The results of this study were published in the peer-reviewed medical journal *Alcohol & Alcoholism* in 2000 (Astley et al., 2000a, 2000b). One of the key findings in this study was that after the diagnosis of the 80 children with FAS, 35 of their mothers gave birth to an additional 62 children, 75% of which were prenatally exposed to alcohol and 80% of which were born without the use of contraception. Although these 62 children were not formally followed to assess their cognitive/behavioral outcomes, it is known that a minimum of six have FAS. The goal of the FASDPN Primary Prevention Program will be to measurably reduce the risk of exposure and brain damage in these children.

Two programs to date have demonstrated that reduction in risk can be achieved. The Parent-Child Assistance Program (P-CAP), directed by UW Professor Therese Grant Ph.D., has demonstrated that a measurable reduction in risk factors leading to alcohol use and poor family planning (Grant et. al., 1996) can be achieved among pregnant women abusing drugs and alcohol. A key motivating force in P-CAP is the bond between the mother and her newborn. The women who will be targeted in the FASDPN program will not be pregnant for it will be paramount to target them before they conceive. This will present a unique challenge. The ongoing work by Dee Robertson, M.D. in Portland Oregon, however, provides compelling evidence that the risk of FAS can be reduced in women who are not currently pregnant (Interagency, 1997). Dr. Roberts has demonstrated that family planning and advocacy intervention targeted to high-risk Native American women reduced the incidence of FAS in their tribes to zero over a two-year period. The FASDPN will work collaboratively with P-CAP and will solicit consultation from Dee Robertson, M.D. in Oregon during the design and implementation of the FASDPN Primary Prevention Program. The estimated cost to society to raise a single child with FAS from birth to 18 years of age is one million dollars (Abel & Sokol, 1987). Prevention of just a single FAS birth can pay for up to ten years of the primary prevention program proposed below. This program has the potential for preventing many FAS births per year in Washington State.

One of the primary goals of the FASDPN is to identify the birth mothers of children diagnosed with prenatal alcohol exposure and cognitive/behavioral dysfunction and to link these high-risk women to community-based primary prevention services such as P-CAP to reduce their risk of bearing additional

children exposed to prenatal alcohol. The FASDPN identified 80 birth mothers of children diagnosed with FAS in WA State in 1992-97 and has the potential of identifying an additional 70 birth mothers annually; birth mothers of children diagnosed with FASD through the FASDPN. During the 1998-99 fiscal year, the FASDPN maternal advocate (Diane Bailey, MSN) provided comprehensive advocacy services to three of these high-risk women, enrolled two additional women in P-CAP, and provided referral and support services to ten birth mothers who attended their child's diagnostic evaluation at the U.W. FASDPN clinic. Ms Bailey also provided in-service training on motivational interviewing and birth control to P-CAP advocates and participated in case conferencing, two to three times a month, at the Seattle and Tacoma P-CAP offices. In 1999, Ms Gendler, M.S.W. joined the FASDPN as the maternal advocate, replacing Ms Bailey who went on to work for the WA State Department of Health. A grant to establish and assess the FASDPN Primary Prevention Bridges Program was submitted to NIAAA in March 1999 in response to their FAS Primary Prevention request-for-proposals. This grant was submitted by Dr. Carmichael Olson (FASDPN clinical psychologist) and represents a collaborative effort between the FASDPN, P-CAP and the FAS Interagency Work Group. The grant proposed to establish and assess a primary prevention program (the First Bridges Program) that links high-risk women identified by the FASDPN to appropriate community-based primary prevention services. The proposal received a favorable review, but the reviewers requested pilot data be collected prior to re-submission. In response, the FASDPN piloted the "FASDPN First Bridges Program." This is an approach to primary prevention that is a natural extension of the existing FASDPN clinical services and uses empirically-supported brief intervention techniques.

The FASDPN First Bridges Program established a clinically feasible protocol for identifying, locating, and providing FAS prevention services to eligible high-risk women who have given birth to an alcohol-exposed child with confirmed evidence of CNS dysfunction. These women were still fertile and either actively drinking or at high risk for relapse. Aims of the prevention services were to: (1) Enhance the woman's "readiness to change" her alcohol and/or contraceptive use; and (2) Reduce self-reported "need for help" via brief intervention and linkage with community services. The results of this study were published in Alcoholism: Clinical and Experimental Research, 2002 (Carmichael et al., 2002).

In the course of providing services to the pilot group of birth mothers, FASDPN staff received training on the issues and concerns of women giving birth to children with alcohol-related disabilities. A social work internship training program was initiated, with the first student completing a nine-month practicum focused on the First Bridges Program. Data on the needs and issues of birth mothers, and methods of FAS prevention, were part of the quarterly FASDPN trainings.

WA State is Successfully Preventing FAS: The prevalence of FAS is estimated to be 1 to 3 per 1,000 live births and is the leading known cause of intellectual disabilities in the Western World. To prevent FAS, maternal alcohol consumption during pregnancy must be reduced. To assess the effectiveness of FAS prevention efforts, one must be able to accurately estimate the prevalence of FAS over time in population-based samples. Accurate estimates of prevalence, in turn, require accurate diagnostic methods. With the establishment of the Washington State FAS Diagnostic and Prevention Network (FASDPN) of clinics, the development of the FAS Facial Photographic Screening/Diagnostic Tool, the creation of the FAS 4-Digit Diagnostic Code, the establishment of the Foster Care FAS Screening Program, and the collection of Pregnancy Risk Assessment Management System (PRAMS) data on maternal use of alcohol during pregnancy, the tools, methods and infrastructure for assessing the effectiveness of FAS primary prevention efforts in Washington State are in place. An overview of the history of FASD from discovery to prevention in WA State is presented in a webcast by Susan Astley

Hemingway PhD (Seattle Children's Grand Rounds August 2012). A cross-sectional study was conducted to determine if the prevalence of FAS among children in a foster care population, born between 1993 and 1998, decreased with the documented decrease in prevalence of maternal use of alcohol during pregnancy from 1993 and 1998 in Washington State. The prevalence of maternal drinking during pregnancy in Washington State declined significantly ($p < 0.001$) from 1993 to 1998 as did the prevalence of FAS among foster children born from 1993 to 1998 ($p < 0.03$). These observations strongly support that FAS prevention efforts in Washington State are working (Astley, 2004). The results of this study were published and showcased on King5 News in Seattle as an important public health message.

A comprehensive summary of WA State efforts to prevent FASD from 1968-2004 is posted on the WA FASD website in a document entitled FASD: WA State History. It is paramount that WA State sustain its successful efforts to reduce FASD. Unfortunately, the most recent PRAMS data documents a steady increase in maternal reporting of drinking during pregnancy, in contrast to the steady decline observed in the 1990s. Preliminary data documents this increase in drinking is associated with an increase in prevalence of FAS in foster care among children born after 1998. Most recently, data from the FASDPN confirms that the incidence of FAS is dropping significantly in WA across birth cohorts spanning 1940 through 2009 (see Tableau Dashboard).

IV.E. Intervention

The FASDPN has engaged in all levels of FASD intervention from guiding public health policy to conducting randomized control trials to establish an evidence base for intervention efforts. These efforts to date are summarized below.

- Diagnosis leads to successful interventions. Twenty years of patient surveys confirm FASD diagnostic evaluations conducted by the WA FASDPN afforded patients substantial access to interventions that met their needs (Astley, 2014).
- NOFAS WA (now FASD Focus NW). Directed by Julie Gelo, B.A. Established in 2006, the mission of FASD focus NW is to educate, advocate and support individuals with FASD and their families. They envision building bridges that connect and unify professionals, individuals with FASDs, families, and community members.
- Family Intervention: Families Moving Forward" (FMF) is a CDC-sponsored, intervention research project, conducted through the FASDPN, exploring evidence-based services for children with fetal alcohol spectrum disorders (FASDs), their families, and the professionals who care for them. The program was established by a Professor of Psychology from the FASDPN, Dr. Heather Carmichael Olson PhD. At its heart, the FMF intervention model is aimed at: 1) providing ongoing support to parents and helping them better understand their challenging children 2) helping parents hone skills they already have, while adding specialized parenting techniques to their care-giving repertoire, 3) adding value to community resources and providers that families find helpful, 4) helping families boost their progress in a positive direction, giving them reason to be more optimistic about the future, and helping reduce the chance their children will have secondary disabilities later in life. This project completed it's tenth year of funding in 2010. Sixty WA State families raising children with FASD received 9 months of in-home intervention services for free. FMF is now a program available to WA families. In 2017, Dr. Jirikowic, the OT on the FASDPN diagnostic team submitted a grant to expand the FMF program to focus on infants, birth to three.
- SNACS Clinic: The SNACS Clinic model (developed through the FMF program) is a short-term assessment and consultation service (3 to 5 sessions) using materials from the FMF Program. The

research and clinical team is led by Dr. Heather Carmichael Olson and Dr. Michelle Kuhn. SNACS services are carried out by providers with advanced degrees in clinical or school psychology. This "Specialized Neurodevelopmental Assessment and Consultation Service" (SNACS) offers: (1) mental health diagnosis of conditions on the fetal alcohol spectrum (and co-occurring mental health issues); (2) customized referrals and ideas for linkages to community resources; and (3) tailored short-term consultation on issues important to individual children and families.

- Brooks Powers Group Assessment Team: Established by a psychologist serving in the FASDPN (Allison Brooks PhD), provides a range of assessments at the request of caregivers and schools. Their evaluations are intended to provide information about a child's profile of strengths in addition to identifying potential diagnoses and areas in need of intervention and support. Their providers have experience and training in FASD and understanding how information obtained from a clinical evaluation is used in an educational setting. They aim to provide information that can be useful in the process of developing educational plans, counseling and therapy interventions, parenting supports, and helping care providers coordinate services.
- Sound Families Pediatric Therapy: Established in 2024 by an occupational therapist from the FASDPN (Jennifer Nash PhD, OTR/L, IMH-E). With expertise in FASD, Dr. Nash provides OT services via telehealth for families of children 0-9 years old. Dr. Nash has been serving families in the Puget Sound community and beyond for more than twenty years as a pediatric occupational therapist and infant mental health specialist with multiple areas of focus including early intervention, trauma-informed care, child development, challenging behaviors, and sensory processing.
- DDA Eligibility Criteria: In 2015, the FASDPN worked effectively with the WA Developmental Disabilities Administration (DDA) leading to the acceptance of FASD for determination of eligibility for DDA (DDA Management Bulletin D15-012, March 13, 2015). "Diagnoses of a condition that is similar to Intellectual Disability and attributable to prenatal maternal consumption of alcohol may be accepted as an "another neurological or other condition similar to Intellectual Disability" under 388-823-0600. The diagnosis must be supported by evidence confirming prenatal alcohol exposure. This evidence may be found in medical records or other documentation."
- Early Support for Infants and Toddlers (ESIT) qualifying diagnoses: In 2020, the FASDPN worked effectively with ESIT leading to the acceptance of prenatal alcohol exposure as a qualifying condition for ESIT.

IV.F. Systematic Information Retrieval and Tableau Dashboards

In 1995, Dr. Astley Hemingway began the development one of the world's largest, most comprehensive clinical databases on FASD with patient consent and University of Washington Human Subjects approval. The data allows the FASDPN to track regional FASD diagnostic demand, diagnostic capacity and diagnostic outcomes over time. It also allows the FASDPN to develop state-of-the-art screening and diagnostic tools and support intervention research that directly benefits WA children and their families living with FASD. The database contains information on over 5,000 families requesting diagnostic evaluations and over 3,000 patients who have received diagnostic evaluations. There are over 3,000 fields of information on each patient. A seminal report profiling the first 1,400 patients evaluated at the WA FASDPN was published in 2010 (Astley, 2010). Over 100 peer-reviewed publications have been published in the medical literature by FASDPN clinical team members using the data from the FASDPN database. The database has also supported a multitude of Master's Theses and Doctoral Dissertations by graduate students in public health, psychology,

medicine, nursing, dental, social work, speech-language and occupational therapy. The database also serves as a patient registry allowing patients to enroll in FASD research studies that often provide direct benefits to participants (e.g., free neuropsychological and medical assessments, free intervention services, etc.). This patient registry paved the way for the development of the evidence-based Families Moving Forward FASD intervention program established and directed by Heather Carmicheal Olson.

An Institutional Review Board application was submitted to the University of Washington Human Subjects Division on September 5 1995 for approval to collect, store and summarize data collected in by the UW FASD clinic. The application was approved on September 28 1995 and now has ongoing approval. All procedures are HIPAA compliant. All staff received HIPAA and IRB training. A copy of the initial approved application was submitted in Appendix H of the Year 01, Quarter 01 Report in 1995. As per IRB policy, all research studies proposing to enroll study subjects from the FASDPN are required to submit separate IRB applications. In May 2000, the UW FASDPN clinic database received University of Washington IRB approval to serve as a FAS Research Registry. This UW IRB zipline application has been renewed as an ongoing study with no end date. This facilitates the invitation and voluntary enrollment of patients with prenatal alcohol exposure into clinical research studies designed to identify effective interventions and diagnostic tools. Several million dollars in funding was received in 2001-2010 from the CDC and NIAAA to conduct these clinical research studies, providing several hundred WA State families and children with free medical care and intervention services.

With the advent of "Interactive Data Platforms", Dr. Astley Hemingway has constructed and launched an endless array of Tableau dashboards that allow people worldwide free, interactive access to the entire FASDPN database (in aggregate format without identifiers). Included are dashboards entitled FASD Diagnoses by WA State County; 4-Digit Code FASD Diagnoses Worldwide; FASD WA State FASD Diagnostic Outcomes by Patient's Birth Cohort, etc.).

In 2024, Dr. Astley Hemingway along with colleagues in Alaska published a seminal paper entitled "*WA and AK Statewide FASD Diagnostic Clinical Networks: Comparison of Three Decades of 4-Digit Code Diagnostic Outcomes and Prenatal Alcohol Exposure Histories*". FASD screening, diagnosis, intervention, research and prevention hinges on establishment of interdisciplinary FASD diagnostic clinics using an evidence-based method of diagnosis. In 1993, Washington State opened the first interdisciplinary FASD diagnostic clinic sponsored by the CDC as a FASD primary prevention study. Clinic data was used to develop the evidence-based FASD 4-Digit Diagnostic Code, paving the way for the clinic's expansion into a Statewide network of FASD diagnostic clinics (Washington Fetal Alcohol Syndrome Diagnostic & Prevention Network), now in its 31st year. Alaska adopted this Washington model in 1999. Both States have also participated in the CDC Pregnancy Risk Assessment Monitoring System and Behavioral Risk Factor Surveillance System since the 1990s. Study objectives were to describe the two Statewide FASD diagnostic networks; graphically compare the 4-Digit-Code FASD diagnoses and Prenatal Alcohol Exposure (PAE) over 2-3 decades and illustrate how network data helped guide FASD public health policies and track successful prevention efforts. Both States demonstrated the feasibility and value of establishing Statewide interdisciplinary FASD diagnostic clinical networks using the FASD 4-Digit-Code. Legislative support, centralized data collection, and use of a single, evidence-based FASD diagnostic system have been key to the long-term, ongoing success of these two diagnostic networks.

V. Funds Attracted to WA State (over 15 million dollars for WA children and families)

The University of Washington Core FASDPN clinic has successfully obtained over **15 million dollars** in additional funding to support FASD screening, diagnosis, and intervention for families in

Washington State. Hundreds of WA State families and children have received free medical care and intervention services through these public health/research activities. Washington State's support of the FASDPN was instrumental in our being able to attract these funds and service opportunities to our State. The Washington State FASDPN continues to work directly with the NIAAA, CDC, NIH, FASD United and SAMSHA in a national effort to diagnose and prevent FASD.

1. *Centers for Disease Control*. FAS Prevention through development of first FASD interdisciplinary diagnostic clinic at the University of Washington This funding established the Core WA FASDPN clinic. (1992-1997).

2. Funding Source: *Washington Research Foundation* Title: Development of the FAS Facial Photographic Screening/Diagnostic Software. The FASDPN developed software to allow medical professionals to analyze facial photographs for the presence of FAS facial features. This software was used to screen all children entering the King County Foster Care Passport Program for FAS from 1999 to 2009. This software is also used in all FASDPN diagnostic clinics. Funding period: 8/1/02 through 2/28/03. Total Costs: $ 10,000.

3. Funding source: *Centers for Disease Control.* Title: Intervening with children with FASD. This study provided 60 WA State families raising children with FASD free in-home intervention for 9 months. Study period: 9/30/01 through 9/29/10. Total Costs: $2,396,497.

4. Funding Source: *National Institutes of Alcohol Abuse and Alcoholism*. Title: MRI/S in children/adolescents with FASD. This project used (magnetic resonance spectroscopy (MRS), magnetic resonance imaging (MRI), and functional MRI (fMRI)) to determine if prenatally alcohol-exposed children, with and without FAS, who present along the full continuum of mild to severe cognitive/behavioral dysfunction, have irrefutable evidence of organic brain damage in the form of chemical, structural and/or functional alterations of the brain. Sixty WA State children with FASD received free neuropsychological assessments and MRI scans. Study period: 03/01/02 through 02/28/06. Total Costs: $ 996,694.

5. Funding Source: *National FAS Center of Excellence.* Title: FAS Summer Conference. The objective of the summer camp conference was to bring together families raising children with FASD for the purpose of having fun and networking with other families and community professionals. Funding Period: August 28-31, 2003. Total Costs: $35,000.

6. Funding Source: *University of Washington Educational Outreach and Technology Transfer*. This project supported the development of the FASD 4-Digit Diagnostic Code online course targeted to medical/social service providers. Over 600 professionals have completed the course to date. Funding Period: 2003. Total Costs: $56,000.

7. Funding Source: *SAMSHA FASD Center of Excellence*. FASD Screening, Diagnosis and Intervention in Juvenile Justice. 8/2004 through 7/2007. Subcontract to FASDPN. Total Costs: Over $200,000. FASD Screening, Diagnosis and Intervention in High-Risk Populations. 6/2008 through 5/20012. Subcontract to FASDPN. Total Costs: $50,000.

8. Funding Source: *SAMSHA FASD Center of Excellence*. Provide consultation on national FASD screening, diagnosis and intervention in high-risk populations. 6/2008 through 5/20012. Subcontract to FASDPN. Total Costs: $12,000.

9. Funding Source: *National Institutes of Alcohol Abuse and Alcoholism*. Title: Sensorimotor Intervention to Affect Balance, Engagement, and Learning for Children with FASD. This study is providing WA State children with FASD free sensorimotor interventions. Funding period: 2009-2015. Total Costs: $1,000,000.

10. *Centers for Disease Control:* Arctic FASD Regional Training Center. The FASDPN team is serving as consultants for Alaska's creation of a CDC-sponsored FASD Regional Training Center. (2009-2017).

11. *National Institutes of Health:* National Child Study. The FASDPN took the lead in establishing the methodology for assessing facial anomalies from photographs for 100,000+ children who will be enrolled from birth to 21 years of age in the country's largest ever longitudinal study of child development. This study will allow the FASDPN to estimate the prevalence of FAS in the U.S. general population as well as the WA State population. (2010-2012).

12. *FASD United Policy & Training Center* https://nofaspolicycenter.org/.

13. UW ADAI; Title: Language Learning in Children with Neurodevelopmental Disorders. Kover PI. This study enrolled 50 patients from the FASDPN clinic. The children were provided free language assessments. (2016-18): Total Costs: $29,900.

14. UW ADAI; Title: Characterizing Auditory Processing in Individuals with FASD. McLaughlin PI. This study enrolled 15 children from the FASDPN clinic. These children received free language and auditory processing assessments (2016-18) Total Costs $29,586.

15. UW Rehabilitation Medicine; PhD Dissertation (2024) Title: Toward earlier identification and strength-based intervention for infants and toddlers with prenatal alcohol exposure: Evidence from the Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network Clinical Database. Key finding: The majority of infants/toddlers presented with clinically significant delays in development, sensory processing and/or behavioral functioning. Adverse developmental outcomes were significantly correlated with PAE and/or postnatal risk factors. Early diagnosis led to early intervention.

16. "Advancing FASD Research, Prevention and Services Act" FASD Respect Act authorizes $50 million for FASD prevention efforts, screening and identification and FASD-informed services by federal, state, local, tribal and private stakeholders. The FASDPN team in conjunction with FASD United advocated for this congressional act in February 2021 in conference calls with Senator Patty Murray's office. This Act continues to receive endorsements from senators nationwide as of June 2024.

VI. References and Key FASDPN Research Publications:

FASD Research: The UW FASD diagnostic clinic started in 1993 as a CDC-sponsored FASD prevention research study (Astley, et al., 2000a, b). Over the next 3 decades, the core FASDPN clinic at the University of Washington has engaged in a multitude of research studies resulting in over 100 peer-reviewed publications. The FASDPN completed an NIAAA-sponsored research study assessing the diagnostic value of magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS) and functional MRI (fMRI) in 2009. These non-invasive tools allow medical professionals to assess the impact alcohol had on an individual's brain structure, brain chemistry, and brain function. This research would not have been possible without the FASDPN and its large clinical/research patient population. The results confirm the validity of these diagnostic tools and confirm that children along the full spectrum of FASD (not just the subset with full FAS) present with clear evidence of brain damage. The results are published in the peer-reviewed medical literature (Astley et al., 2009a, 2009b, 2009c, 2009d). A comprehensive report documenting the validation of the FASD 4-Digit Diagnostic Code was published by Astley in 2014. In 2016, the FASDPN clinical team published a seminal paper documenting the essential role of growth deficiency in the diagnosis of FASD (Astley et al., 2016). Growth deficiency is a powerful predictor of which infants with prenatal alcohol exposure will present with severe brain dysfunction later in childhood. In 2019 the FASDPN clinical team published the world's largest twin study in FASD confirming that fetal genetics contributes to fetal vulnerability to prenatal alcohol exposure (Astley, et al., 2019). The FASDPN also published a comprehensive assessment of 4 FASD diagnostic systems worldwide documenting the superior performance of the FASD 4-Digit Code. (Astley et al., 2019) Dr. Hemingway was invited to present this study to the European Union FASD meeting held in Norway in 2022 and the International FASD Conference in 2024 held in Seattle. As of 2024, the annual International FASD Conference that has been held in Vancouver BC for over 15 years will now be hosted in Seattle. In 2020, the FASDPN published seminal studies documenting the high specificity of the 4-Digit Code FASD facial phenotype (Astley et al., 2020a) and confirming prenatal alcohol exposure as the dominant risk factor among children presenting with neurobehavioral impairments (Astley et al, 2020b).

All publications written by members of the FASDPN are posted on the FASDPN literature website as free, downloadable pdf files. Below are selected publications sorted alphabetically by first author.
