In first describing the dysmorphic features of FAS, Jones and colleagues focused on short palpebral fissure, maxillary hypoplasia (with prognathism), and the presence of epicanthal folds that were observed for a majority of the children described. However, other features also were noted for some patients, including altered palmar fexional crease patterns (i.e., hockeystick crease), cardiac anomalies, joint disability, overlapping fingers, ear anomalies, hemangiomas, ptosis, hypoplastic nails, and pectus deformities (4,5). Over the next 30 years, additional features described included: microcephaly, short nose, smooth philtrum with thin vermillion border, cleft lip, micrognathia, protruding auricles, short or webbed neck, vertebra and rib anomalies, short metacarpal bones, menigomyelocele, hydrocephalus, and hypoplastic labia majora (43).

Despite the heterogeneity of expression for dysmorphic features related to prenatal exposure to alcohol, core facial dysmorphia have emerged through human and animal studies. Experimental studies with a mouse model and primates indicate that the facial dysmorphia observed for individuals with FAS are the result of disturbances of cellular migration during organogenesis along the midline of the face (58). Using anthropomorphic measurements of all facial features, clinical researchers have confirmed the midline feature abnormalities (59). Studies of clinic-referred samples also support these features as discriminant for FAS (60-61). Based on these scientific findings and the extensive clinical experience of the SWG, the following facial dysmorphic features were determined to meet the dysmorphia criteria essential for FAS (based on racial norms):

- Smooth philtrum (measured as 4 or 5 on Lip-Philtrum Guide*)
- Thin vermillion border (measured as 4 or 5 on Lip-Philtrum Guide) (i.e., upper lip)
- Small palpebral fissures (measured as ≤10th percentile according to age and racial norms)

The individual must exhibit all three characteristic facial features; however, additional features also can be present. For example, maxillary hypoplasia is often noted for individuals with FAS as well as those associated features described previously. Cross-sectional and longitudinal studies indicate that many features can change with age or development. After puberty, the characteristic facial features associated with FAS can become more difficult to detect (62). However, recent findings indicate that these three key features remain for the majority of individuals with FAS (47,50).

* University of Washington Lip-Philtrum Guide (49-50).

Use of these three cardinal features (smooth philtrum, thin vermillion border, and small palpebral fissures) to assess whether an individual's dysmorphia is consistent with FAS, is compatible with the IOM report and other diagnostic systems currently in use. Specific criteria were chosen by the SWG to maximize inclusiveness of potential cases on this diagnostic parameter and, therefore, might differ somewhat from other systems currently in use. For example, the 1999 version of University of Washington 4-digit code system uses the same philtrum and vermillion border criteria (as noted by reference to its Lip-Philtrum Guide), but uses a cutoff of the 3rd percentile (2 or more standard deviations below the norm) for palpebral fissures , which is a more conservative cutoff (50). This more conservative approach results in fewer individuals meeting the dysmorphia criteria for an FAS diagnosis but also reduces potential false positives for the diagnosis. Other ways to assess dysmorphia for the FAS diagnosis include checklists or weighted checklists (63-65). Of those checklists reviewed by the SWG, all designated the philtrum, vermillion border, and palpebral fissures as the cardinal facial features of FAS (either by higher weighting or explicit notation). However, because of the cumulative nature of some such lists, an individual who has several of the associated features but not the cardinal features could still be given the FAS diagnosis. Thus, the checklists tend to be more inclusive than the current guidelines, with greater potential for false-positive diagnoses. Review of available diagnostic systems seems to indicate that the dysmorphic criteria agreed upon by the SWG provide a balance between conservative and overly inclusive diagnostic systems.

Differential diagnosis of dysmorphia. Individual dysmorphic features are not unique to any particular syndrome. Even rare defects or certain clusters of dysmorphic features can appear in a variety of syndromes. Therefore, a process of differential diagnosis is essential in making an accurate FAS diagnosis. Following, in Table 1 is a list of syndromes with dysmorphic features that overlap with the primary features of the FAS diagnosis (43). As can be seen from Table 1, none of the syndromes with single overlapping features (except for Toluene embryopathy) have the full constellation of small palpebral fissures, thin vermillion border, and smooth philtrum. However, there are some syndromes in which the constellation of features (primary, occasional features, or both) give a "gestalt" that is similar to the "gestalt" of FAS. These syndromes should be considered in particular when completing the differential diagnosis. Table 2 lists these syndromes, along with the overlapping and differentiating features.

Growth problems. Growth retardation, variably defined, has been documented consistently in individuals with FAS. However, these observations used a variety of parameters (e.g., height, weight, and head circumference), severity levels (below 25th percentile, below 10th percentile, or below 3rd or 2nd percentile), and timing of growth problems (current, birth or present at any point during life). The SWG reviewed available literature, clinical expertise, and practical issues to arrive at benchmarks for each of these three aspects of growth abnormalities.

The primary parameters of growth that need to be impaired to meet the growth retardation criteria of FAS are height, weight, head circumference, or a combination thereof. Anecdotally, a small number of children with FAS have been found to have disproportionate height in relation to weight. However, because multiple organic factors can lead to growth deficiencies (e.g.,. brain structure abnormalities leading to poor skeletal growth or disruption of endocrine function leading to poor weight gain), and because most children with FAS are symmetrical for height and weight (66), it was determined that deficiencies in *either* height or weight, but not height for weight, should be included as growth parameters that might be affected by FAS. Thus, children with growth retarda-

Table 1. Differential diagnosis of individual features associated with FAS

Feature	Syndromes
Smooth philtrum	Cornelia de Lange syndrome Floating-Harbor syndrome Geleophysic dysplasia Opitz syndrome Toluene embryopathy
Thin Vermillion border	Miller-Dieker (Lissencephaly) syndrome Fetal Valproate syndrome Geleophysic dysplasia Cornelia de Lange syndrome Toluene embryopathy
Small palpebral fissures	Campomelic dysplasia DiGeorge sequence Dubowitz syndrome Duplication 10q sequence Duplication 15q sequence FG syndrome Maternal phenylketonuria (PKU) fetal effects Oculodentodigital syndrome Opitz syndrome Trisomy 18 syndrome Williams syndrome Velocardiofacial syndrome Toluene embryopathy

Note: Features that discriminate these disorders from FAS can be found in Jones, 1997.

tion in height or weight would meet the growth retardation criteria for the FAS diagnosis. Consistent with poor brain development, it was determined that head circumference should be included as a CNS parameter rather than a growth parameter (67-68).

Severity of growth retardation has been defined for each parameter as at or below the 10th percentile or at or below the 3rd percentile by a majority of FAS studies. The primary issue for severity is inclusion or exclusion of children for the FAS diagnosis. Use of the 10th percentile would result in more false-positive FAS diagnoses; while use of the 3rd percentile would result in a greater number of false-negatives. For public health reasons of capturing the largest number of children who might need services, the 10th percentile was chosen by the SWG. As noted previously in the dysmorphia section, use of the 10th percentile strikes a balance among criteria used in other diagnostic systems. Again, the 1999 edition of the University of Washington 4-digit code takes a conservative approach, using the 3rd percentile as the cutoff. Checklist systems often do not specify a particular level of growth retardation and some do not specify which growth parameters should be considered (i.e., height, weight, or height relative to weight). This lack of specificity could lead to inconsistency in diagnostic method, which in turn, could lead to inconsistent application of the FAS diagnosis.

Table 2. Differential diagnosis of syndromes similar to FAS

Syndrome	Overlapping Features	Differentiating Features
Aarskog syndrome	Small nose with anteverted nares, broad philtrum, maxillary hypoplasia, and wide-spaced eyes	Rounded face, down-slant to palpebral fissures, widow's peak, crease below lower lip, incomplete out folding of upper helices, and dental eruption problems.
Williams syndrome	Short palpebral fissures, anteverted nares, long philtrum, depressed nasal bridge, and epicanthal folds	Wide mouth with full lips, stellate pattern of the iris, periorbital fullness, and connective tissue disorders.
Noonan's syndrome	Low nasal bridge, wide-spaced eyes, and epicanthal folds	Down-slant to palpebral fissures, keratoconus, wide mouth, and protruding upper lip
Dubowitz syndrome	Short palpebral fissures, wide spaced eyes, and epicanthal folds	Shallow supraorbital ridge with nasal bridge near the level of the forehead, and broad nasal tip
Brachmann-DeLange syndrome	Long philtrum, thin vermillion border, anteverted nares, and depressed nasal bridge	Single, bushy eyebrow extending across forehead, long eyelashes, downturned mouth, high arched palate, and short limbs (yielding short stature)
Toluene embryopathy	Short palpebral fissures, midface hypoplasia, smooth philtrum, and thin vermillion border	Micrognathia, large anterior fontanel, down-turned mouth corners, hair patterning abnormalities, bifrontal narrowing, and ear abnormalities
Fetal hydantoin syndrome (Fetal dilantin syndrome)	Wide-spaced eyes and depressed nasal bridge	Short nose with bowed upper lip
Fetal valproate syndrome	Epicanthal folds, anteverted nares, long philtrum with thin vermilion border, and wide-spaced eyes	High forehead, infraorbital crease or groove, and small mouth
Maternal PKU fetal effects	Epicanthal folds, short palpebral fissures, long underdeveloped philtrum, and thin vermillion border	Small upturned nose, round facies, and prominent glabella

The current guidelines provide consistent growth parameters that should be assessed, as well as a more inclusive level of the 10th percentile.

The primary issue that emerged in the discussion of timing of growth retardation was whether growth retardation needs to be present at the time of the diagnosis, or whether it could have occurred previously and been resolved. This is particularly important when including prenatal growth retardation or early growth problems due to failure to thrive. Because a great number of treatments exist for growth problems (e.g. feeding tubes or hormone therapy), the SWG adopted the criteria that any history of growth retardation, including prenatal growth deficiencies, should be allowed within the diagnostic criteria (61).

Thus, the growth retardation criteria adopted by the SWG are: confirmed prenatal or postnatal height, weight, or both at or below the 10th percentile documented at any one point in time (adjusted for age, sex, gestational age, and race or ethnicity). The committee noted that the examiner should make sure that the single point in time when the growth deficit was present does not correlate with a point in time when the child was nutritionally deprived.

Differential diagnosis of growth problems. Growth retardation and growth deficiencies occur in children, adolescents, and adults for a great many reasons. Some of the most obvious reasons have to do with insufficient nutrition. This could be a particular problem for infants with poor sucking responses who experience failure to thrive. In addition, several genetic disorders result in specific growth deficiencies (e.g., dwarfism). Prenatal growth retardation can be due to a variety of factors, including maternal smoking or other behaviors leading to hypoxia, poor maternal nutrition, or genetic disorders. Both environmental and genetic bases for growth retardation should be considered for differential diagnosis when considering the FAS diagnosis.

Central nervous system abnormalities (CNS). More than 2,000 scientific papers regarding the teratogenic effects of alcohol exposure for CNS have been published over the past 30 years (69-71). Studies of the impact of fetal exposure to alcohol show a range of short- and long-term cognitive and behavioral outcomes resulting from these CNS abnormalities. Complicating detection of these abnormalities is that FAS neurobehavioral presentation changes across the lifespan (4,61,72-79). Despite this developmental process, CNS deficits generally persist throughout the lifespan (80). Longitudinal studies have found that many adults affected by FAS have complex mental health disorders, are affected by the consequences of neurobehavioral deficits, and are unable to sustain independent living (81).Prenatal exposure to alcohol can result in an array of structural, functional, neurological problems, or a combination of these, as well as abnormalities of the CNS (40). To meet the FAS diagnostic criteria for CNS abnormality, structural, neurological, or functional deficits, or a combination thereof, must be documented. Note that it is also possible for an individual to present with more than one CNS structural, neurological, functional deficit or abnormality. Guidelines for each type of CNS abnormality follow.

I. Structural

1. Documented small or diminished overall head circumference (OFC at or below the10th percentile) adjusted for age and gender (including head circumference at birth; 4,68). For children who have overall growth deficiency (i.e., height and weight below the 10th percentile) to meet this criteria for CNS abnormality, the child's head circumference should be disproportionately small to his or her overall size (i.e., OFC at or below the 3rd percentile).

2. Clinically significant brain abnormalities observable through imaging techniques (e.g. reduction in size, or change in shape of the corpus callosum, cerebellum, or basal ganglia) as assessed by an appropriately trained professional (4,58,82-88).

   Note: An individual could meet the CNS abnormality criteria for the FAS diagnosis through a structural abnormality, yet not demonstrate detectable functional deficits.

II. Neurological

Documented evidence of neurological damage to the CNS. Neurological problems of CNS can include seizures not due to a postnatal insult or fever or other soft neurological signs outside normal limits (e.g., in coordination, visual motor difficulties, nystagmus, or difficulty with motor control; 89-92). As with head circumference, abnormal neurological findings can be most predictive of underlying CNS abnormality due to prenatal alcohol exposure, rather than later environmental factors, in younger children. The use of norm-referenced measures of neurological functioning is recommended.

III. Functional

Assessment findings that indicate deficits, problems, or abnormalities in functional skills of the CNS. Early brain damage is usually generalized rather than specific, with increased specificity of abnormalities revealed as development progresses. The functional abilities affected by prenatal exposure to alcohol vary greatly from person to person, depending on the amount of alcohol exposure, timing of exposure, and pattern of exposure (e.g., chronic exposure versus binge episodes). Despite this inherent variation in effects, several areas of significant functional vulnerability have been observed consistently by clinicians and clinical researchers with particular damage to corresponding structures reported (e.g., corpus callosum, cerebellum, or basal ganglia). Variability in exposure impact results in variability of structural, neurological, or functional deficits, or a combination thereof in affected individuals.

For functional deficits, it is generally accepted that multiple locations in the brain (and corresponding functional capability) are affected by prenatal exposure to alcohol. To address this issue, functional deficits that fulfill the CNS abnormality criteria can be met in two ways:

(1) Global cognitive deficit (e.g., decreased IQ)
or significant developmental delay in children too young for an IQ assessment;

OR

(2) Deficits in THREE or more specific functional domains

These two ways of meeting the criteria for a functional CNS abnormality were adopted because of the composite nature of cognitive/intellectual and developmental measures (93-94). Decreased performance on a standardized measure of cognition/intelligence or development assumes deficits in multiple domains. In the absence of such a measure, several specific domains need to be assessed individually to determine that multiple functional domains have been affected. The specific domains most often cited as areas of deficit or concern for individuals with FAS are described below, although other domains and abilities can be affected and this list is not exhaustive. It should

be noted that for each of the following specific domains described, other agents and environmental factors can produce deficits or outcomes similar to prenatal alcohol exposure, making care differential diagnosis essential. Finally, these descriptions are intended to be suggestive and examples of likely and possible problems a clinician might encounter then need to assess using psychometric instruments. The exemplars are not intended to be exhaustive, or to present a necessary list of behaviors to be used as a checklist without reliable and valid assessment.

a) **Cognitive deficits or significant developmental discrepancies.** It is important to note that global deficits or delays can leave the child scoring in the normal range of development, but below what would be expected for his or her environment and background (61,95-99). In addition to formal testing (either through records or current testing), behaviors that may be observed (or reported) in the clinical setting that suggest cognitive deficits or developmental delays that should be assessed by standardized testing include but are not limited to **specific learning disabilities (especially math and/or visual-spatial deficits); uneven profile of cognitive skills; poor academic achievement; discrepancy between verbal and nonverbal skills; and slowed movements or reaction to people and stimuli (e.g., poor information processing)**. (75,100-103)

b) **Executive functioning deficits.** Executive functioning (EF) is defined as the ability to maintain an appropriate problem solving set for attainment of a future goal and that this ability includes the more specific skills of inhibition, planning, and mental representation (104). Behaviors that can be observed (or reported) in the clinical setting that might indicate an EF deficit that should be assessed by standardized testing include, but are not limited to **poor organization, planning, or strategy use; concrete thinking; lack of inhibition; difficulty grasping cause and effect; inability to delay gratification; difficulty following multistep directions; difficulty changing strategies or thinking of things in a different way (i.e., perseveration); poor judgment; and inability to apply knowledge to new situations.** (105-108)

c) **Motor functioning delays or deficits.** Both gross motor and fine motor skills can be impaired for individuals with FAS (109-111). Visual-motor/visual-spatial coordination is a particularly vulnerable area of functioning (99,112-113). Behaviors that can be seen (or reported) in the clinical setting that indicate motor problems that should be assessed by standardized testing include, but are not limited to **delayed motor milestones; difficulty with writing or drawing; clumsiness; balance problems; tremors; and poor dexterity. For infants, a poor suck is often observed.** (61,114-116)

d) **Attention and hyperactivity problems.** Attention problems are often noted for children with FAS, with many children receiving a diagnosis of attention-deficit hyperactivity disorder (AD HD; 117). Although such a diagnosis can be applied, some research has shown that the attention problems for children with FAS do not seem to fit the classic pattern of ADHD. Individuals with FAS tend to have difficulty with the encoding of information and flexibility (shifting) aspects of attention; whereas children with ADHD typically display problems with focus and sustaining attention (118-119). Individuals with FAS also can appear to display hyperactivity because their impulsivity may lead to increased activity levels. Behaviors that may be observed (or reported) in the clinical setting that suggest attention problems related to FAS that should be assessed by standardized testing include, but are not limited to **described by adult as "busy"; inattentive; easily distracted; difficulty calming down; overly active; difficulty completing tasks; and/or trouble with transitions. Parents might report inconsistency in attention from day to day (e.g., "on"**

days and "off" days). (79,120-125)

e) **Social skills problems.** The executive, attention, and developmental problems described previously often lead to clinically significant difficulty for people with FAS when interacting with peers and others. Because of the mental representation problems, individuals with FAS often have social perception or social communication problems that make it difficult for them to grasp the subtler aspects of human interactions (107,126-127). Consistent difficulty understanding the consequence of behavior or inappropriate behavior is frequently described for individuals with FAS (62,80). Behaviors that can be observed (or reported) in the clinical setting that indicate these types of social difficulties that should be assessed by standardized testing include, but are not limited to **lack of stranger fear; often scape-goated; naiveté and gullibility; easily taken advantage of; inappropriate choice of friends; preferring younger friends; immaturity; superficial interactions; adaptive skills significantly below cognitive potential; inappropriate sexual behaviors; difficulty understanding the perspective of others; poor social cognition; and clinically significant inappropriate initiations or interactions.** (128-130) It should be noted that standardized assessment of social problems can be quite difficult. Social functioning is a multifaceted domain that can require several areas of assessment.

f) **Other potential domains that can be affected.** In addition to these five most often cited problem areas, deficits and problems to be assessed by standardized testing can present in several other areas, including **sensory problems (e.g., tactile defensiveness and oral sensitivity); pragmatic language problems (e.g., difficulty reading facial expression; poor ability to understand the perspectives of others); memory deficits (e.g., forgetting well-learned material, and needing many trials to remember); and difficulty responding appropriately to common parenting practices (e.g., not understanding cause-and-effect discipline)**. While abnormalities in these "other" areas have been reported for some individuals with FAS, expert consensus suggests deficits in these areas present at a lower frequency than do those in the other five specific domains (62).

> These guidelines strongly recommend that functional domains be assessed using norm-referenced standardized measures. Domains should be assessed by appropriate professionals using reliable and validated instruments.

Level of functional deficit. In these guidelines, global cognitive deficits and developmental delay, or deficits in three or more specific domains, are defined as performance substantially below that expected for an individual's age, schooling, or circumstances. Several statistical thresholds have been suggested to operationally define performance substantially below expected levels. Previous research indicates that approximately only one-quarter of individuals diagnosed with FAS perform at the most conservative level of below the 3rd percentile (2 standard deviations below the mean) on standardized measures (95). In keeping with this finding, and to adequately capture the full spectrum of effects, the SWG adopted two levels of functional deficits that would meet the criteria for a CNS abnormality: (1) for significant global cognitive deficit performance below the 3rd percentile (i.e., 2 standard deviations below the mean); and (2) for three or more specific domains performance below the 16th percentile (i.e., 1 standard deviation below the mean) on standardized measu res of individual domains. Thus, individuals scoring below the normal range on a global measure of IQ or development and individuals scoring in the below average range on standardized measures of three

specific functional domains would meet the criteria for functional CNS abnormality for diagnostic purposes.

Ideally, functional deficits should be established through appropriate standardized neuropsychological testing by a trained professional. The SWG recognized that such standardized testing might not be readily available in all diagnostic settings. Clinicians are strongly encouraged to supplement their observations by obtaining standardized testing through early intervention programs, public schools, and psychologists in private practice. The SWG emphasizes the need for psychometric testing when evaluating an individual for the FAS diagnosis, and use of clinical judgment alone could veer away from the goal of implementing standard diagnostic criteria for FAS. In addition, such testing will facilitate the development of individualized and appropriate treatment plans for diagnosed individuals. These guidelines are intended to provide information concerning the types of CNS abnormalities that might be observed, as well as the level of deficit that can be expected. In addition, they seek to support the need for quality assessments administered by trained professionals when establishing CNS abnormalities associated with the FAS diagnosis.

These guidelines for assessment of CNS abnormalities for making the FAS diagnosis is in harmony with, although not duplicative of, other diagnostic guidelines and systems. The 1999 version of the University of Washington 4-digit code and the guidelines developed by Health Canada requires performance below the 3rd percentile (2 standard deviations below the mean on standardized testing) in three separate domains in which global deficits count as one domain. Some health systems might find this approach useful in situations in which resources for standardized testing are readily available.

Mental health problems and lifelong consequence. Difficulty in any of the functional CNS areas described above can lead to maladaptive behavior and mental health problems with lifelong consequences. Commonly co-occurring mental health issues (excluding attention problems) reported by clinicians and cited in the scientific literature to date, include ***conduct disorders, oppositional defiant disorders, anxiety disorders, adjustment disorders, sleep disorders, and depression*** *(81,95,131-134)*. Although attention problems can be classified as a mental health issue or psychiatric condition, in these guidelines they are treated as a primary deficit resulting from alcohol-related CNS damage, rather than a secondary mental health issue. There are considerable animal, human, and clinical studies that document attention deficits for many individuals with prenatal exposure to alcohol (117). In addition, decreased adaptive skills and increased problems with daily living abilities have been consistently documented, although further research is needed . Such problems include dependent living conditions, disrupted school experiences, poor employment records and encounters with law enforcement (including incarceration; 95). Although these mental health and very debilitating lifelong consequences should not be used for the purpose of diagnosis, it should be noted that they are very prevalent among individuals with FAS and are very likely to be the presenting conditions that should trigger a referral and comprehensive diagnostic evaluation.

Differential diagnosis of CNS abnormalities. Differential diagnosis of CNS abnormities involves not only ruling out other disorders but also specifying co-occurring disorders. The CNS deficits associated with FAS, in particular functional deficits, can be produced by many different factors in addition to prenatal alcohol exposure. It is important to determine that the observed functional deficits are not better explained by other causes. In addition to other organic syndromes that produce deficits in one or more of the previously cited domains (e.g., Williams syndrome and Down syn-

drome), significantly disrupted home environments or other external factors can produce functional deficits in multiple domains that overlap with the domains that are affected by FAS. In making the differential diagnosis of FAS by ruling out other syndromes, CNS abnormalities should be evaluated in conjunction with dysmorphia and laboratory findings. The more difficult differentiation is for CNS abnormalities resulting from environmental influences (e.g., abuse or neglect, disruptive homes, and lack of opportunities). ***To assist with differential diagnosis between FAS and environmental causes for CNS abnormalities it is important to obtain a complete and detailed history for the individual and his or her family.***

In addition to ruling out other causes for CNS abnormalities, a complete diagnosis should identify and specify other disorders that can co-exist with FAS (e.g., autism, conduct disorder, and oppositional defiant disorder). ***It is very important to note that a particular individual might have a conduct disorder in addition to FAS, but that not all persons with a conduct disorder have FAS and not all individuals with FAS will have a conduct disorder.*** Thus, organic causes, environmental contributions, and comorbidity should all be considered for both inclusive and exclusive purposes when evaluating someone for the FAS diagnosis (62,135). Finally, differential diagnosis for the CNS abnormalities within the FAS diagnosis is extremely difficult and should be conducted by professionals trained not only in the features of FAS, but also in the features of a broad array of birth defects and developmental disabilities so as to understand the distinguishing characteristics.

Maternal alcohol exposure. Documentation and confirmation of prenatal alcohol exposure can be extremely challenging. For birth mothers, admission of alcohol use during pregnancy can be very stigmatizing. The situation can be further complicated if the woman is still using alcohol, especially at high consumption rates. In this situation, information about alcohol use might need to be obtained from other reliable informants, such as a relative. However, the overwhelming situation encountered in the clinical setting is when a child or adult is being evaluated for FAS and little or no information about the index pregnancy is available. This frequently occurs for children in foster and adoptive homes. In this situation, every effort should be made to obtain the necessary information, but lack of confirmation of alcohol use during pregnancy should not preclude an FAS diagnosis if all other criteria are present. This would be considered "unknown prenatal alcohol exposure". In very rare instances, there will be confirmed absence of exposure. Documentation that the birth mother did not drink any amount of alcohol from conception through birth would indicate that the FAS diagnosis is not appropriate. This typically implies that the birth mother knew the date of conception (e.g., a planned pregnancy) and did not consume alcohol from that day forward, or she was prevented from drinking for some reason (e.g., incarceration). It must be noted that simple denials of alcohol use might or might not be credible and corroborating evidence should be obtained whenever possible. However, given the imprecise nature of exposure information, the following two qualifiers for prenatal alcohol exposure were suggested by the SWG:

I. **Confirmed prenatal alcohol exposure** requires documentation of the alcohol consumption patterns of the birth mother during the index pregnancy based on clinical observation; self-report; reports of heavy alcohol use during pregnancy by a reliable informant; medical records documenting positive blood alcohol levels, or alcohol treatment; or other social, legal, or medical problems related to drinking during the index pregnancy.

II. **Unknown prenatal alcohol exposure** indicates that there is neither a confirmed presence nor a confirmed absence of exposure. Examples include: the child is adopted and prenatal exposure(s) is unknown; the birth mother is an alcoholic, but confirmed evidence of exposure during pregnancy does not exist; and conflicting reports about exposure exist that cannot be reliably resolved.

CRITERIA FOR FAS DIAGNOSIS

A diagnosis of FAS requires the presence of all three of the following findings:

1. Documentation of all three facial abnormalities (smooth philtrum, thin vermillion border, and small palpebral fissures);

2. Documentation of growth deficits; and

3. Documentation of CNS abnormalities (structural, neurological or functional, or combination thereof).

It should be noted that confirmed prenatal alcohol use can strengthen the evidence for diagnosis, but is not necessary in the presence of all the previous findings. Confirmed absence of alcohol exposure would rule out the FAS diagnosis. The FAS diagnosis should be made only after ruling out other possible diagnoses associated with each criterion. A brief outline of the diagnostic criteria for FAS is presented in Table 3.

Changes in presentation of criteria across development. As would be expected for any congenital syndrome, presentation of the diagnostic features can change over development. With regards to facial features (small palpebral fissures, smooth philtrum, and thin vermillion border), it has generally been accepted that these features are most evident during infancy and the early preschool years. However, longitudinal data that specifically address this issue are not available currently. One also might expect growth parameters to change (and generally normalize) with development. This might especially be the case for children who receive nutritional or other interventions. Perhaps the criterion for which the most change over development is observed is CNS abnormalities. While structural abnormalities would remain consistent, neurological and functional deficits could resolve or change presentation at various stages of development. During the newborn and infancy periods, difficulty with arousal or behavior regulation might be observed. Slightly older infants could display delayed or abnormal motor skills. During late infancy approaching the preschool period, general cognitive developmental delay is generally reflected through delayed milestones, especially early language acquisition (note, however, that basic language skills of vocabulary and syntax generally are not areas of deficit for children with FAS). During the preschool period, attention problems and hyperactivity can emerge. In typically developing children, the late preschool through early school age (e.g., 4 through 7 years of age) is when many executive functioning and social perception skills are acquired. For example, simple planning or organization skills are learned, as well as understanding the physical and mental perspective of others. Preschoolers and school-aged children often do not fully acquire these skills. Throughout the school-age period, children with FAS can exhibit deficits or difficulty with any of the CNS domains listed in the diagnostic criteria. However, each child's pattern of strengths and weaknesses is likely to be very individualized. During adolescence and through adulthood, the pattern of deficits continues to be present and in addition, lifelong conse-

Table 3: Brief Outline of Diagnostic criteria for Fetal Alcohol Syndrome

Facial dysmorphia
Based on racial norms, individual exhibits all three characteristic facial features:

- Smooth philtrum (University of Washington Lip-Philtrum Guide rank 4 or 5)
- Thin vermillion border (University of Washington Lip-Philtrum Guide rank 4 or 5)
- Small palpebral fissures (at or below 10th percentile)

Growth problems
Confirmed prenatal or postnatal height or weight, or both, at or below the 10th percentile, documented at any one point in time (adjusted for age, sex, gestational age, and race or ethnicity).

Central Nervous System Abnormalities

I. Structural

1) Head circumference (OFC) at or below the 10th percentile adjusted for age and sex.
2) Clinically significant brain abnormalities observable through imaging.

II. Neurological

Neurological problems not due to a postnatal insult or fever, or other soft neurological signs outside normal limits.

III. Functional

Performance substantially below that expected for an individual's age, schooling, or circumstances, as evidenced by:

1. *Global cognitive or intellectual deficits representing multiple domains of deficit (or significant developmental delay in younger children) with performance below the 3rd percentile (2 standard deviations below the mean for standardized testing)*
   or
2. *Functional deficits below the 16th percentile (1 standard deviation below the mean for standardized testing) in at least three of the following domains:*
   a) cognitive or developmental deficits or discrepancies
   b) executive functioning deficits
   c) motor functioning delays
   d) problems with attention or hyperactivity
   e) social skills
   f) other, such as sensory problems, pragmatic language problems, memory deficits, etc.

Maternal Alcohol Exposure

I. Confirmed prenatal alcohol exposure
II. Unknown prenatal alcohol exposure

Criteria for FAS Diagnosis
Requires all three of the following findings:

1 Documentation of all three facial abnormalities (smooth philtrum, thin vermillion border, and small palpebral fissures);
2. Documentation of growth deficits
3. Documentation of CNS abnormality

quences of those deficits emerge, including mental health problems, inability to achieve independent living, and criminal activity (62,95,126-137).

Individuals who do not meet the full diagnostic criteria for FAS. The 1996 IOM report noted that most individuals with deficits resulting from prenatal exposure to alcohol do not express all of the features necessary to meet the criteria for an FAS diagnosis. This was confirmed in the comments of researchers, clinicians, and members of the NTFFAS/FAE during the deliberations of the SWG. Consensus has not been reached by either of these groups, or the scientific and clinical community at large regarding evidenced-based diagnostic criteria for any prenatal alcohol-related condition other than FAS. However, there is grave concern that individuals who present with the same neurodevelopmental deficits as individuals diagnosed with FAS, but who do not present with the full facial features or growth deficits, are not being afforded services because they are not given a diagnosis of FAS. Ongoing funding has been provided by the National Institute on Alcohol Abuse and Alcoholism (NIAAA) to conduct research that might result in evidence-based diagnostic criteria for individuals with other conditions caused by prenatal alcohol use. Currently, CDC is using a collaborative database of neurodevelopmental data from five intervention studies to explore the nature of individuals who could be considered in the diagnostic category of ARND, as well as data from a prospective cohort study of 5-year-olds in Denmark. However, at this time, the only diagnostic category with scientific evidence to support clinical criteria is FAS. As future data and science are available, these guidelines can be refined and expanded to delineate other conditions resulting from prenatal alcohol exposure.

CONSIDERATIONS FOR A REFERRAL FOR AN FAS DIAGNOSTIC EVALUATION

Very often the front-line providers of services (medical, educational, or social) are faced with making the decision of whether or not to refer a child, individual, or family for a full FAS diagnostic evaluation. The SWG recognizes that this may be a difficult decision. For biological families, there may be social stigma associated with any evaluation concerning prenatal alcohol exposure. In other families, direct information about alcohol use during pregnancy may not be available or only suspected. Thus, the following guidelines were developed to provide assistance in making the referral decision, although, it is recognized that each case must be evaluated individually. Further, these guidelines were developed with the idea that when in doubt, it was preferable to refer for full evaluation by a multidisciplinary team with experience in evaluating prenatal alcohol exposure.

- For situations with known prenatal alcohol exposure: A child or individual should be referred for full FAS evaluation when there is confirmed significant prenatal alcohol use (i.e., 7 or more drinks per week or 3 or more drinks on multiple occasions, or both). If prenatal alcohol exposure in the high risk range is known in the absence of any other positive screening criteria, the primary healthcare provider should document this exposure and closely monitor the childs ongoing growth and development.

- For situations with unknown prenatal alcohol exposure: A child or individual should be referred for full FAS evaluation when:
  - there is any report of concern by a parent or caregiver (foster or adoptive parent) that his or her child has or might possibly have FAS.
  - all three facial features are present (smooth philtrum, thin vermillion border, and small palpebral fissures).

– one or more facial features are present in addition to growth deficits in height or weight, or both.
– one or more facial features are present, along with one or more CNS abnormalities.
– one or more facial features are present, along with growth deficits and one or more CNS abnormalities.

SERVICES APPROPRIATE FOR AFFECTED INDIVIDUALS AND THEIR FAMILIES

Diagnosis is never an endpoint for any individual with a developmental disability and his or her family. This is particularly true for individuals with FAS, their families, and their community. As described in the framework section, the FAS diagnosis and the diagnostic process (especially the neuropsychological assessment) are part of a continuum of care that identifies and facilitates appropriate health care, education, and community services. The learning and life skills affected by prenatal exposure vary greatly among individuals, depending on the amount of alcohol exposure and the timing and pattern of exposure, as well as each individual's current and past environment (138-139). As a result, the services needed for individuals with FAS and their families vary according to what parts of the brain have been affected, the age or level of maturation of the person, the health or functioning of the family, and the overall environment in which the person is living. Thus, service needs for any particular individual and his or her family can be quite individualistic (140).

Despite the required individualization in service needs, some general areas of service and specific services have been identified as helpful to people with FAS and their families (62). While the ideal circumstance are services and interventions that have been specifically developed for individuals with FAS and their effectiveness has been established through rigorous scientific evaluation, such programs are only now being researched and developed. Thus, most evidence for the benefit of services has been gleaned from research with other populations, clinical wisdom, and family experiences. These three sources have drawn heavily from information obtained concerning risk and protective factors that have been found through systematic research, using natural history methodology, to promote positive development or reduce the incidence of negative long-term consequences of FAS (i.e., reduce secondary conditions; 141). First, these factors will be reviewed. Then, services that are applicable to all individuals with FAS, regardless of life stage will be presented. Finally, essential services appropriate for individual life stages will be presented.

Risk and Protective factors. In a landmark study of secondary conditions for individuals with FAS, Dr. Ann Streissguth and her colleagues delineated not only the lifelong consequences of FAS, but also several basic factors that are protective or increase the risk of negative outcomes (95). This study identified many lifelong negative consequences of FAS, including disrupted school experiences, legal problems, incarceration, mental health problems, substance abuse problems, inappropriate sexual behavior, dependent living, and poor employment history. Importantly, these risks are not mutually exclusive. Any individual can (and most likely will) experience multiple risk factors that can have a cumulative effect (141). Moreover, these risks can be exacerbated by family and community expectations. Research has shown a relation between the number of risk factors encountered by an individual and poor outcomes. Reducing the number and severity of risk factors is an important step in providing services to individuals with FAS and their families. The disorder of FAS has often been described as a "hidden" disability because of the subtlety of the dysmorphia and good basic language skills (e.g., vocabulary and syntax) of many affected individuals. These factors lead to individuals with FAS being treated inappropriately because of caregivers' unrealistic

developmental expectations. FAS might be either not recognized or mislabeled as stubbornness or "bad" behavior by a caregiver, or others who encounter the affected individual (e.g., teachers, extended family, and friends). Families raising children with developmental disabilities typically report considerable parental stress related to this aspect, particularly for parents of children with FAS (62).

Several factors have been identified that can potentially reduce the odds of long-term negative outcomes in children with FAS (protective factors), including a stable and nurturing home environment during the school years, early diagnosis (before 6 years of age), absence of exposure to violence, few changes in caretaking placements, and eligibility for social and educational services. Interventions and services that maximize these protective factors while reducing risk factors will provide the best benefit to anyone with FAS and improve their chances for achieving their developmental potential (95,138).

General Needs. Helpful interventions should include those that stabilize home placement and improve parent-child interaction (138). One method for accomplishing this goal is to increase the understanding of the disorder by parents, teachers, law enforcement personnel, and other professionals who might become involved with the affected individual. Children with FAS often need unique parenting because of their difficulty with cause and effect reasoning and other executive functioning skills. Caregiver education should highlight and explain differences in the thought processes of children with FAS from typically developing children and children with other developmental disabilities. This would enable parent s to avoid potentially difficult situations (e.g., avoiding overly stimulating environments) and better manage problems when they do arise. Overall, a better functioning family that results from caregiver education promotes the stable, nurturing home that has been shown to be a positive protective factor for children with FAS (142).

Beyond the home environment, other professionals also need increased education and information concerning FAS (135). Parents can facilitate this understanding by learning to become advocates for their child. Such advocacy includes both linking families with needed community resources and making sure that the child receives maximum benefit from that service. Because the myriad of service systems is confusing and inconsistent across states, families must be educated about them at the local level. The world of social and educational services can be overwhelming, confusing, and inconsistent, and usually has a unique vocabulary that must be learned. Thus, it is important that along with a diagnosis, clinicians need to help caregivers in learning about available services, how to determine which services are appropriate for their child, and how to work productively with service providers (62).

Many prenatally exposed infants and children enter the foster or adoptive care system at an early age. A recent study estimated that the prevalence of children with FAS (or a related disorder) in the foster care system is 10 times that of the general population (143). However, while protective service agencies (PSAs) might have information about a child's prenatal history, staff members are generally not knowledgeable about FAS, do not understand the impact of the child's having FAS, or do not communicate the child's FAS status to other service systems. As a result, foster and adoptive families are most often not educated about the long-term effects and are unprepared to meet their child's needs. However, most PSAs require foster parents to take a specified number of educational courses annually. These courses should include education about the effects and developmental needs

of the child with FAS since the majority of foster parents will encounter at least one child with FAS or a related disorder during their time as a foster parent.

The assessment process is integral to a well-developed treatment plan. As has been emphasized in these guidelines, part of the diagnostic process is a comprehensive neuropsychological assessment, not only to establish CNS abnormities for the diagnosis, but also to develop the best treatment plan possible. Such a treatment plan minimizes risk factors for lifelong negative consequences and promotes protective factors that maximize developmental potential. Clinicians and s ervice providers must ensure that assessments include communication and social skills; emotional maturity; verbal and comprehension abilities; language usage; and, if appropriate, referral for medication assessments. Finally, it is the responsibility of the community at large to ensure that children with disabilities, including children with FAS, have access to and are assimilated into school, recreational, and social activities.

Age-specific services. Basic child development informs clinicians and service providers that the abilities of any one individual change dramatically at different stages of development. Intervention research informs providers that the most effective programs are those that are geared towards an individual's developmental level. There are specific "turning points" during which children demonstrate rapid and fundamental changes in their understanding of the world and in their problem-solving skills (e.g., development of object permanence or acquisition of formal operational thought). The services identified in the following sections include those for both the child and the family, grouped broadly by developmental stage. It is recognized that many of these services span beyond a single age category with considerable overlap, especially for the family.

Prenatal services. Significant development of all major organ systems occurs throughout gestation; thereby, making it imperative that women who drink during pregnancy be identified by the medical community as early as possible and be provided intervention services. Findings have indicated that children born to women who stop drinking at any point during their pregnancy have better outcomes than those who continue to drink throughout pregnancy (73). To ensure this happens, physicians, nurses, and other allied health professionals need to be trained to screen patients for possible alcohol use, to understand the detrimental effects of prenatal exposure to alcohol, to understand alcoholism as a treatable disorder, and to be familiar with treatment services. Many women who drink during pregnancy and their partners are not educated about FAS or the harmful effects of drinking during pregnancy. These prospective parents might not be prepared to address their shame or the needs of their children. Some women who experience an alcohol-exposed pregnancy might have been exposed themselves prenatally to alcohol. Therefore, treatment personnel need to be educated about both FAS and needed services to provide more appropriate treatment, as well as provide ongoing support and monitor these families closely.

Services for birth to 3 years of age. The first years of life are an important time for physical, cognitive, and emotional development. Decades of research have consistently shown the benefits of early intervention for children with developmental disabilities. Clinicians working with this age group need to familiarize themselves with the state systems that service this population. In particular, Part C of the Individuals with Disabilities Education Act (IDEA) provides early intervention for children 0 to 3 years of age . In many states, this program is administered through local health departments. A particularly appealing aspect of the Part C portion of IDEA is that FAS is considered a "presumptive eligibility" diagnosis. Presumptive diagnoses allow children "at risk" of later develop-

mental delay to be served without meeting particular eligibility criteria. That is, children who are at risk for later developmental problems can receive services, even if they test in the normal range or do not meet other eligibility criteria. This is very important for children with FAS because only about 25% score in the significantly developmentally delayed range (or the range of mental retardation for older children; 95). Referring children who have the FAS diagnosis as well as children who are exposed but do not meet the full diagnostic criteria for FAS, ensures that these children are monitored and, at appropriate ages, referred to appropriate ancillary services as needed. Many states maintain birth defects registries that track the ICD-9 code encompassing FAS (i.e., 760.71 Fetal Alcohol Syndrome) which also can facilitate such monitoring. All infants who are known to have been exposed prenatally included in these registries can be referred to the state's special child health services (note: each state will have its own name for this service) that are part of all states' maternal and child health systems. Special child health services programs provide case management and referral services for children with birth defects or developmental disabilities as well as facilitate evaluation for early intervention programs.

As noted previously, a stable and nurturing caregiving environment is a protective factor for children with FAS. Child development literature states that stable and nurturing environments promote secure attachments between infants and caregivers (144). Secure attachment facilitates emotional, social, and personality development in positive ways. Insecure or negative attachment can lead to inappropriate development in these areas, and at the most severe end of the continuum, the psychopathology of reactive attachment disorder (RAD). The time between birth and 3 years of age has been shown to be a particularly salient time for development of child and caregiver attachment. Disruption in the caregiving environment can lead to poor or negative attachment between infant and caregiver (145). Because many children with FAS are in the foster care system and experience multiple placements (due both to the nature of the system and the difficulty in parenting a child with FAS), they are at tremendous risk for negative attachment including RAD.

Services for children 3 to 6 years of age and school age. It is often during the toddler period that children with FAS will be identified and can be diagnosed. It is essential that states establish FAS diagnostic centers or ensure that their child evaluation centers have clinicians who are trained in the dysmorphic and other diagnostic criteria associated with prenatal exposure.

Following the families themselves, the educational system serves as the most constant service provider for individuals with FAS from early childhood through adolescence. Therefore, beginning with preschool programs and through secondary education, generalized essential services can be delineated. When a child reaches three years of age, early intervention services (IDEA Part C) end and families are referred to preschool handicapped programs (sometimes called special needs preschool) that are administered through IDEA Part B. Part B of IDEA differs from Part C in that there are no presumptive eligibility diagnoses. Eligibility for educational services under this program is related entirely to functional criteria and their relation to educability. As noted previously, this can make it difficult for children with FAS to qualify for these special education services because only a quarter of the children with FAS achieve standardized test scores in the range of significant developmental delay (or mental retardation), the usual eligibility threshold. However, within the IDEA framework, there are a few categories that allow children with FAS who score above the eligibility threshold to still qualify. A few children with FAS will qualify in the category of learning disabled (LD). This category is for children who demonstrate a statistically significant discrepancy (2 standard deviations or more) between overall IQ and one or more academic skills (e.g., math).

Another eligibility category that has been helpful in qualifying children with FAS is behavior disorder. However, this category should be used with care because children with FAS can learn negative behaviors from other children without receiving the benefits of a structured environment. Finally, the category of other health impaired (OHI) can be used at the discretion of the individual education plan (IEP) committee, which includes parents as well as school personnel. Services available through the school system go beyond classroom settings. Children can receive various therapies, including physical therapy (usually most appropriate for very young children), speech and language therapy, occupational therapy, or social skills training. These last two areas are particularly helpful to children with FAS because of the visual-motor deficits and problems in social interactions they encounter.

Training parents to be effective educational advocates is essential to maximize the benefits of their child's special education and to understand their child's rights. The purposes of the IEP are to insure access to appropriate habilitation and rehabilitation services (physical, occupational, speech, behavioral, mental health, and other related services) and to ensure that academic curricula are balanced with vocational training and skills of daily living (e.g., personal hygiene, money management, and family life education), when appropriate. In addition to training parents about the educational system, the preschool period, as well as elementary school years, are times when parents become more acutely aware of their child's imitations. Reinforcement and updating of information learned in early parent education settings will benefit both the child and the parents. Reviewing lessons learned will help parents adjust their expectations for the child's current functioning, as well as his or her future possibilities.

As noted previously, it is important that school staff be trained to recognize possible characteristics associated with FAS, as well as appropriate techniques for instructing students with FAS. Irrespective of whether alcohol-exposed children are in regular or handicapped preschool programs, educational methodologies need to be developed that best address their learning styles and that appropriate behavioral or mental health services are available and initiated.

Beyond services available through the educational system, families raising preschool and school-aged children continue to need services to promote positive family functioning. Such services might include behavior management training, family (or child) counseling, parenting workshops that focus on the unique aspects of parenting a child with FAS, or other types of continuing education. One service that becomes very important during these years is respite care. Such care allows a trained individual to stay with the affected child while caregivers or other family members take advantage of some time away from the child with FAS. Respite care has been shown to significantly reduce family stress and improve family functioning (146-147). Unfortunately, respite care, especially formalized and high-quality respite care, is not readily available in most communities. A clinician can help in this situation by working with the family to develop informal respite care situations, such as help from an extended family member working with the family and to provide the necessary education about FAS to such a respite care provider.

Services for adolescents. Adolescence, and even preadolescence, is one of the major turning points in the life of an individual with FAS. His or her body is changing, cognitive abilities are changing, peer groups are changing, and community expectations are changing. Because of the confusing nature of all these changes, adolescence often is the period when behavioral and mental health problems become more pronounced. Depression or anxiety, or both, can set in as the individual

struggles to cope with these changes. Increased opportunities to experience alcohol and/or drugs can lead to substance abuse problems. Families could become involved with juvenile or criminal justice systems. These are some of the most serious secondary conditions that research has identified for individuals with conditions associated with prenatal alcohol exposure (95).

It is often during adolescence that families experience high levels of stress and tension. As such, the need for individual counseling (for both child and parent), family counseling, and a strong support network becomes more crucial. However, this can be the exact stage at which agencies are reluctant to provide such services, especially if the FAS-related disability factor is not recognized. Because some amount of rebellion is expected during adolescence, the challenging behaviors of the teenager with FAS might be dismissed as transient. At the other end of the spectrum, the challenging behaviors of the adolescent with FAS can be so severe as to involve the criminal justice system.

Because adolescents will soon be leaving the safety and structure of the educational system, vocational and transitional services become essential during this stage. These services often represent a shift from academic skills and achievements to daily living skills, including employment skills. It is very important that these services be started in early adolescen ce, and not left until the individual is about to age-out of the educational system. In addition, beyond teaching the specific skills that go with a particular job, it might be necessary to explicitly teach those skills related to being a good employee (e.g., punctuality and minimized socializing). Most individuals will learn these skills through basic maturity and observational learning. Individuals with FAS often need explicit instruction as well as lifestyle supports (e.g., a job coach).

As for all adolescents, sexual behavior often becomes a critical issue during this stage. The boundaries for appropriate interaction with the opposite sex, the subtle nature of social cues, and impulse issues are difficult for any adolescent, but more so for the adolescent with FAS. Close supervision is the first line of defense during the adolescent years. However, such supervision often conflicts with the adolescent's growing desire for independence. This must be navigated with care to avoid alienating the adolescent. Also, it is probably best to be open and explicit with the teenager with FAS concerning the issues of contraception, sexually transmitted diseases, and sexual harassment. Failure to address these issues can have serious, and possibly life-threatening consequences for the affected individual, his or her family, and any children resulting from unintended pregnancies.

As mentioned previously, individuals with FAS are at high risk for involvement with the juvenile and criminal justice systems. Their lack of executive functioning skills (i.e., poor judgment), fluid language skills, and naïve social skills make them particularly vulnerable to participating in criminal activity. However, these same deficits demand that when they do encounter the justice system, their deficits should be taken into account during all aspects of justice proceedings (i.e., charges, process, punishment, and rehabilitation). As such the juvenile and criminal justice systems are major social systems in need of education regarding FAS. Special rehabilitation programs with staff that are trained to work with adolescents and young adults with FAS should be established. Such programs should be based on scientifically-based research findings that evaluate practicality as well as effectiveness.

Services for adults. In addition to all the services mentioned for the preceding age groups, adults with FAS often need support in every area of their lives. Everyday needs such as transportation issues, job assistance, housing assistance, medication reminders, money assistance, and support and

assistance when unpredicted issues arise should continue to be monitored and supported. Although not consistently available, clearly a system needs to be established that assists people with FAS in living as independently in the community as possible and includes support for housing, healthcare, and employment.

Because of federal, and often state legislation, it is very difficult for people with FAS to receive services from state developmental disability agencies, unless exposed individuals have met the eligibility criteria for services before 22 years of age. Eligibility criteria are generally based on levels of intelligence, as well as functional limitations in at least three areas associated with skills of daily living. As a result, many exposed individuals will not be eligible for services that often include an individual service plan (ISP), case management, residential and employment assistance, and possibly social security disability payments.

People with FAS might be eligible for federal assistance, such as, Medicaid, Supplemental Security Income (SSI), and Section 8 Housing subsidies, not because of their disabilities but because of their low income status. However, obtaining these services can be difficult. For example, most states have long waiting lists for Section 8 housing because of both the high demand and great need often leading to a shortage of rental units. Eligibility criteria for these services, even when based on income, should include a priority category for persons with FAS. Unfortunately, many of these housing options do not offer the support and structure that adults with FAS often need. Housing remains one of the main issues in supporting individuals with FAS for which there are no appropriate services developed or identified.

IDENTIFYING AND INTERVENING WITH WOMEN AT RISK FOR AN ALCOHOL-EXPOSED PREGNANCY

Despite ongoing efforts to inform childbearing-aged women of the risk associated with alcohol use during pregnancy, surveys conducted by the CDC and SAMHSA indicate that 9% to 12% of pregnant women in the United States report consuming alcohol and that approximately 3% report drinking at levels than have been consistently associated with adverse effects on the fetus (148-149). Also of concern are the high proportions of non pregnant childbearing-aged women whose drinking patterns exceed safe levels as defined by public health agencies (150-151). Currently more that half of all women of childbearing age (18 through 44 years of age) report alcohol use, and one in eight report binge drinking in the past month. Many of these women are sexually active and are not taking effective measures to prevent pregnancy. These women are at risk for an alcohol-exposed pregnancy in that they could have an unrecognized pregnancy and continue drinking early in pregnancy at levels that are harmful to the fetus.

One public health strategy for preventing alcohol-exposed pregnancies is to identify characteristics of women at greatest risk of having a child affected by prenatal alcohol exposure and implement prevention programs in subpopulations with higher proportions of these identified risk factors. Over the past 20 years, concerted efforts have been made to identify factors among childbearing-aged women associated with harmful patterns of alcohol consumption. One extensive review of studies reporting characteristics of women giving birth to a child with FAS found that low socioeconomic status (SES), African-American and American-Indian/Alaska-Native ethnicity, and being a smoker were characteristics commonly found among women in this group (152). Additional studies using cross-sectional survey data and special populations have extended our understanding of char-

acteristics associated with childbearing-aged women at high risk for having an alcohol-exposed pregnancy based on current drinking patterns. Factors associated with risk include being a smoker, having a low SES, being unmarried, having a history of previous or current illicit drug use, having a history of physical or sexual abuse, having psychological stress, and having mental health disorders (153-156). In an attempt to identify community-based settings that have higher proportions of preconceptional women at increased risk for an alcohol-exposed pregnancy, CDC sponsored an epidemiological study of special populations that included: women in alcohol and drug treatment centers, a large urban jail, publicly funded primary care clinics, a university-based gynecology clinic in a large urban hospital, and a cohort of women responding to a newspaper solicitation (27). Being at risk for an alcohol-exposed pregnancy correlated significantly with being (or having ever been) a smoker, having a history of inpatient treatment for drugs or alcohol, having a history of inpatient mental health treatment, having multiple sex partners, and having experienced recent physical abuse.

Primary prevention of alcohol-exposed pregnancies requires the accurate identification of women who are drinking at thresholds that have been associated with adverse pregnancy and infant outcomes before pregnancy occurs. Dietary guidelines from the U.S. Department of Health and Human Services recommend that women drink no more than one drink per day to avoid increased risk for adverse health conditions and that women who are pregnant, planning a pregnancy, or at risk of pregnancy abstain from alcohol use altogether. Research findings support these recommendations with evidence of increased risk for birth defects, spontaneous abortions, and deficits in neurocognitive development and growth at levels of seven or fewer drinks per week in some studies (157-162).

Of further concern is the pattern in which alcohol is consumed. Heavy episodic drinking, as in binge drinking, can result in increased severity of the teratogenic exposure effects because of the higher peak blood alcohol levels achieved in this pattern of consumption as opposed to lower level daily consumption (40,163). Historically, a binge episode has been considered to be five or more drinks on any one occasion, but evidence of the presence of gender effects in alcohol metabolism and higher morbidity and mortality among women than men with similar consumption patterns has prompted recommendations for defining a binge episode for women as four or more drinks on any one occasion or on any one day. Current recommendations on clinical thresholds published by the NIAAA are that women drinking more than seven drinks per week or more than three drinks on any given day in the past month be further assessed for risk of developing alcohol-related problems. As stated earlier, pregnant women are advised to abstain from alcohol use. This is a long-standing federal advisory and one supported by major professional societies as well (9,164).

Measurement of current alcohol consumption can be enhanced through the use of reliable screening and assessment methods. A number of screening instruments have been developed that offer the practitioner options for clinical assessment of childbearing-aged women. When selecting a screening tool for routine implementation, healthcare professionals should consider factors such as the goals of the screening process, the target population, and the ease of administration. All women of childbearing age should be screened for alcohol use, including women who are pregnant or nursing, women who are planning a pregnancy, and women who are sexually active and not using contraception (such as teens and college-aged women).

Methods and Considerations for Establishing Reliable Estimates of Alcohol Use. Measures most commonly used in alcohol assessment include items that address quantity, frequency, and pattern (variability) of drinking. Quantity-frequency measures (QF) inquire about average or typical consumption patterns. The simplest measures assess the amount of drinking on average drinking days (Q), and the average number of days on which alcohol is consumed (F). QF measures can be used to estimate a woman's average number of drinks per day or the amount of absolute alcohol consumed per day (AA score). To assess for binge drinking, some investigators have recommended that screening questions should include measures of maximum quantity consumption and frequency of maximum quantity consumption (165). *Helping Patients with Alcohol Problems: A Practioner's Guide,* developed by the NIAAA, (166) recommends quantity-frequency and maximum quantity questions as the primary screening test. These questions have been shown to have relatively high sensitivity and specificity, are easy to use, and can be incorporated into a health practice with minimal cost and effort (167).

Additional considerations for alcohol screening include measurement of the types of alcoholic beverages the woman consumes. The development of new ways of marketing wine and beer, including higher alcohol concentration malt liquors and beer in 20- to 45-ounce containers, has increased the need to provide women who drink with more specific standards to estimate their consumption. Studies show that reliance on standard drink measurements when assessing drinking practices of heavier drinkers or those consuming higher alcohol content beverages can result in considerable underestimation of alcohol consumption (168-169). Moreover, beverage-specific questions have been shown to be more accurate than grouped beverage questions (170).

One of the most reliable assessment tools for gathering accurate self-reported alcohol use is the timeline follow back (TLFB) measure (171). This method of alcohol use assessment typically asks respondents to think back over the past 90 days and report daily drinking amounts during that period of time. Respondents are given a calendar and asked to identify special events that occurred during that time period, such as parties, birthdays, or holidays that might serve to trigger recall of drinking occasions. A major strength of the TLFB measure is its ability to capture both average daily drinking and sporadic drinking that might entail drinking at higher levels of consumption. Because of the time requirements necessary for gathering information using the TLFB approach, it is not easy to use in primary care settings but it has been used in clinical research to establish the reliability and validity of other briefer screening and assessment tools (172).

Screening Tools. Several brief questionnaires have been developed over time to screen for problematic alcohol use in adults in diverse populations and settings. Screening tools currently in use include the CAGE, AUDIT, T-ACE, TWEAK, MAST, S-MAST, NET, RAPS4, and RAPS4-QF (173). The CAGE (174)is a four-item alcohol use measure designed to detect alcoholism and is one of the most commonly used screening instruments for men and women. The four questions ask the respondent: (C) Have you ever felt you should CUT down on your drinking? (A) Have people ever ANNOYED you by criticizing your drinking? (G) Have you ever felt bad or GUILTY about your drinking? and (E) Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (EYE OPENER)? Each item is scored as a 0 (no) or 1 (yes) and scores of 2 or greater are considered clinically significant.

The AUDIT is a 10-item self-report questionnaire developed by the world health organization (WHO) for identifying individuals whose alcohol consumption has become hazardous or harmful

to their health (175). The items on the AUDIT are constructed to measure frequency of alcohol consumption, dependence symptoms, and the personal and social consequences of drinking. The first three questions of the AUDIT address the quantity, frequency, and maximum amount of alcohol consumed. The remainder of the questionnaire has two items from the CAGE, (feelings of guilt about drinking and the need for a drink first thing in the morning after a heavy drinking session—eye-opener) in addition to questions on the frequency of being unable to stop drinking once drinking starts, frequency of being unable to do what is normally expected because of alcohol use, frequency of memory loss of the previous night due to drinking, frequency of injury to self or others as a result of drinking, and frequency of others expressing concern over the individual's drinking (a relative, friend, or doctor). A score of eight or more is considered significant for high-risk consumption. The measure has good psychometric properties and has an advantage over other screening tools in that it measures not only experienced consequences of drinking, but also whether an individual is currently drinking at levels likely to eventually result in problems (176). The instrument has been used and validated in cross-cultural populations (177). One review of 38 studies on screening for alcohol problems in women and men in primary care settings found the AUDIT was more effective in identifying individuals with at-risk, hazardous, or harmful drinking patterns, while the CAGE proved superior in detecting alcohol abuse and dependence (178). Another study of women who were receiving outpatient care through the Veterans' Administration found that the AUDIT-C (comprised of the first three items of the AUDIT on quantity, frequency, and maximum drinks per drinking occasion) proved to be more sensitive than the full 10-item AUDIT (179). Such findings suggest that when time of administration is a consideration, the shorter AUDIT-C might be used as the screener of choice.

Two screening tools that have been specifically developed and used with pregnant women are the T-ACE and the TWEAK (180-183). The T-ACE has four questions that take less than a minute to ask. The questions are: (**T**) TOLERANCE, how many drinks does it take to make you feel high? (**A**) Have people ANNOYED you by criticizing your drinking? (**C**) Have you ever felt you ought to CUT DOWN on your drinking? (**E**) EYE OPENER, Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover? One point is given for each affirmative answer to the **A, C, E** questions, two points when a pregnant woman reports a tolerance of more than two drinks to feel high. A positive screen is a score of two or more points. The T-ACE has been shown to be an efficient screen for risk drinking in pregnant women and out-performs medical staff assessment alone (184). Its brevity (four-items) is an important asset and increases its utility for clinical practice.

Like the T-ACE, the TWEAK attempts to elicit information on the following: (**T**) TOLERANCE for alcohol; (**W**) WORRY or concern by family or friends about drinking behavior; (**E**) EYE OPENER, the need to have a drink in the morning; (**A**) "blackouts" or AMNESIA while drinking; and (**K**) the self-perception of the need to CUT DOWN on alcohol use. Scores range from zero to seven. The tolerance and worry questions each contribute two points and the other three questions contribute one point each. Any endorsement of the worry question is scored a two. On the tolerance question, if three or more drinks are needed to feel high, the question is scored as a two. Other versions of the tolerance question ask: How many drinks does it take before the alcohol makes you fall asleep or pass out? Or, if you never drink till you pass out, what is the largest number of drinks you have or can hold? These questions are scored as a two if the woman answers five or more drinks. Using these questions, however, results in lower sensitivity and specificity. A total score of three or more on the TWEAK is suggestive of harmful drinking pat terns (185).

Studies assessing the relative effectiveness of various screening tools have yielded different findings depending on the populations studied. Bradley et al. (186) summarized data from 13 published, peer-reviewed articles that contained information on the performance of alcohol screening questionnaires with non pregnant women and with obstetric patients during the periconceptional period. The results revealed that, for non pregnant women, the CAGE had low sensitivity in predominantly White female populations, but was a reasonable choice for identifying past year or lifetime alcohol dependence in predominantly African American female populations. Overall, the five-item TWEAK appeared to be the optimal screening questionnaire for identifying heavy drinking or alcohol abuse and dependence in racially mixed populations of non pregnant and pregnant women.

Some clinicians have suggested that the use of screeners best suited for identifying high-risk heavy drinkers might not be optimal for identifying pregnant women with irregular or lighter patterns of consumption that might still pose a risk for fetal development. Using confidential reporting procedures, one study examined the effectiveness of the TWEAK for assessing any report of drinking following pregnancy recognition in a group of low-income pregnant women participating in WIC (187). With a cut point score of two or greater, the specificity of the TWEAK was high for all ethnic groups studied; however sensitivity, while high for White non-Hispanic women, was low for African-American non-Hispanic and Hispanic women. Because any endorsement of alcohol use was sufficient for classification as a drinker in this sample, low sensitivity on the TWEAK might have been due to the fact that women were drinking at levels that were too low to result in alcohol-related problems but, were still high enough to be detrimental to the developing fetus. From a practical standpoint, the high specificity of the TWEAK supports its utility in busy clinic settings. High specificity suggests the TWEAK is effective in screening women who are not high risk, and as shown in the study cited previously, women who report not drinking at all. Nevertheless, the fact that the TWEAK had variable sensitivity for women from different ethnic backgrounds suggests that additional methods of screening should be employed in order to increase the detection of women who might need intervention.

Drinking among adolescents and college students has long been recognized as a significant problem with far-reaching public health implications (188-189). Although the most problematic drinking in adolescence has been documented among males when compared to females, alcohol use in females has been associated with decreased use of contraception (increasing the likelihood of an unintended pregnancy), increased sexual assault, and more sexually transmitted diseases. Because of these significant negative health consequences, the American Medical Association Guidelines for Adolescent Preventive Services recommend screening of adolescents for alcohol and other drug use as part of routine medical care (190). To effectively screen adolescents, the ideal screening tool must be developmentally appropriate and practical for use in busy medical offices or clinics. Although the CAGE and the AUDIT are relatively brief, their developmental appropriateness is questionable. Indeed, current research suggests that the CAGE is not appropriate for screening adolescents and that a much lower cut point of two (rather than the eight recommended for adults) on the AUDIT is optimal for identifying alcohol use problems in this population (191).

Several measures have been developed specifically for use with adolescents, such as the Rutgers Alcohol Problem Index (192) and the College Alcohol Problem Scale (193); however, these tools might not be practical for universal screening. One brief screening device, the CRAFFT, developed for adolescents, is simple to score, inquires about alcohol and drug use, and was found to have good psychometric properties in a sample of predominately female youths 14 through 18 years of age

(194). CRAFFT is an acronym for the first letters of key words in the test's six questions: (**C**) Have you ever ridden in a CAR driven by someone (including yourself) who was high or had been using alcohol or drugs? (**R**) Do you ever use alcohol or drugs to RELAX, feel better about yourself, or fit in? (**A**) Do you ever use alcohol or drugs while you are by yourself, ALONE? (**F**) Do you ever FORGET things you did while using alcohol or drugs? (**F**) Does your family or FRIENDS ever tell you that you should cut down on your drinking or drug use? (**T**) Have you ever gotten into TROUBLE while you were using alcohol or drugs? Each question on the CRAFFT is given a score of one and a cut point of two provides moderate sensitivity (.70) and excellent specificity (.94) for identifying alcohol use disorders in adolescents. The authors CRAFFT recommend that any positive answer on this measure be followed by further assessment of quantity, frequency, and pattern of use to increase sensitivity and to guide decisions about the need for intervention.

A number of studies have shown a strong association between alcohol intoxication and trauma (195). The Trauma Questionnaire was developed to screen patients in an unobtrusive way without asking them directly about their alcohol use (196). The questionnaire consists of four questions asking about injuries in the last five years (fractures or dislocations of bones or joints, traffic accidents, head injury, or injury during a fight or assault). The questionnaire has been shown to have high sensitivity and specificity for identifying high-risk alcohol use and to be acceptable to respondents and physicians.

Computer-Assisted Interviews and Laboratory Screening Measures. The method of delivery of questions about alcohol use has been shown to influence truthful reporting. Clinical interviews might not be as effective in eliciting truthful responses from women because practitioners are not always comfortable asking these questions in a face-to-face interview. Moreover, women could underestimate their alcohol use because of reluctance to discuss this potentially sensitive subject. For this reason, self-administered questionnaires might improve the validity of self-report.

The Audio Computerized Self-Report Interview has been successfully used in prenatal clinics serving disadvantaged low-literacy minority women (197). Questions asked by a recorded voice through earphones are drawn from the TWEAK with quantity and frequency questions pertaining to three months before and during pregnancy are included. Acceptability studies have revealed that patients liked this method of screening.

Laboratory screening measures offer promise for obtaining objective evidence of problem drinking (198-199). The most common biomarkers are gamma glutamyltransferase (GGT) and carbohydrate-deficient transferring (CDT). Fatty acid ethyl esters synthase (FAEE) can be found in the hair of alcohol using women. This biomarker could hold promise for screening for alcohol use in pregnant women, although the dynamics of enzyme expression appear to be complex and changes occur only at high alcohol doses. Low sensitivity in non alcoholic women and the high cost of laboratory analysis make these measures less feasible for use in more universal screening.

Brief Intervention. Brief intervention (BI) has been shown to be a low-cost, effective treatment alternative for alcohol problems that uses time-limited, self-help, and preventative strategies to promote reductions in alcohol use in nondependent individuals, and in the case of dependent people, to facilitate their referral to specialized treatment programs (200-203). Overall, BI for alcohol problems has been shown to be more effective than no intervention and often as effective as more extensive intervention (204). Effective prevention programs frequently employ a multicomponent

approach combining cognitive-behavioral techniques with norms clarification, education, and motivational enhancement interventions. BI is usually restricted to fewer than four sessions and is typically performed in a treatment setting that is not specific for alcoholism. It is often performed by personnel who are not specialists in the treatment of alcohol use and abuse, and is provided to individuals at varying levels of risk for negative consequences because of drinking, rather than those who are considered alcohol dependent (205).

Six elements characterize the key ingredients of standardized brief intervention summarized by the acronym FRAMES (206). These are: **F**eedback of personal risk, **R**esponsibility for personal control, **A**dvice to change, **M**enu of ways to reduce or stop drinking, **E**mpathetic counseling style, and **S**elf-efficacy or optimism about cutting down or stopping drinking. The intervention also involves establishing a drinking goal in the form of a signed contract and follow up of progress with ongoing support. Studies reveal that supportive, nonjudgmental techniques in which trained personnel counsel women can lead to decreased alcohol consumption during pregnancy. The most effective intervention approaches avoid the use of moral or volitional injunctions and instead focus on reduction of alcohol use without criticism or provocation of guilt (205). Effective interviewers have been found to have a thorough knowledge of the intervention technique, an optimistic attitude about change, a compassionate style, genuineness and respect for clients, an ability to avoid arguments that evoke patient defensiveness, and comfort discussing alcohol problems (207-208).

Motivational Interviewing. A technique often used in brief interventions is motivational interviewing (MI). MI uses an empathic , client-centered counseling approach to increase readiness for change by resolving ambivalence about behavior change (207). The process explores the client's ambivalence in an atmosphere of acceptance, warmth, and positive regard. Although the session is structured and to the point, direct persuasion and coercion are avoided. The goal is to enhance the discrepancy between the reasons for changing versus staying the same. More than 24 studies of MI have found beneficial effects in decreasing problem drinking and other health-related problem behaviors (209).

Manualized Brief Intervention. Although the findings of the previously cited studies provide the foundation for intervention and prevention efforts, the usefulness of MI in a busy clinic or medical practice might be limited in that it requires additional training and clinical skills development. Recently, standardized manualized BI techniques to reduce alcohol consumption have been developed. One such intervention is Project CHOICES (Changing High-risk alcohol use and Increasing Contraception Effectiveness Study), which is funded by CDC. Project CHOICES is an example of a brief intervention using motivational interviewing techniques aimed at preventing alcohol-exposed pregnancies among high-risk women in various community settings (210). This project focused on both alcohol risk reduction and pregnancy postponement until alcohol use was decreased in a group of non pregnant women who were of childbearing age, fertile, sexually active, and using ineffective or no contraception. Phase I results revealed that at six-month follow up, 68.5% of the women were no longer at risk of having an alcohol-exposed pregnancy, 12.6% had reduced their drinking only, 23.1% reported using effective contraception only, and 32.9% reported doing both. A Phase II randomized controlled trial is currently underway testing the efficacy of this approach and is slated for completion in fall 2004. Another recent CDC-funded study still underway is Project Balance, which uses a briefer adaptation of Project CHOICES and is aimed at female college students, encouraging them to abstain from alcohol or to use contraception if they drink.

Four randomized controlled studies, funded by NIAAA, serve as further examples of the utility and effectiveness of this approach. These studies included women of different socioeconomic and cultural backgrounds and were conducted in doctors' offices and community settings. Two of the studies found that manualized BI was successful in decreasing alcohol use during subsequent pregnancies in high-risk women, thus preventing possible negative developmental sequelae in their offspring (211). The other two studies, one working with high-risk, White, middle class pregnant women in physicians' offices and one working in WIC community clinics with primarily low risk, low-income Hispanic clients, also found manualized BI to be a promising approach (212-214). In the WIC study, better infant outcomes were reported, including longer birth lengths and a lower infant mortality rate. Significantly, in both studies, the control conditions that included an assessment of alcohol consumption and simple advice to stop or cut down on drinking were almost as effective as the manualized BI itself. The success of these projects in reducing alcohol consumption in both experimental and control groups was postulated to be due to the desire of pregnant women to have healthy pregnancies and to the time and attention that interventionists provided for women in both groups.

Computerized Brief Intervention One recently developed study is investigating the use of a computerized method of a BI that incorporates the use of vessel size and normative education that allows a woman to evaluate her own consumption levels (169). Once a woman has been educated about her consumption levels, she then participates in a standardized BI. This approach is promising in that it incorporates many recommended aspects of screening, educating, and assisting women in recognizing that they might have a drinking problem, and then providing a brief intervention. The automated computerized assessment is designed for use in prenatal clinics and is currently being tested at a large HMO through an NIAAA grant. Although the effectiveness of this intervention has yet to be validated, it offers a potentially useful method that could be expanded nationally.

Improving Use of Screening and Brief Intervention Technology by Clinicians. Research devoted to finding ways to encourage clinicians to use brief interventions indicates that routine educational approaches might not be effective. Effective strategies include (1) conducting educational programs at the intervention site; (2) using specific step -by-step, evidence-based clinical protocols; (3) using skills-based role playing; (4) holding peer group discussions; and (5) using a credible expert trainer or educator. Brevity, repetition, and reinforcement of recommended practices are also key program elements (215). In an effort to enhance physician uptake of current screening and intervention approaches for preventing alcohol-exposed pregnancies, the NIAAA and the Office of Research on Minority Health recently collaborated in the development of a guide for primary care providers for screening pregnant and non pregnant women on selected health behaviors, including alcohol use, and recommendations for appropriate advice depending on the level of alcohol use and consequences (166). More recently, CDC funded four regional training centers on FAS to provide education and training to medical and allied health professionals and students about identification and diagnosis of children affected by prenatal alcohol exposure and effective approaches for intervening with and preventing these conditions. More information about these and other resources can be found by accessing the websites provided at the end of this section.

Universal screening for alcohol use should be conducted among all women of childbearing age. Screening can be done in both physicians' offices and in community health settings. Simple screening techniques that include measures of quantity, frequency, and heavy episodic drinking, as well as

behavioral manifestations of risk drinking, have proven to be most beneficial. For non pregnant women, the AUDIT, TWEAK, and CAGE have been found to be useful screening tools depending on the population characteristics of the community as described in the studies reviewed earlier. However, studies on gender-specific modifications of these screening tools have been recommended because women report increased psychosocial problems at lower levels of consumption than men. Based on some empirical evidence, reduced cut points for women have been recommended, including a cut point of 4 or more for the AUDIT, 2 or more for the TWEAK, and 1 or more for the CAGE (186). For pregnant women, the T-ACE and the TWEAK are the recommended screening tools of choice. The CRAFFT shows promise as an alcohol and other drug screener for female adolescents. Findings support better identification when screening instruments are used versus clinical assessment alone. Brief interventions administered by physicians and allied health professionals in medical and non medical settings are effective in bringing about reductions in drinking.

Women who are pregnant, planning a pregnancy, or at risk of pregnancy should be advised not to drink, as no safe threshold of alcohol use during pregnancy has been established. Non pregnant childbearing-aged women should be advised to drink no more than seven drinks per week and no more than three drinks on any one occasion.

Both BI approaches and MI techniques have been found to be efficacious with pregnant and non pregnant women in promoting reduction in alcohol consumption. Furthermore, some evidence suggests pregnant women are motivated to stop drinking even if the intervention includes only an assessment of alcohol use with simple advice to stop or reduce drinking. Research also indicates that interventions are effective with pregnant women who are light as well as high-risk drinkers. Moreover, preconceptional counseling of women of childbearing age who are at risk for an alcohol-exposed pregnancy and who are not using effective contraception has been demonstrated as a promising method of prevention as well as computerized versions of standardized methods of intervention. This year the U.S. Preventive Services Task Force released recommendations calling for use of the screening and behavioral counseling interventions for adults in primary care setting, including pregnant women (216-217). These evidence-based recommendations mirror the content of these guidelines with respect to the specific types of screening tools recommended and the components of effective brief interventions to be used. The recommendations of the U.S. Preventive Services Task Force, which is supported by the federal Agency for Healthcare Research and Quality, provide further support for the need for widespread public health implementations of these prevention technologies to reduce the harmful consequences of alcohol misuse, including FAS and other prenatal alcohol-related conditions. Information about reported and other federally sponsored studies in FAS and prenatal alcohol screening and intervention can be obtained at the following websites: www.nih.gov; www.cdc.gov; www.samhsa.gov; and www.preventiveservices.ahrq.gov.

SUMMARY AND FUTURE STEPS

In 2002, CDC was congressionally mandated to develop diagnostic guidelines for FAS and other prenatal alcohol-related disorders and integrate them into medical and allied health education.

With input from a SWG composed of clinicians, experts, and families, and from the NTFFAS/FAE, scientific and clinical evidence was reviewed to develop guidelines that offer a balance between conservative and overly inclusive definitions of FAS. Criteria for conditions not meeting the clinical definition of FAS (e.g., ARND) were not established because scientific evidence is insufficient at this time. Clinical and scientific research on FAS and those conditions resulting from prenatal alcohol exposure that do not meet the criteria for an FAS diagnosis is currently underway. These findings and advances will contribute to further refinement of the FAS criteria, and could potentially delineate additional diagnostic categories and criteria for conditions other than FAS. The development of these FAS guidelines is a continuous process. Efforts to develop and refine other diagnostic categories to identify FAS and related conditions need to continue.

During this guidelines development process, several key issues emerged that deserve mention.

1. More information on the neurodevelopmental effects of prenatal exposure to alcohol is needed. Particular emphasis should be placed on finding the unique aspects of FAS that will help differentiate it from other birth defects or developmental disabilities, or both.

2. Efforts to improve the clinical assessment tools (e.g., facial and growth measures) used to diagnose FAS should continue, particularly in terms of racial and ethnic variations and age.

3. All children should be screened for the possibility of an FAS diagnosis. As physicians and other allied health professionals become educated about this disorder, screening for FAS should become routine.

4. Better communication between obstetricians, gynecologists, and pediatricians is needed to improve documentation on prenatal alcohol use. This would help with the diagnosis of prenatal alcohol exposure in the child and could help identify women at risk for future alcohol-exposed pregnancies.

5. Service agencies must provide a way to qualify children with FAS and related disorders who do not meet their traditional eligibility requirements.

6. Further research and resources are needed to identify and treat women at risk for an alcohol-exposed pregnancy.

7. Awareness, both in the public and professional arenas, about the dangers of drinking alcohol during pregnancy and about FAS and how the condition affects children and their families is essential. A key avenue to avoiding FAS is active promotion of programs to increase awareness of the dangers of drinking alcohol during pregnancy and promotion of prevention activities that increase understanding of the risks of alcohol as well as the risks for an alcohol-exposed pregnancy.

Over 30 years ago, researchers first described FAS . Much has been learned about the disorder since that time, as is reflected in these guidelines. However, there is still much more to learn about the entire spectrum of effects from prenatal alcohol exposure. Future work will address these gaps. To reduce FAS and other prenatal alcohol-related conditions, the key is prevention. Federal, state, and local agencies; clinicians and researchers; educational and social service professionals; and families

need to work together to educate women of childbearing age and communities across the country about the risks of drinking alcohol during pregnancy.

ARTICLE

Comparison of the 4-Digit Diagnostic Code and the Hoyme Diagnostic Guidelines for Fetal Alcohol Spectrum Disorders

Susan J. Astley, PhD

Department of Epidemiology, School of Public Health and Community Medicine, University of Washington, Seattle, Washington

ABSTRACT

OBJECTIVE. The 4-Digit Diagnostic Code for fetal alcohol spectrum disorders and the Hoyme fetal alcohol spectrum disorders diagnostic guidelines differ markedly. The performances of the 2 diagnostic systems were compared.

METHODS. The fetal alcohol syndrome diagnostic criteria from the 4-Digit Code and Hoyme guidelines were applied to 952 patients who had received an interdisciplinary, fetal alcohol spectrum disorders, diagnostic evaluation at the University of Washington with the 4-Digit Diagnostic Code and 16 children with confirmed absence of prenatal alcohol exposure.

RESULTS. The prevalence of fetal alcohol syndrome was 3.7% with the 4-Digit Code and 4.1% with the Hoyme guidelines. Although the prevalences were similar, the patients identified were not. Only 17 individuals met the fetal alcohol syndrome criteria for both systems. An extraordinary number of patients (35%) met the Hoyme criteria for the fetal alcohol syndrome facial phenotype, but only 39 of those 330 patients met the Hoyme criteria for fetal alcohol syndrome. Even some children with no alcohol exposure (25%) had the Hoyme fetal alcohol syndrome face. The specificities of the Hoyme fetal alcohol syndrome face for the Hoyme fetal alcohol syndrome diagnosis and prenatal alcohol exposure were low in these populations.

CONCLUSIONS. Without a specific facial phenotype, a valid diagnosis of fetal alcohol syndrome cannot be rendered for patients with prenatal alcohol exposure, because a causal link between their outcomes and exposure cannot be established, and a valid diagnosis of fetal alcohol syndrome cannot be rendered for patients with unknown alcohol exposure, because the face cannot serve as a valid proxy measure for alcohol exposure. Diagnostic guidelines must confirm the specificity of their fetal alcohol syndrome facial criteria to validate their diagnostic criteria.

FETAL ALCOHOL SPECTRUM disorders (FASD) is a general term used to describe the full spectrum of adverse outcomes observed among individuals with prenatal alcohol exposure. Fetal alcohol syndrome (FAS) and partial FAS are 2 of several medical diagnoses that fall under the designation of FASD. In the past 10 years, several diagnostic guidelines for FASD have been published, including the Institute of Medicine (IOM) FASD guidelines in 1996,[1] the FASD 4-Digit Diagnostic Code (Fig 1) in 1997, 1999, and 2004,[2–5] the Centers for Disease Control and Prevention (CDC) FAS guidelines in 2004,[6] the Canadian FASD guidelines in 2005,[7] and the Hoyme FASD guidelines in 2005.[8] An interdisciplinary approach to diagnosis, with a more case-defined approach, as proposed originally by Astley and Clarren and colleagues,[4,9,10] was adopted in principal in all subsequent guidelines. Key contrasts do exist, however (Table 1). Of all guidelines published after the 4-Digit Code, the Canadian guidelines are most similar to the 4-Digit Code. Both systems cover the full spectrum of diagnostic outcomes and adhere to strict criteria that use the standard medical statistical definition of "abnormal" as ≥2 SDs below the mean or its equivalent, ≤2.5th percentile. The criteria used by the 2 systems to define each diagnosis under the designation of FASD are nearly identical.

In contrast to the 4-Digit Code and Canadian guidelines, the CDC guidelines address only FAS and have more-relaxed facial and central nervous system (CNS) criteria, using diagnostic cutoff values of ≥1 SD below the mean or ≤10th percentile. By definition, the 10th percentile and −1 SD are both within the normal range. One standard deviation below the mean is equivalent to the 16th percentile. The 10th percentile is equivalent to 1.3 SDs below the mean.

The Hoyme guidelines, while addressing the full spectrum of outcomes, diverge considerably from the 4-Digit Code, the CDC guidelines, and the Canadian guidelines. For the diagnosis of FAS, the Hoyme guidelines further relax the facial criteria, requiring only 2 of the 3 diagnostic features specified by the CDC; restrict the CNS criteria to structural abnormalities only; and relax the criterion for small head circumference from the medical definition of microcephaly (≤2.5th percentile) to ≤10th percentile. Hoyme et al[8] referred to their FASD diagnostic guidelines as a clarification of the 1996 IOM criteria. The 2 sets of guidelines are authored by separate groups, however.

All 4 sets of guidelines require prenatal alcohol exposure to be confirmed but allow a diagnosis of FAS to be rendered if prenatal alcohol exposure is unknown. The Hoyme guidelines go farther by requiring that the confirmed exposure be excessive. The 4-Digit Code does not require confirmation of excessive exposure because (1) there is no known threshold of exposure below which all fetuses are not at risk for FAS; (2) requiring excessive exposure may send an unsafe message that only high levels of alcohol use are damaging to the fetus; and (3) it is rarely, if ever, possible to confirm the accuracy of the quantity, frequency, and timing of exposure reported to a diagnostic clinic. There are many potential threats to the reliability of a prenatal alcohol exposure history. Birth mothers may be reluctant to report that they drank during pregnancy. They may be unable to recall accurately how much they drank, because the child's diagnostic evaluation is often conducted several years after the pregnancy. Furthermore, frequently the birth mother is not present at the time of the child's diagnostic evaluation. Eighty-one percent of children diagnosed at Washington State FAS Diagnostic and Prevention Network (DPN) clinics are in foster or adoptive care; therefore, information on maternal alcohol exposure is obtained frequently from indirect sources. The 4-Digit Code has demonstrated, however, that rendering a diagnosis of FAS, as defined by the 4-Digit Code, when alcohol exposure is unknown is medically valid. This is because the rank 4 FAS facial phenotype (Fig 2), as defined by the 4-Digit Code, is so specific to FAS (99.8%)[11–14] that it serves as a valid proxy measure of prenatal alcohol exposure. The sensitivity (100%) and specificity (99.8%) of the rank 4 FAS facial phenotype to the 4-Digit diagnosis of FAS have been derived from properly designed split-half empirical studies[12,13] and validated through population-based screening and surveillance programs.[11,14] As the FAS facial criteria are relaxed,

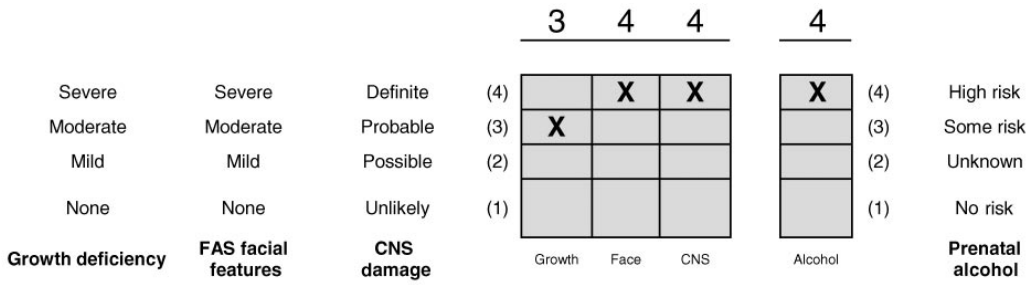

FIGURE 1
Four-Digit Diagnostic Code grid. The 4-Digit Code (3444) that is inserted in the grid is 1 of 12 codes that meet the diagnostic criteria for FAS.[5]

TABLE 1 Comparison of Key FAS Diagnostic Criteria Across 5 FASD Diagnostic Guidelines

	IOM (1996)	4-Digit Code (2004)	CDC (2004)	Canadian (2005)	Hoyme (2005)
Growth	At least 1 of the following: low weight for height, low birth weight, or decelerating weight	Prenatal or postnatal height or weight of ≤10th percentile (growth ranks 2, 3, or 4)	Prenatal or postnatal height or weight of ≤10th percentile	At least 1 of the following: prenatal or postnatal height or weight of ≤10th percentile or low weight-to-height ratio (10th percentile)	Prenatal or postnatal height or weight of ≤10th percentile
Face	Characteristic pattern that includes features such as short PFL, flat upper lip, flattened philtrum, and flat midface	All 3 of the following (facial rank 4; Fig 3): PFL of ≤3rd percentile, philtrum rank 4 or 5, and lip rank 4 or 5	All 3 of the following: PFL of ≤10th percentile, philtrum rank 4 or 5, and lip rank 4 or 5	All 3 of the following: PFL of ≤3rd percentile, philtrum rank 4 or 5, and lip rank 4 or 5	Two of the following 3: PFL of ≤10th percentile, philtrum rank 4 or 5, and lip rank 4 or 5
CNS	At least 1 of the following: OFC of ≤3rd percentile (microcephaly), abnormal structure, or hard/soft signs	At least 1 of the following (brain rank 3 or 4): OFC of ≤3rd percentile (microcephaly), abnormal structure, seizure disorder, hard signs, ≥3 domains with impairment ≥2 SDs below the mean (domains may include but are not limited to cognition, memory, language, executive functioning, and attention-deficit/hyperactivity disorder), or global deficits	At least 1 of the following: OFC of ≤10th percentile, abnormal structure, seizure disorder, hard/soft signs, ≥3 domains (cognitive or developmental, executive functioning, motor, attention-deficit/hyperactivity disorder, social, or other) with impairment ≥1 SD below the mean, or global deficits	Impairment[a] in ≥3 of the following domains: hard/soft signs, structure, cognition, communication, academic achievement, memory, executive functioning, abstract reasoning, attention-deficit/hyperactivity disorder, adaptive behavior, social skills, and social communication	At least 1 of the following: OFC of ≤10th percentile or abnormal structure
Alcohol	Confirmed or unknown	Confirmed (alcohol rank 3 or 4) or unknown (alcohol rank 2)	Confirmed or unknown	Confirmed or unknown	Confirmed to be excessive or unknown

[a] Impairment indicates scores ≥2 SDs below the mean, discrepancies of 1.5 to 2 SDs among subtests, or ≥1 SD discrepancy between subdomains.

their sensitivity and specificity for FAS decrease markedly. Neither the CDC guidelines nor the Hoyme guidelines assessed or reported the sensitivity or specificity of their relaxed criteria for the FAS facial phenotype as their criteria for a FAS diagnosis.

The Hoyme diagnostic criteria for FAS also differ from the 4-Digit Code, CDC guidelines, and Canadian guidelines in that the diagnosis is based solely on physical features of growth, facial anomalies, and structural brain abnormalities. Therefore, an interdisciplinary clinical team (eg, psychologist, occupational therapist, and speech/language pathologist) would have no role in the derivation of a FAS diagnosis. Typically, the most disabling feature of FAS is the cognitive/behavioral impairment. With the Hoyme guidelines, a child would meet the CNS criteria for FAS by having nothing more than an occipital frontal circumference (OFC) in the 10th percentile, even in the presence of normal or above-normal cognitive/behavioral function. An OFC in the 10th percentile does not meet the medical definition of microcephaly (≤2.5th percentile). By definition, 10% of the general population has an OFC of ≤10th percentile. In contrast, a child who presents with severe mental retardation (IQ of 55) but no evidence of structural brain abnormalities would fail to meet the Hoyme diagnostic criteria for FAS, because brain dysfunction is not included as a diagnostic feature of FAS in the Hoyme guidelines.

Because of concerns regarding the Hoyme FAS diagnostic criteria, namely, (1) they relax the FAS facial phenotype criteria without confirming the phenotype's specificity for FAS or prenatal alcohol exposure, (2) they allow FAS to be diagnosed when prenatal alcohol exposure is unknown, with the use of FAS facial criteria of unknown specificity for prenatal alcohol exposure, (3) they require confirmation of excessive prenatal alcohol exposure, when documentation of prenatal alcohol exposure is typically unreliable, (4) they include only structural/morphologic measures of CNS damage and exclude functional and neurologic measures of CNS damage, (5) they allow a single structural abnormality to serve as evidence of CNS damage, while relaxing the criterion for one of the key structural features (OFC) into the normal range (≤10th percentile), and (6) the diagnostic guidelines were created by using a nonrepresentative population base (South Africans and Native Americans) and invalid application of a measurement tool (white lip-philtrum guide), this study was conducted to assess the performance of the Hoyme FAS diagnostic criteria when applied to 2 populations, namely, the University of Washington FASD clinical population (a large population that is highly representative of a US population seeking FASD diagnostic services) and a group of high-functioning children with confirmed absence of prenatal alcohol exposure, enrolled as control subjects in a research study. The specific aims of this study were (1)

A

5-point Likert Rank for philtrum and lip	*z* score[a] for palpebral fissure length	Circle the ABC scores for: Palpebral fissure length	Philtrum smoothness	Upper-lip thinness
4 or 5	≤−2 SD	**C**	**C**	**C**
3	>−2 SD and ≤−1 SD	**B**	**B**	**B**
1 or 2	>−1 SD	**A**	**A**	**A**

B

4-digit facial rank	Level of expression of FAS facial features	Palpebral fissure: philtrum-lip ABC-score combinations
4	Severe	CCC
3	Moderate	CCB, CBC, BCC
2	Mild	CCA, CAC, CBB, CBA, CAB, CAA BCB, BCA, BBC, BAC ACC, ACB, ACA, ABC, AAC
1	None	BBB, BBA, BAB, BAA ABB, ABA, AAB, AAA

FIGURE 2
The 4-Digit facial rank[5] (rank of 1–4) is calculated by deriving the facial ABC-Score, which reflects the PFL, philtrum smoothness, and upper lip thinness (A), and converting the facial ABC-Score to the 4-digit rank for face (B). For example, an individual with PFL of −3 SD, philtrum rank 3, and lip rank 1 would receive a facial ABC-Score of CBA and a 4-Digit facial rank of 2. [a]The *z* score reflects how many SDs above or below the mean the patient's PFL is.

to assess the specificity of the Hoyme FAS facial phenotype for the Hoyme FAS diagnosis when the Hoyme guidelines were applied to the University of Washington FASD clinical population, (2) to assess the specificity of the Hoyme FAS facial phenotype to prenatal alcohol exposure when the Hoyme diagnostic guidelines were applied to a study population with confirmed absence of prenatal alcohol exposure, (3) to compare the prevalence of FAS (with and without confirmed prenatal alcohol exposure) between the Hoyme and 4-Digit Code criteria for FAS, when the 2 sets of criteria were applied to the University of Washington FASD clinical population, and (4) to compare, on a case-by-case basis, which patients did and did not receive a diagnosis of FAS when the Hoyme and 4-Digit Code FAS criteria were applied to the University of Washington FASD clinical population.

METHODS

FASD Clinical Population

The target clinical population for this study included all patients diagnosed to date at the University of Washington FAS DPN clinic. A comprehensive set of data (>2000 fields of information, documenting prenatal and lifetime exposures and outcomes, including standardized facial photographs) is collected and entered into a database for each patient who receives a FASD diagnostic evaluation at the FAS DPN clinic, with informed consent and University of Washington Human Subjects Review Board approval. More than 98% of patients provide consent; therefore, the data set is highly representative of the entire University of Washington FAS DPN patient population. All FAS DPN patients have been diagnosed by an interdisciplinary clinical team[10] with the 1997, 1999, or 2004 version of the 4-Digit Diagnostic Code.[2–5] The records of all patients who met the inclusion criteria were included in this study; there were no exclusion criteria. The inclusion criteria were as follows: (1) the patient received an interdisciplinary FASD diagnostic evaluation at the University of Washington FAS DPN clinic with the FASD 4-Digit Diagnostic Code; (2) the patient gave consent for use of the FAS DPN clinical data for research purposes; and (3) all data required to render a FAS diagnosis with the Hoyme guidelines (ie, measures of growth, face, brain growth and/or morphogenesis, and prenatal alcohol exposure) were available in the patient's record.

Research Population With No Alcohol Exposure

The records of 16 children with confirmed absence of prenatal alcohol exposure, who were enrolled as control subjects in a recently completed MRI research study, were also included in this study.[15] The MRI study was

conducted with subject consent and University of Washington Human Subjects Review Board approval. Because only 4 of the 952 patients in the FASD clinical population had a confirmed absence of prenatal alcohol exposure, this larger data set of unexposed subjects was included for better assessment of the specificity of the Hoyme FAS facial phenotype for prenatal alcohol exposure. If the Hoyme FAS facial phenotype is specific to (caused only by) prenatal alcohol exposure, then none of these children should have the FAS facial phenotype. The 16 children in this study population were 8 to 15 years of age; 8 were female, 13 were white, 2 were black, and 1 was Asian American. Their Wechsler Intelligence Scale for Children-III full-scale IQs ranged from 112 to 133.

Hoyme FASD Diagnostic Guidelines

The Hoyme criteria (Table 2) for the diagnostic classifications of FAS with confirmed maternal alcohol exposure and FAS without confirmed maternal alcohol exposure were applied to the 2 study populations. These criteria were used to generate 2 outcome variables, namely, Hoyme FAS facial phenotype (present or absent) and Hoyme FAS diagnosis with or without confirmed maternal alcohol use (present or absent). Because the criteria for these diagnostic outcomes are based solely on physical features measured on numeric scales (eg, height, weight, palpebral fissure length [PFL], and head circumference), computer algorithms were written and applied to the electronic data sets to generate the outcome variables. This eliminated any potential for human error, bias, or interrater discordance.

FASD 4-Digit Diagnostic Code (2004)

All patients in the clinical study population (n = 952) had been diagnosed previously by the University of Washington interdisciplinary FASD diagnostic team. Their 4-Digit Diagnostic Codes and all exposure and outcome data collected for their diagnostic evaluations were recorded in the FAS DPN clinical database. The FASD 4-Digit Diagnostic Code was first printed in 1997 and was updated in 1999 and 2004. For the purposes of this study, all FASD 4-Digit Codes were updated to reflect the 2004 version of the FASD 4-Digit Diagnostic Code.[5] These updates included use of the black lip-philtrum guide and black PFL normative values[16] for all black patients, use of the upper lip circularity tables to rank lip thinness, use of the new growth rank tables, and coding of full-scale IQ of ≤60 as CNS rank 3 rather than rank 4. Because all updates were simply numeric transformations of existing numeric data, the 4-Digit Codes were updated to the 2004 criteria by writing computer transformation algorithms and applying them to the existing data set. Therefore, there was no risk of human error, bias, or interrater discordance in the updating process. All subjects in the MRI study population received a 2004, 4-Digit Diagnostic Code at the time of the MRI study. Therefore, their 4-Digit Codes did not require updating.

The 4 digits of the diagnostic code reflect the magnitude of expression of the 4 key diagnostic features of FASD, in the following order: (1) growth deficiency, (2) FAS facial phenotype, (3) CNS abnormalities, and (4) prenatal alcohol exposure (Figs 1–3). A detailed description of the 4-Digit Code is presented in the *Diagnostic Guide for Fetal Alcohol Syndrome and Related Conditions: The 4-Digit Diagnostic Code*.[5] Briefly, the magnitude of expression of each feature is ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic" presence of the FAS feature. Each Likert rank is specifically case defined. There are 256 possible 4-digit diagnostic codes, ranging from 1111 to 4444. Each 4-digit diagnostic code falls into 1 of 22 unique clinical diagnostic categories (labeled A through V). Eight of the 22 diagnostic categories (categories A–C and E–I) fall broadly under the designation of FASD. This study focuses on diagnostic categories A and B, that is, FAS (alcohol exposed) and FAS (alcohol exposure unknown), respectively. The 2004 criteria for these 2 diagnostic categories are presented in Table 3 in a format to facilitate direct comparison with the Hoyme FAS criteria in Table 2. This study also focuses on the FAS facial phenotype. The 4-point ranking system for the 4-Digit Code FAS facial phenotype is presented in Figs 2 and 3. The 4-point ranking system for growth deficiency is as follows: rank 1, height and weight of >10th percentile; rank 2, height or weight of ≤10th percentile but >3rd percentile; rank 3, height or weight of ≤3rd percentile; rank 4, height and weight of ≤3rd percentile. The 4-point ranking system for the CNS is as follows: rank 1, no evidence of dysfunction/delay; rank 2, evidence of

TABLE 2 Hoyme Diagnostic Criteria for FAS With or Without Confirmed Maternal Alcohol Exposure[8]

FAS with confirmed maternal alcohol exposure requires all features A–D
A Evidence of prenatal and/or postnatal growth retardation
1. Height or weight of ≤10th percentile, corrected for racial normative values, if possible
B. Evidence of a characteristic pattern of minor facial anomalies, including ≥2 of the following:
1. Short palpebral fissures (≤10th percentile, equivalent to ≥1.28 SDs below the mean)
2. Thin vermilion border of upper lip (score 4 or 5 on the Lip-Philtrum Guide)
3. Smooth philtrum (score 4 or 5 on the Lip-Philtrum Guide)
C. Evidence of deficient brain growth or abnormal morphogenesis, including ≥1 of the following:
1. Structural brain abnormalities
2. Head circumference of ≤10th percentile
D. Confirmed maternal alcohol exposure; a pattern of excessive intake characterized by substantial regular intake or heavy episodic drinking
FAS without confirmed maternal alcohol exposure requires features A, B, and C

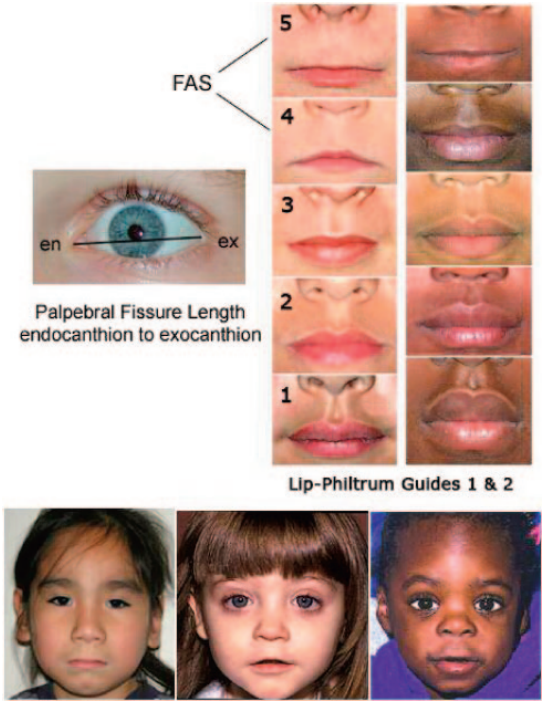

FIGURE 3
Four-Digit Code FAS facial phenotype. The rank 4 FAS facial phenotype determined with the 4-Digit Diagnostic Code[5] requires the presence of the following 3 anomalies: (1) PFL below −2 SD, (2) smooth philtrum (rank 4 or 5 on the Lip-Philtrum Guide), and (3) thin upper lip (rank 4 or 5 on the Lip-Philtrum Guide). Examples of the rank 4 FAS facial phenotype for Native American, white, and black children are shown. The endocanthion and exocanthion are standardized facial landmarks.

moderate dysfunction; rank 3, evidence of severe dysfunction; rank 4, evidence of structural or neurologic damage. The 4-point ranking system for prenatal alcohol exposure is as follows: rank 1, confirmed absence of alcohol exposure from conception to birth; rank 2, alcohol exposure unknown; rank 3, exposure is confirmed and the level of exposure is low-moderate or unknown; rank 4, exposure is confirmed and level is high. More-detailed case definitions of these ranks have been published.[5]

This study did not compare the other diagnoses (partial FAS, alcohol-related neurodevelopmental disorder [ARND], and alcohol-related birth defects [ARBD]) under the designation of FASD across the 2 diagnostic systems, for the following reasons. The Hoyme criteria for partial FAS and ARND include "evidence of a complex pattern of behavioral or cognitive abnormalities," but the Hoyme description of this complex pattern is not specific enough for reliable application of the criteria to the FAS DPN data set. For example, the Hoyme guidelines do not define how severe the abnormalities must be (1 SD below the mean? 2 SDs below the mean?) or how many domains of function must be impaired (2 domains? 3 domains?) to constitute a complex pattern. In contrast, the 4-Digit Code, CDC guidelines, and Canadian guidelines provide specific thresholds (eg, ≥3 domains of function, ≥2 SDs below the mean) (Table 1). The Hoyme criteria for ARBD could not be compared across the 2 systems because, like the CDC guidelines and the Canadian guidelines, the 4-Digit Code does not recognize ARBD as a medical diagnostic classification.

Analysis

The prevalence of FAS in the FASD clinical population was computed by using the 2004, 4-Digit Code and Hoyme criteria for FAS (with and without confirmed prenatal alcohol exposure). The number of patients who met the Hoyme criteria for the FAS facial phenotype was computed for both study populations. The specificity of the Hoyme FAS facial phenotype for the Hoyme FAS diagnosis was computed as follows: number of patients without the Hoyme FAS facial phenotype divided by number of patients without a Hoyme diagnosis of FAS. The specificity of the Hoyme FAS facial phenotype for prenatal alcohol exposure was computed as follows: number of patients without the Hoyme FAS facial phenotype divided by number of patients with a confirmed absence of prenatal alcohol exposure. Each estimate of specificity was accompanied by a 95% confidence interval (CI). Specificity refers to the ability of a test or outcome to indicate nondisease when no disease is present. If an outcome is not specific, then it indicates falsely the presence of disease in nondiseased subjects. A binomial test was used to compare the observed frequency of the Hoyme FAS facial phenotype with the expected frequency (0%) among the 16 children with confirmed absence of prenatal alcohol exposure.

RESULTS

Hoyme Guidelines Applied to the FASD Clinical Population

Study Group

Of the 956 patients diagnosed to date in the FAS DPN Clinic, 952 (99.6%) met the inclusion criteria for this study (Table 4). Therefore, this study population is highly representative of the entire FAS DPN patient population seen over 13 years. The study population represents a racially diverse group, ranging in age from 0.2 and 50.8 years of age at the time of the FASD diagnostic evaluation. A total of 732 of the patients (77%) had 2004, 4-Digit Codes that fell under the general designation of FASD. An additional 147 (15%) had growth, facial, and/or CNS abnormalities but their prenatal alcohol exposures were unknown. An additional 4 patients had a confirmed absence of prenatal alcohol exposure. Therefore, this patient population reflects the range of outcomes and exposures encountered typically by a FASD diagnostic clinic; not all patients referred to

TABLE 3 **Four-Digit Code Diagnostic Criteria for FAS With and Without Confirmed Prenatal Alcohol Exposure[5]**

FAS with confirmed prenatal alcohol exposure requires all features A–D[a]
- A. Evidence of prenatal and/or postnatal growth retardation (growth rank 2, 3, or 4); height and/or weight of ≤10th percentile, corrected for race and midparental height when possible
- B. Presence of all 3 of the following minor facial anomalies (facial rank 4):
  1. Short palpebral fissures (≥2 SDs below the mean, equivalent to ≤2.5th percentile)
  2. Thin upper lip (rank 4 or 5 on Lip-Philtrum Guide 1 or 2, as appropriate for race)
  3. Smooth philtrum (rank 4 or 5 on Lip-Philtrum Guide 1 or 2, as appropriate for race)
- C. Evidence of ≥1 of the following (CNS rank 3 or 4):
  1. Structural brain abnormalities
     a. Structural brain abnormalities (as may be viewed by brain imaging)
     b. Microcephaly (head circumference ≥2 SDs below the mean, equivalent to ≤2.5th percentile)
  2. Neurologic abnormalities
     a. Seizure disorder of prenatal origin
     b. Hard neurologic signs (eg, cerebral palsy)
  3. Significant brain dysfunction
     a. Three or more domains of brain function, ≥2 SDs below the mean, when assessed with validated, standardized, psychometric tools; domains may include but are not limited to executive function, memory, cognition, and language
- D. Confirmed prenatal alcohol exposure (alcohol rank 3 or 4); a specific pattern or level of exposure is not required because it is rarely known when this information has been obtained reliably in a clinical setting and the risk of a specific pattern of exposure is not identical across all fetuses

FAS without confirmed prenatal alcohol exposure requires features A, B, and C, with prenatal alcohol exposure not confirmed to be present and not confirmed to be absent[b]

[a] These criteria reflect the following 2004, 4-Digit Diagnostic Codes: 2433, 2434, 2443, 2444, 3433, 3434, 3443, 3444, 4433, 4434, 4443, and 4444.
[b] These criteria reflect the following 2004, 4-Digit Diagnostic Codes: 2432, 2442, 3432, 3442, 4432, and 4442.

the clinic receive a diagnosis under the designation of FASD.

Specific Aim 1

Thirty-five percent of the patients (330 of 952 patients) met the Hoyme criteria for the full FAS facial phenotype. Only 39 (11.8%) of the 330 patients with the Hoyme FAS facial phenotype met the Hoyme criteria for a diagnosis of FAS (with or without confirmed maternal alcohol use). The specificity of the Hoyme FAS facial phenotype for the Hoyme FAS diagnosis in this clinical population was 68% (622 of 913 patients; 95% CI: 65%–71%). Of the 330 patients with the Hoyme FAS facial phenotype, most did not present with other features of FAS; 60% presented with no growth deficiency (height and weight percentiles of >10th percentile), 74% did not have the 4-digit FAS facial phenotype (rank 4), 82% did not have microcephaly (OFC of ≤2.5th percentile), 77% had an OFC of >10th percentile; 89% of the 32 clinically indicated MRI studies were normal; and 64% of subjects did not have confirmed, excessive, prenatal alcohol exposure. It is worth noting that an additional 84 (25%) of the 330 patients would likely meet the Hoyme criteria for partial FAS (with or without confirmed maternal alcohol use). This is based on the assumption that the Hoyme criteria for a complex pattern of behavioral or cognitive abnormalities are comparable to the 4-digit CNS rank 3. However, 24 of these 84 children had no evidence of brain damage/dysfunction. Their only impairment was growth deficiency. If the specificity of the Hoyme FAS facial phenotype is computed for the Hoyme diagnoses of FAS plus partial FAS, then specificity increases, but only to 75% (622 of 829 subjects; 95% CI: 72%–78%).

Specific Aim 3

The prevalence of FAS (with or without confirmed prenatal alcohol exposure) determined with the 2004, 4-Digit Code was 3.7% (35 of 952 subjects). The prevalence of FAS (with or without confirmed maternal alcohol use) determined with the Hoyme FASD guidelines was 4.1% (39 of 952 subjects). Although the prevalences were similar, the patients identified with the 2 systems were not. Only 17 patients met both the 4-Digit Code and Hoyme criteria for FAS.

Specific Aim 4

Of the 39 patients who met the Hoyme criteria for FAS, 22 (56.4%) did not meet the 4-Digit Code criteria for FAS. The 22 patients ranged in age from 0.8 to 21.4 years and were racially diverse (white, 64%; black, 14%; Native American, 0%; other, 22%). They did not meet the 4-Digit Code criteria for FAS for ≥1 of the following reasons. Thirteen (59%) had facial phenotypes within the normal range (facial rank 2), as defined with the 4-Digit Code. Two had unknown prenatal alcohol exposures and facial features that were too mild (rank 2 or 3, not sufficiently specific for FAS) to allow labeling of the outcome as FAS in the absence of confirmed exposure. Seven (32%) met the 4-Digit Code for Partial FAS.

To portray just how different the Hoyme and 4-Digit Code criteria for FAS are, the outcomes for 1 of the 22

[a] These categories fit under the designation FASD.

children (a 14-year-old white youth) who met the Hoyme criteria for FAS but not the 4-Digit criteria for FAS are presented in Fig 4. The 4-Digit Code did not classify this child as having FAS or any diagnosis under the designation of FASD, because alcohol exposure was unknown and the outcomes observed in this child (short stature and microcephaly) were not specific to FAS. Because the Hoyme guidelines require that only 2 of the 3 FAS facial features be present (in this case, PFL in the 1st percentile and philtrum rank 4), this child can and does present with a very thick upper lip (Lip-Philtrum Guide rank 1). This results in a facial phenotype that neither looks dysmorphic nor resembles FAS (Fig 4). The facial features of this child were measured at the time of diagnosis, directly by 2 clinicians and through photographic analysis, with concordance across all 3 measurements. Photographic examples of the rank 4 FAS facial phenotype, as defined with the 4-Digit Code, are presented for comparison in Fig 3.

Conversely, of the 35 patients who met the 4-Digit Code criteria for FAS, 18 (51.4%) did not meet the Hoyme criteria for FAS. The 18 patients ranged in age from 1.5 to 24.3 years and were racially diverse (white, 39%; black, 11%; Native American, 0%; other, 50%). They did not meet the Hoyme criteria for FAS for ≥1 of the following reasons. Seven (39%) did not have evidence of structural brain anomalies, but all 7 had evidence of significant brain dysfunction (4-Digit Code CNS rank 3) (Table 1), including 3 with IQ scores between 56 and 64. Twelve (67%) had confirmed prenatal alcohol exposure (4-Digit Code alcohol rank 3), but information was not available to confirm that exposure was excessive (4-Digit Code alcohol rank 4). Six of these 12 children had 4-digit codes of 4443, which demonstrates clearly that confirmed excessive exposure is not required for a child to present with the most severe end of the spectrum for growth deficiency, FAS facial features, and CNS damage. Six children (33%) likely would have met the Hoyme criteria for partial FAS. These individuals had significant brain dysfunction (4-Digit CNS rank 3) but no known evidence of structural brain anomalies.

Hoyme Guidelines Applied to the Population With Confirmed Absence of Prenatal Alcohol Exposure

Specific Aims 2 and 3

When the Hoyme criteria for the FAS facial phenotype were applied to the 16 children with confirmed absence of prenatal alcohol exposure who were enrolled as control subjects in a MRI research study, 4 (25%) of the 16 children met the Hoyme criteria for the FAS facial phenotype. This observed frequency of 25% was significantly greater than the expected frequency of 0% (binomial test, $P < .001$). The specificity of the Hoyme FAS facial phenotype for prenatal alcohol exposure in this study population was 75% (12 of 16 children; 95% CI: 50%–89%). All 4 subjects had normal growth, normal facial phenotypes according to the 4-Digit Code (facial rank 2), normal OFCs, normal cranial MRI results, and neuropsychological performance significantly above average, including full-scale IQ scores between 124 and 128. None of the 16 children met the 4-Digit Code criteria for the FAS facial phenotype (rank 4). The sole purpose of including these 16 children in this study was to assess the specificity of the FAS facial phenotype for prenatal alcohol exposure. For the sake of completeness,

Features		4-Digit Code
Growth	[a]Height 1st percentile (parental heights unknown) Weight 12th percentile	Rank 3
Face	[a]PFL: 1st percentile (-2.9 SD) [a]Philtrum: somewhat smooth: rank 4 Lip: thick: rank 1 No other facial anomalies present 	Rank 2
CNS	[a]OFC 1st percentile (-2.2 SD) Brain function in the low-normal range, including an FSIQ = 95	Rank 4 Rank 2
Alcohol	[a]Unknown	Rank 2
4-digit code diagnosis	Sentinel physical findings/static encephalopathy/alcohol exposure unknown	3242
Hoyme diagnosis	FAS (unknown maternal alcohol exposure)	

FIGURE 4
Example of a 14-year-old child who met the Hoyme FAS criteria but not the 4-Digit Code FAS criteria. [a]Features that allowed the child to meet the Hoyme criteria for FAS (maternal alcohol exposure unknown). FSIQ indicates full-scale IQ.

it could be stated that none of the 16 children met the Hoyme or 4-Digit criteria for a diagnosis of FAS, but this was known from the start. By definition, an individual who was not exposed to alcohol cannot be at risk for FAS.

It is interesting to note that, although only 4 of the 952 patients in the FASD clinical population had a confirmed absence of prenatal alcohol exposure, 1 (25%) of those 4 also met the Hoyme criteria for the full FAS facial phenotype. The child had a normal facial phenotype according to the 4-Digit Code (rank 2) and was growth deficient (rank 4). This observation also reflects a specificity of 75%.

DISCUSSION

Specificity of the FAS Facial Phenotype and Its Impact on Diagnosis

This study demonstrated that an extraordinary number of patients in the FAS DPN clinic met the Hoyme criteria for the full FAS facial phenotype (35%; 330 of 952 subjects), whereas very few of them met the Hoyme criteria for a diagnosis of FAS (11.8%; 39 of 330 subjects). If the Hoyme FAS facial phenotype were specific to FAS, then it would be expected that the vast majority of those with the FAS face would have FAS; the opposite was observed, however. The vast majority of those with the FAS face (88.2%; 291 of 330 subjects) did not have FAS. If the Hoyme FAS face were specific to (caused only by) prenatal alcohol exposure, then individuals could not have the FAS face if they had not been exposed to alcohol. However, this study found that 25% of the children with confirmed absence of prenatal alcohol exposure, in both study populations, met the criteria for the Hoyme FAS face.

Although these results are concerning, they were not unexpected. By relaxing 1 of the facial criteria into the normal range (PFL of ≤10th percentile), requiring only 2 of 3 features to be present, and allowing the 2 features to be expressed at the mildest end of the spectrum (for example, a white subject with a PFL in the 10th percentile with a somewhat smooth philtrum [rank 4] but a very thick upper lip [rank 1]), the diagnostic criteria identify many individuals with normal facial phenotypes. One hundred fifty of the 330 patients with the Hoyme FAS facial phenotype had facial phenotypes that were only rank 2 according to the 4-Digit Code. Rank 2 (by definition) is well within the normal range for the general population.

Although the primary focus of this study was on the diagnosis of FAS, the relaxed Hoyme FAS facial criteria also jeopardize the clinical validity of the Hoyme criteria for partial FAS. The Hoyme criteria for partial FAS use the same relaxed criteria for the FAS facial phenotype and require only 1 other feature to be present (growth deficiency, deficient brain growth or abnormal morphogenesis, or evidence of a complex pattern of behavioral or cognitive abnormalities). Confirmed prenatal alcohol exposure is not required. Therefore, a white individual who presents with the following features would meet the Hoyme criteria for partial FAS: growth, height in the 10th percentile and weight in the 95th percentile; face, PFL in the 10th percentile, somewhat smooth philtrum (rank 4), and very thick upper lip (rank 1); CNS, normal structure and function; alcohol, unknown exposure. With the 4-Digit Code, this child would not even fall under the designation of FASD, because the outcomes are in the normal to very mildly impaired range, the only impaired outcome (height in the 10th percentile) is not specific for prenatal alcohol exposure, and alcohol exposure is unknown. In contrast to the Hoyme guidelines, the 4-Digit Code requires confirmed prenatal alcohol exposure for partial FAS, because the 4-Digit diag-

nosis of Partial FAS allows the facial criteria to be relaxed to facial rank 3 in some instances. Facial rank 3 is less specific for FAS and prenatal alcohol exposure; therefore, the 4-Digit Code does not allow it to be used as a proxy measure of prenatal alcohol exposure for partial FAS when prenatal alcohol exposure is unknown.

Why are the sensitivity and specificity of the FAS facial phenotype so important for the medical validity of a diagnosis of FAS? When we make a diagnosis of FAS, we are stating implicitly that the individual has a syndrome caused by prenatal alcohol exposure. We are also stating implicitly that the birth mother drank alcohol during pregnancy and, as a result, harmed her child. These are bold conclusions to draw and are not without medical and ethical consequences. How confident are we when we infer a causal link between an individual's prenatal alcohol exposure and his or her syndromic features, especially when 2 of the 3 diagnostic features of this syndrome (growth deficiency and CNS damage/dysfunction) are not specific to (caused only by) prenatal alcohol exposure. The validity of the diagnosis rests solely on the specificity of the facial phenotype for the exposure (alcohol) and the outcome (FAS). If a cluster of facial features truly is unique to prenatal alcohol exposure (meaning that alcohol is the only agent that can cause this facial phenotype) and is unique to the diagnosis of FAS (meaning that this exact phenotype is not present in any other medical condition), then we would expect to observe the following: (1) the face would be highly sensitive for FAS (individuals with FAS would have the FAS facial phenotype), (2) the face would be highly specific for FAS (individuals without FAS would not have the FAS facial phenotype), and (3) the face would be highly specific for prenatal alcohol exposure (individuals without prenatal alcohol exposure would not have the FAS facial phenotype). The rank 4 FAS facial phenotype, as defined with the 4-digit code, demonstrates all 3 of these qualities.[4,11–14] A highly specific FAS facial phenotype validates the FAS diagnosis, because the presence of the face confirms that individuals were affected by their prenatal alcohol exposure. The face not only confirms that individuals were affected by prenatal alcohol exposure but also confirms that they were exposed to alcohol. We depend on the latter when we render a diagnosis of FAS in the absence of confirmed prenatal alcohol exposure. If the face is truly specific to alcohol, then individuals cannot have the face if they were not exposed to alcohol. This is why all diagnostic guidelines can and do allow FAS to be diagnosed even when prenatal alcohol exposure is unknown. The face is so specific for alcohol exposure that it serves as a valid proxy measure for exposure. This is also why all diagnostic guidelines cannot and do not allow ARND (or its equivalent) to be diagnosed when alcohol exposure is unknown. Because the FAS facial phenotype is not present in ARND, it cannot serve as a proxy measure for alcohol exposure. In the absence of a highly specific facial phenotype, the validity of the diagnostic process breaks down precipitously; individuals' outcomes cannot be linked to their prenatal alcohol exposure, FAS becomes indistinguishable from ARND/fetal alcohol effects, and diagnoses cannot be made when alcohol exposure is unknown. Considering the fundamental role that the FAS facial phenotype plays in FAS diagnosis, its specificity cannot be assumed and must be confirmed through properly designed empirical studies.

The Evidence Base Underlying the FAS Facial Phenotype

A series of empirical laboratory,[17] clinical,[4,12,13] and population-based screening and surveillance[11,14] studies were conducted by Astley, Clarren, and colleagues over the course of 10 years, to establish the evidence base that supports the diagnostic validity of the 4-Digit Code rank 4 FAS facial phenotype. In 2004, the CDC incorporated the 3 facial anomalies into their FAS guidelines but relaxed the PFL criterion from ≤2.5th percentile to ≤10th percentile. The CDC did not report measures of sensitivity or specificity to validate their relaxed facial criteria. The CDC guidelines[6] cite a series of studies that are intended to support their FAS facial phenotype criteria, but relaxation of the PFL criterion actually goes against the evidence-based literature. For example, the CDC guidelines report, "Use of these three cardinal features (smooth philtrum, thin vermilion, and small palpebral fissures) to assess whether an individual's dysmorphia is consistent with FAS is compatible with the IOM report and other diagnostic systems currently in use."[6] The 3 features are "compatible" with the IOM and 4-Digit Code guidelines, but the magnitude of expression of the PFL is not. The IOM guidelines state, "In this area, the palpebral fissures (eye slits) are short, usually measuring well below −2 SD (standard deviation) for age."[1] The mean PFL among all patients diagnosed as having FAS in the Washington State FAS DPN clinic was −4.0 SD (±1.3 SD).[13] Both the IOM and FAS DPN PFL references are substantially below the 10th percentile (or its equivalent, −1.28 SD) criterion set by the CDC. The CDC does report that use of the 3rd percentile cutoff value for the PFL reduces potential false-positive results for the diagnosis. The CDC guidelines also reported that, "Using anthropometric measurements of all facial features, clinical researchers have confirmed the midline feature abnormalities.[18]"[6] In actuality, the study by Moore et al[18] did not include all facial features. Two of the 3 key midline facial features (philtrum smoothness and lip thinness) were never assessed, and the mean PFL among the 41 alcohol-exposed subjects was −3.6 SD (±1.6 SD), again well below the 10th percentile set by the CDC. Finally, the CDC guidelines reported, "Studies of clinic-referred samples also support these features as discriminant for FAS.[13,19]"[6] But Astley and Clarren[13] did not report that these features are discriminant for FAS

when the PFL is relaxed to the 10th percentile. Coles et al[19] did not include a study group diagnosed as having FAS, did not report what facial features were assessed, and did not conduct a discriminant analysis to delineate the FAS facial phenotype.

In 2005, the Hoyme criteria[8] further relaxed the diagnostic criteria for the FAS facial phenotype to ≥2 of the 3 CDC facial criteria. Like the CDC, Hoyme et al[8] did not provide measures of sensitivity or specificity to validate their relaxed criteria. They also did not report what methods they used (eg, discriminant analyses) to conclude that the facial criteria should be relaxed to 2 features. It is interesting to note that these relaxed criteria are no longer consistent with the facial criteria defined by David Smith, who originally coined the term FAS. In 1979, Smith[20] reported,

> As far as the diagnosis is concerned, perhaps the most important point to emerge in the last few years is that the facial abnormalities seen in affected infants are the key cluster of features that tend to make FAS a clinically discernible entity. Many disorders result in mental and growth deficiency, but in FAS the deficiencies are typically present in a patient whose face has short palpebral fissures, a hypoplastic upper lip with a thinned vermilion border, and a smoothed or absent philtrum. Up to now, the descriptions of the facial features of FAS that have appeared in the literature have not always emphasized the same abnormalities. This has led to some confusion, but inspection of the photographs accompanying these reports leaves no doubt about the facial similarities of FAS patients.

Strengths and Limitations That Affect Validity

The study design and methods used by Hoyme et al[8] to formulate their diagnostic guidelines present both strengths and limitations. Key strengths include the use of skilled multidisciplinary teams led by experts in the field of FASD diagnosis; use of standardized objective measurement tools to enhance reliability; and access to a reasonably large, population-based, study sample. Several limitations, however, jeopardize the validity of the guidelines. (1) Hoyme et al[8] reported that the objective of their study was to formulate more-precise clarifications of the 1996 IOM diagnostic guidelines[1] for "general pediatric practice." However, the racial distribution of their study population (92 South Africans[21] and 72 Native Americans[22]) is not representative of their intended target population (general pediatric practice). (2) Hoyme et al[8] used data for previously diagnosed South African and Native American patients (1998–2003)[22] to formulate their diagnostic criteria. However, an incorrect lip-philtrum guide (white) was used to measure lip thinness in their South African population. Use of a white Lip-Philtrum Guide for a predominantly South African population would result in substantial diagnostic misclassification. The direction of error would be to underestimate the prevalence of the FAS facial phenotype. Creation of diagnostic criteria from a data set predominated by subjects who had a key facial feature measured with an incorrect tool would jeopardize the clinical validity of those criteria. Hoyme et al[8] reported, "A weakness of the proposed diagnostic approach is that the normative values currently used for growth and facial morphologic features are based largely on white populations." The black Lip-Philtrum Guide was made available to clinicians in 2003, before the publication of the Hoyme diagnostic guidelines in 2005. Because the black Lip-Philtrum Guide was not available at the time the South African population was being diagnosed, the South African population may not have been an appropriate population to include in the formulation of the Hoyme guidelines. (3) The Hoyme guidelines described the Lip-Philtrum Guide as follows: "A score of 1 is considered completely normal, whereas a score of 5 is most indicative of FAS."[8] This is incorrect; a score of 1 is highly abnormal. The Lip-Philtrum Guide reflects a normal curve in which rank 3 is the mean (50th percentile) and ranks 1 and 5 reflect the extreme ends of the normal curve (<2.5th percentile and >97.5th percentile, respectively). Rank 4 for the lips and philtrum is not 4 ranks above normal but only 1 rank above normal. Therefore, relaxation of the facial criteria to just 2 of the 3 features, while allowing the 2 features to be expressed near or within the normal range (rank 4 or 10th percentile), would identify a preponderance of individuals with normal facial phenotypes. This is exactly what occurred when the Hoyme FAS facial criteria were applied to the FAS DPN clinical population and a control population of children with confirmed absence of prenatal alcohol exposure. (4) Finally, Hoyme et al[8] reported, "Our aim was to improve both the reliability and validity of diagnoses within the FASD continuum." They concluded, "Application of our guidelines to our extensive database of children prenatally exposed to alcohol demonstrated that the method was rigorous and accurate."[8] The authors convey an important point, that is, guidelines should undergo rigorous evaluation of their performance. However, the authors did not report standardized measures of reliability (eg, test-retest and interrater reliability), validity (eg, construct validity, convergent validity, and criterion validity), or accuracy (eg, sensitivity, specificity, and positive and negative predictive values). These measures have been assessed, confirmed to be high, and published for the 4-Digit Code.[4,11–14]

Hoyme et al[8] used data for 164 children to formulate their FASD diagnostic guidelines. These children were diagnosed originally by May and colleagues[21,22] between 1998 and 2003, with a gestalt approach to diagnosis. Hoyme et al[8] reported that 97 of the 164 children received an original gestalt diagnosis of FAS. When Hoyme et al[8] applied their 2005 guidelines to the 164 children, only 59 of the 97 children retained their diagnosis of FAS. Ten of the 59 children did not have confirmed

prenatal alcohol exposures. The remaining 38 received revised diagnoses across the entire spectrum of FASD, documenting the magnitude and prevalence of errors in the original FAS diagnoses. Sixteen of those who were diagnosed originally as having FAS were reclassified as having ARND (ie, reclassified from the full FAS facial phenotype to a complete absence of the FAS facial phenotype). The inaccurate and highly variable diagnostic outcomes that result from the gestalt approach to diagnosis were demonstrated in 2000 by Astley and Clarren.[4] When the 1997 version of the 4-Digit Code was applied to 69 patients who had received previously a gestalt diagnosis of FAS at the University of Washington FAS DPN clinic, only 9 maintained their FAS diagnosis. Sixty lost their diagnosis of FAS because 37 had no evidence of growth deficiency, 27 had only 1 of the 3 FAS facial features, 29 had no psychometric or structural evidence of brain damage, and 5 had unknown exposure to alcohol. The extraordinarily high FAS prevalence rates (40.5–46.4 cases per 1000 subjects) reported by May et al[21] for a South African community were based on FAS diagnoses that Hoyme et al[8] reported were inaccurate and overestimated.

The Potential to Overdiagnose Alcohol-Related Disabilities

Another marked contrast between the 4-Digit Code and the Hoyme guidelines is in the use of the terms ARND and ARBD. The Hoyme guidelines use the terms, and the 4-Digit Code does not. Both sets of guidelines acknowledge that growth deficiency and CNS damage/dysfunction are not specific to prenatal alcohol exposure, a fact that has been accepted in the field of FASD from the start.[20] With regard to the diagnosis of individuals who present with prenatal alcohol exposure and CNS damage/dysfunction but no FAS facial phenotype, Hoyme et al[8] expressed the following concern about the 4-Digit Code.

> The Washington criteria place much emphasis on the encephalopathy and neurobehavioral disorder present among affected children. These 2 findings are not specifically defined and, as general terms, they are not unique to the prenatal effects of alcohol on fetal development. In addition, the family and genetic background of the child is not adequately integrated into the criteria. Because this highly structured system seems all-encompassing, there is the potential for over-diagnosis of alcohol-related disabilities; any child with a disability who has been exposed to alcohol prenatally can be assigned a diagnostic classification easily, even if the cause of the disability is genetic.

To the contrary, the 4-Digit Code cannot overdiagnose alcohol-related disabilities because the 4-Digit Code does not render "alcohol-related" diagnoses. The only diagnoses that the 4-Digit Code links causally (or relates) to prenatal alcohol exposure are FAS and Partial FAS. This is the most important feature of the 4-Digit Code that distinguishes it from all other FASD diagnostic guidelines. The 4-Digit Code was developed with the premise that a diagnosis should be based on verifiable facts, not supposition. The diagnostic nomenclature used by the 4-Digit Code reflects this. Growth deficiency and CNS damage/dysfunction are not specific to (caused only by) prenatal alcohol exposure. When an individual presents in a clinic with prenatal alcohol exposure and CNS damage/dysfunction but does not have the FAS facial phenotype, the damage/dysfunction may be entirely attributable to the prenatal alcohol exposure, partially attributable to the prenatal alcohol exposure, or unrelated to the prenatal alcohol exposure. Current medical technology is unable to confirm or to exclude the etiologic role of alcohol for an individual patient. This does not pose a problem, however. An accurate diagnosis and effective intervention can proceed without confirmation of an etiologic role of alcohol. When an individual presents with CNS damage/dysfunction and prenatal alcohol exposure, the 4-Digit Code names it exactly what it is, that is, static encephalopathy/alcohol exposed if the CNS damage/dysfunction is severe or neurobehavioral disorder/alcohol exposed if the CSN dysfunction is less severe. The terms do not state or imply a causal association between the exposure and outcomes. Rather, including the phrase "alcohol exposed" in the diagnostic terms serves to alert clinical providers that the individual was exposed to a teratogen and thus is at risk for underlying brain damage. Knowledge of this risk is important, because the presence of underlying brain damage could affect the clinician's future care and intervention efforts for that patient. In contrast to the 4-Digit Code, when an individual presents with CNS damage/dysfunction and prenatal alcohol exposure but no FAS facial phenotype, the Hoyme FASD guidelines label the condition alcohol-related neurobehavioral disorder, stating that the patient's neurobehavioral disorder is related to their alcohol exposure. Aase et al[23] argued effectively that clinical use of the term fetal alcohol effects, with its implications of causation, should be abandoned. Those same arguments apply to ARND and ARBD. Clinicians new to the field of FASD diagnosis are encouraged to read that seminal article. Aase et al[23] urged "simple recording of the verifiable conclusions. . . . If prenatal alcohol exposure has taken place, but FAS cannot be substantiated, the exposure still should be indicated, and any nonspecific abnormalities or problems noted." This is exactly what the 4-digit code does. To convey more completely this important and unique feature of the 4-Digit Code, the guidelines provide clinical summary templates for static encephalopathy/alcohol exposed and neurobehavioral disorder/alcohol exposed, which include the following statement: "The diagnosis of static encephalopathy (or neurobehavioral disorder) does not mean that alcohol is the cause of the problem. A number of other factors could be contributing to the present issues, such as the patient's genetic background, other potential ex-

posures or problems during pregnancy, and various experiences since birth."[3,5] The 4-Digit Code devotes an entire chapter and 4-Digit ranking system to documentation of other prenatal (including genetic) and postnatal exposures and events that occur frequently with prenatal alcohol exposure and likely contribute to the outcomes observed for individuals.[3,5] In fact, the vast majority of the 952 patients seen in the University of Washington FAS DPN clinic presented with multiple risk factors (81% were exposed to illicit drugs in utero, 25% had poor prenatal care, 29% had other complications during pregnancy, 2% had other syndromes, 25% were physically or sexually abused, and 70% were in foster/adoptive care). The impact of prenatal alcohol exposure is never assessed in isolation from other risk factors. The Hoyme guidelines state, "FASD must always be a diagnosis of exclusion. Many genetic and malformation syndromes have some of the other clinical characteristics of FAS. If there is no indication of another genetic or malformation syndrome, then the revised IOM criteria can be applied to categorize a diagnosis within the FASD continuum."[8] Overlap between individual symptoms/anomalies is common throughout medicine. An astute clinician would not mistake FAS for William's syndrome simply because the 2 have some but not all features in common, because it is the constellation of features that distinguish the 2 syndromes. The statement that FASD diagnostic criteria should be applied only if there is no indication of another genetic syndrome implies that alcohol is not a teratogen to a child born with another syndrome. Clearly this is not true. A FASD diagnostic team should consider alternative or co-occurring syndromic diagnoses and medical conditions at all times.

CONCLUSIONS

Accurate, reliable, medical diagnoses across the full continuum of FASD have been available to families and clinicians for almost a decade. As medical technology and our understanding of FASD advance, so must our diagnostic methods and tools. It is imperative that advancements in diagnostic methods be guided by an evidence base of rigorously designed, implemented, and peer-reviewed research. When a diagnosis under the designation of FASD is made, 2 individuals are affected directly, namely, the child and the birth mother. The consequences of an incorrect diagnosis for both mother and child must be considered carefully. Diagnostic guidelines should guide professionals in rendering an accurate medical diagnosis. A diagnosis reflects the condition of a patient; however, because a diagnosis serves many purposes (eg, treatment, prevention, communication among specialists, and qualification for services), the process of rendering a diagnosis can sometimes be influenced by those different purposes. The only diagnosis that serves all purposes most effectively is a correct diagnosis. Access to services should be based on an individual's disabilities and not on what caused their disabilities. Therefore, services should be available for individuals across the full continuum of FASD and not just those with FAS.

It is critical to identify all individuals at risk for FASD. This is achieved through screening and not through relaxation of diagnostic criteria. Screening criteria typically use relaxed diagnostic criteria to identify correctly all individuals with the disease (true-positive results). However, this comes at the risk of incorrectly identifying some individuals who do not have the disease (false-positive results). All subjects identified as screen-positive receive a comprehensive diagnostic evaluation. It is at that time that accurate diagnoses are rendered and the false-positive screens are confirmed to be false-positive results. Through this process, an individual may receive a false-positive screening outcome. No one should receive a false-positive diagnosis, however.

Patients and their families deserve accurate diagnoses. Effective intervention and prevention require accurate diagnoses. Professionals now have access to several FASD diagnostic guidelines. Ultimately they will decide which guidelines are adopted into practice. Their decision will be influenced in large part by a measure of validity that is not easily quantified, namely, construct validity, the extent to which the guidelines produce meaningful results that are commensurate with their clinical impression.

ACKNOWLEDGMENTS

The data used to conduct the secondary analyses for this study were obtained originally through support from the following: grants 216–0, 6437–2, 7158–0, 7923–0, 8403–0, and 8945–0 from the Division of Alcohol and Substance Abuse, Washington State Department of Social and Health Services (1995–2007), and grant AA12915-01A1 from the National Institute on Alcohol Abuse and Alcoholism (2002–2006). Support was also received through the Center on Human Development and Disability (National Institute of Child Health and Human Development grant P30 HD02274).

Special thanks are extended to all individuals and their families who generously contributed data to the FAS DPN databases over the years, to advance the field of FASD and ultimately to help other children and families in need.

Exploring the Utility of Narrative Analysis in Diagnostic Decision Making: Picture-Bound Reference, Elaboration, and Fetal Alcohol Spectrum Disorders

John C. Thorne
Truman E. Coggins
Heather Carmichael Olson
Susan J. Astley
University of Washington

Purpose: To evaluate classification accuracy and clinical feasibility of a narrative analysis tool for identifying children with a fetal alcohol spectrum disorder (FASD).
Method: Picture-elicited narratives generated by 16 age-matched pairs of school-aged children (FASD vs. typical development [TD]) were coded for semantic elaboration and reference strategy by judges who were unaware of age, gender, and group membership of the participants. Receiver operating characteristic (ROC) curves were used to examine the classification accuracy of the resulting set of narrative measures for making 2 classifications: (a) for the 16 children diagnosed with FASD, low performance ($n = 7$) versus average performance ($n = 9$) on a standardized expressive language task and (b) FASD ($n = 16$) versus TD ($n = 16$).
Results: Combining the rates of semantic elaboration and pragmatically inappropriate reference perfectly matched a classification based on performance on the standardized language task. More importantly, the rate of ambiguous nominal reference was highly accurate in classifying children with an FASD regardless of their performance on the standardized language task (area under the ROC curve = .863, confidence interval = .736–.991).
Conclusion: Results support further study of the diagnostic utility of narrative analysis using discourse level measures of elaboration and children's strategic use of reference.

KEY WORDS: assessment procedures, pragmatics, discourse analysis, language sample analysis, diagnostics

Narrative discourse permeates our social lives from an early age, making it a critical area to address in the measurement of language abilities. For more than 2 decades, narrative analysis has been recommended as an ecologically valid way to assess the production of meaningful language in socially integrated discourse (see Owens, 1999). Underlying this recommendation is the assumption that narrative analysis provides a more integrated appraisal of a child's communicative abilities than is possible via standardized language measures (Adams, Lloyd, Aldred, & Baxendale, 2006; Botting & Adams, 2005; Culatta, Page, & Ellis, 1983; Norbury & Bishop, 2003; Wagner, Nettelbladt, Sahlen, & Nilholm, 2000). Thus, narrative analysis should be able to identify children with meaningful communicative impairments that might be missed using conventional standardized assessment instruments. The current study examined this largely untested assumption by retrospectively comparing narratives produced by school-aged children with a fetal alcohol spectrum disorder (FASD) with those produced by age- and gender-matched

typically developing (TD) peers. Comparisons were made via the Semantic Elaboration Coding System[1] (Thorne, 2004), which systematically measures the use of pragmatically appropriate strategies of reference and the semantic elaboration of concepts.

FASDs and Language

Children with prenatal alcohol exposure exhibit a wide range of abilities across all body systems (Astley & Clarren, 2000; Carmichael-Olson, Morse, & Huffine, 1998; Streissguth, 1997). When specific growth, facial, and central nervous system impairments are present within a well-specified range, a diagnosis from within the continuum of FASD can be rendered (see Astley, 2004; Chudley et al., 2005). Because the development and use of language have been reported to be affected by high levels of prenatal alcohol exposure (Mattson & Riley, 1998; Streissguth, Barr, Kogan, & Bookstein, 1996), measurement of language ability has been an important feature of interdisciplinary assessment of these individuals. The preponderance of evidence regarding language behavior in children with an FASD has been gathered using standardized, norm-referenced tests (Abkarian, 1992; Becker, Warr-Leeper, & Leeper, 1990; Carney & Chermak, 1991; Church, Eldis, Blakley, & Bawle, 1997; Church & Kaltenbach, 1997; Gentry et al., 1998; Janzen, Nanson, & Block, 1995; Weinberg, 1997). The goal of these studies has been to establish how well children with an FASD comprehend and/or produce language structures in standardized contexts. Typically, these contexts measure language using discrete responses at or below the level of single-sentence utterances. Although the results have revealed an array of performance deficits, no core deficit profile has emerged.

Because no recognizable deficit profile has resulted from research using standardized language tests, researchers have begun to look at suprasentential discourse in school-aged children diagnosed with an FASD. In preliminary research, discourse level deficits have been documented in children with an FASD including reduced ability to provide sufficient information for listeners both during conversations (Hamilton, 1981) and in narratives (Coggins, Friet, & Morgan, 1998; Coggins, Olswang, Carmichael-Olsen, & Timler, 2003). In addition, caregivers report that children with an FASD often fail to accommodate the perspectives of others during interaction (Timler, Olswang, & Coggins, 2005). This early research suggests that despite widely variable performance on standardized tests, children with an FASD may have difficulty producing integrated extended discourse that requires them to balance linguistic and social–cognitive task demands (Coggins et al., 2003). This emerging profile, when coupled with our ability to identify an FASD independent of communication ability, makes this heterogeneous group of children an ideal population to test the discriminative utility of a narrative analysis system.

Narrative Analysis

As a primary form of extended discourse, narratives provide children with a means of verbally recapitulating experiences (Bishop & Edmundson, 1987; Feagans & Appelbaum, 1986; Feagans & Short, 1984) and are an important source of knowledge about inference, social cognition, and perspective taking (Owens, 1999). The ability to produce contextually integrated extended discourse is difficult to measure using the discrete responses typical of standardized tests. Analysis of narrative samples offers a viable alternative.

Unlike standardized measures, narrative analysis allows for measurement of discourse level parameters of communication that result directly from the pragmatics of a relatively communicative interaction (Owens, 1999). These parameters of behavior manifest in the history of concepts as they are developed across sentences in the narrative text and should provide information regarding language ability that is unavailable in the noncommunicative context of standardized testing. Arguably, the most informative context in which to sample children's narrative ability is one that obligates them to organize and generate narratives without an adult model or other contextual supports (Curenton & Justice, 2004; Juncos-Rabadan, Pereiro, & Rodriguez, 2005; Norbury & Bishop, 2003). This decontextualized narrative discourse stresses the language system by limiting the nonlinguistic tools available during discourse. These limitations determine the type of discourse breakdowns that can be predicted in children with compromised cognitive systems. The Semantic Elaboration Coding System (Thorne, 2004) was designed to capture these predictable discourse level behaviors in school-aged children.

The Semantic Elaboration Coding System

The Semantic Elaboration Coding System implements a framework for narrative analysis based upon cognitive linguistics (Croft & Cruse, 2004; Langacker, 1991; Talmy, 2000b; Tomasello, 2003). *Cognitive linguistics* seeks to account for structural properties of language in terms of its relation to more general conceptual structures and functions. It has, therefore, examined "the linguistic structuring of basic ideational and affective categories attributed to cognitive agents, such as attention, perspective, volition, and intention, and expectation and effect" (Talmy, 2000b, Vol. I, p. 3).

[1]An unpublished training manual for the Semantic Elaboration Coding System is available from the first author via jct6@u.washington.edu.

In a detailed look at the conceptual structuring of narrative, Talmy (2000a) identified a series of conceptual parameters in narrative that constitute a "set of organizing principles that apply in common across all major cognitive systems" (p. 422). The Semantic Elaboration Coding System is organized along two of these parameters that would be expected to vary monotonically with quality in a decontextualized narrative. The first involves the strategic use of linguistic reference to assure that concepts are explicit and uniquely identifiable in the text. The second involves the degree to which semantic concepts are elaborated or well specified in the text.

The strategic use of reference in narrative. In any narrative, it is essential that the concepts involved (both entities and events) are kept distinct from each other to reduce ambiguity. The linguistic strategies used to make distinctive reference to various concepts in a narrative may vary in form from semantically complete phrases and clauses to semantically ambiguous forms like pronouns dependent upon the presuppositions the narrator has about the listener's current knowledge and attention state regarding those concepts. Wong and Johnston (2004) identify three basic *reference functions* in narrative tasks related to presuppositions about the knowledge and attention state of the listener: (a) the *introduction* of new concepts into the discourse (presupposes no knowledge of the concept), (b) the *maintenance* of foreground/in-focus concepts (presupposes both knowledge of and attention to the concept), and (c) the *reintroduction* of previously introduced background/out-of-focus concepts in the discourse (presupposes knowledge of, but limited attention to, the concept). The distinction between adequate and inadequate use of various strategies for meeting these discourse functions cannot be made without consideration of both the textual and extratextual context of the particular instance of use (see Cornish, 1999, for a discussion; see also Levine & Klin, 2001; Maratsos, 1976; van Hoek, 1997; Wong, 2001; Wong, Au, & Stokes, 2004).

In decontextualized narrative discourse, strategies for meeting all three basic reference functions are restricted to the linguistic code (see Halliday & Hasan, 1976). To maintain unambiguous reference, storytellers must use discourse strategies that do not presuppose unwarranted knowledge or attention on the part of their listener or require extralinguistic support to be interpreted meaningfully. This can be particularly challenging for younger storytellers as they continuously adapt their narratives to the ever-changing knowledge and attention states of their listeners (Coggins et al., 1998; Cornish, 1999; Lewis, 2004; Wong & Johnston, 2004).

School-aged children are learning to effectively incorporate a variety of reference strategies into their language production (Stephens, 1988), allowing differentiation between children with typical and delayed language development (see Liles, Duffy, Merritt, & Purcell, 1995; Wong, 2001, for example). Measurement of the strategic use of reference in narrative serves as a primary component of the Semantic Elaboration Coding System.

Semantic elaboration. Decontextualized discourse also demands a greater density of ideas, or *semantic elaboration,* from the storyteller. An analysis of narrative elaboration must account for the contribution of particular words or syntactic structures to the listener's growing conceptualization of a concept in a way that accounts for the history of that concept in the preceding discourse (Croft & Cruse, 2004; Fauconnier, 2004; Klin, Weingartner, Guzman, & Levine, 2004; Talmy, 2000b). This requires that the measurement of elaboration be integrated with the measurement of successful reference to those concepts because a structure cannot contribute to the elaboration of a concept if it does not unambiguously make reference to that concept.

Investigators have heretofore used a variety of lexically based and syntactically based measures to capture elaboration in discourse. These measures have differentiated children with different overall language ability as measured by standardized language tests (Condouris, Meyer, & Tager-Flusberg, 2003; Hammer, Yont, & Tomblin, 2005; Loban, 1976). Most approaches treat the structures they quantify independent of the textual history of the concepts they describe, much as is done with standardized tests of lexical knowledge or syntactic competence. Consequently, they are unlikely to provide information regarding language ability beyond that available through standardized testing (a largely untested assumption, but see Hesketh, 2004). A system that integrates measurement of elaboration and reference strategy may provide information about integrated language abilities that is inaccessible to the more traditional approaches.

Purpose

The Semantic Elaboration Coding System is designed to be used with decontextualized narratives produced for a naive listener by school-aged children as they look through the wordless picture book, *Frog Where Are You?* (Mayer, 1969). It integrates analysis of two narrative discourse parameters that would be difficult to quantify using standardized measures: (a) *ambiguity,* the use of inappropriate strategies of reference, and (b) *elaboration,* the semantic elaboration of concepts as they develop across the narrative (see Thorne & Coggins, 2004; see also Thorne & Coggins, 2005).

With respect to children diagnosed with an FASD, the Semantic Elaboration Coding System must be able to (a) identify children with an FASD who perform poorly on a standardized test to establish a level of concurrent

validity with that standardized test and (b) identify those children with an FASD who perform like typically developing (TD) children on the standardized language test to establish superior classification accuracy when compared with that test. This study was designed to test the potential for the Semantic Elaboration Coding System to make these key discriminations. Specifically, the research questions under study were as follows:

1. Can narrative analysis using the Semantic Elaboration Coding System correctly classify a group of school-aged children into separate groups based on typical development versus an identified FASD?
2. Can narrative analysis using the Semantic Elaboration Coding System accurately predict which children with an identified FASD have either average or low performance on a standardized language task?
3. Which specific measure or combinations of measures from within the Semantic Elaboration Coding System are most accurate in performing these discrimination tasks, and, therefore, reasonably warrant further development?

Method

Participants

Thirty-two school-aged children from two previous studies (Carmichael-Olson & Astley, 2005; Coggins, 1995) participated. They ranged in age from 8;5 years to 11;7 years (M = 9;11 years) and presented a range of socioeconomic and ethnic profiles. Sixteen of the children presented key clinical features consistent with an FASD while the remaining children were considered TD.

Children with an FASD. The 16 FASD participants had a diagnosis of either (a) full or partial fetal alcohol syndrome or (b) a confirmed alcohol exposure accompanying static encephalopathy or neurobehavioral disorder. Diagnosis was performed by an interdisciplinary team at the University of Washington Fetal Alcohol Syndrome Diagnostic and Prevention Network. All children were originally diagnosed using the 1999 version of the 4-Digit Diagnostic Code (Astley & Clarren, 1999). All codes were translated into the 2004 version of the 4-Digit Diagnostic Code (Astley, 2004) to provide an up-to-date diagnostic standard for comparison. Participants reflected "the true diversity and continuum of disability associated with prenatal alcohol exposure" (Astley, 2004, p. 13). Table 1 specifies each participant's 4-Digit Diagnostic Code, which provides information regarding their growth, facial morphology, brain development, and alcohol exposure (see Astley, 2004, for details of code interpretation).

Existing nonverbal and verbal measures provided an additional basis for selection and are also provided in Table 1. The Matrices subtest from the Kaufman Brief Intelligence Test (Kaufman & Kaufman, 1990) provided an overall measure of nonverbal problem solving, with participants excluded based on a score 1.5 standard deviations below the mean (range: 79–130; M = 101). The 16 participants in the FASD group were dichotomized into two performance groups based on their scores from the Re-Creating Sentences subtest of the Test of Language Competence (RS-TLC; Wiig & Secord, 1989): (a) an average-performance group (n = 9) with standard scores within one standard deviation of the mean (between 7 and 10) and (b) a low-performance group (n = 7) with standard scores two or more standard deviations below the mean (between 3 and 4).

The resulting sample included 9 females and 7 males. Family income for the group ranged from $15,000 to $220,000 per annum ($M$ = $88,000, Mdn = $75,000). The group included 11 children identified as Caucasian, 3 as bi- or multiracial, and 1 each as African American and Native American. Only 3 of the children were still living with their biological parent(s) at the time data were collected. The remaining 13 were in adoptive or legal guardianship placements (5 with relatives).

TD peers. Each participant with FASD was paired with a TD peer matched on chronological age (±12 months, mean difference = 3.5 months). Thirteen TD age-matched peers also matched the gender of their FASD counterpart (15 females, 17 males). Table 1 displays age and gender for all participant pairs.

The TD aged-matched peers were recruited from elementary schools representing two school districts in the greater metropolitan Seattle area. Median family incomes were similar across school districts ($61,435–$62,195). The sample included 12 children identified as Caucasian, 2 as Asian, and 1 each as African American and Hispanic (representative of the home county for both districts).

No intelligence or standardized language measures were available for TD participants. However, a school psychologist familiar with the 16 children and with the profile of FASD screened school records for each child with respect to school performance, social ability, and general behavior. Based on this review of available records, each was judged to be following a typical developmental course due to their unremarkable behavior and adequate school achievement. The TD participants did not undergo the same interdisciplinary assessment as the children with FASD.

Materials

Self-generated, decontextualized narratives were selected from two independent databases: one from a study

Table 1. Participant characteristics: diagnosis, language performance group, test scores, age, and gender.

Diagnostic Code & Category[a]	Re-Creating Sentences—Test of Language Competence[b]	Kaufman Brief Intelligence Test—Matrices[c]	FASD Group		TD Group	
			Gender	Age	Gender	Age
2443 = A	3: low	79	F	8;9	F	8;8

1223 = H	9: average	122	F	10;6	F	10;10
1224 = H	7: average	98	F	11;2	M	11;5
3233 = E	10: average	105	M	11;5	M	11;7
Mean	Average: 8; low: 3	101		9;11	9;10	

Note. Diagnostic code provides information, from left to right, regarding growth, facial morphology, brain development, and alcohol exposure. Scores range from 1 (*unremarkable*) to 4 (*severe*). FASD = fetal alcohol spectrum disorder; TD = typical development; F = female; M = male; FASD categories: A = FAS (alcohol exposed); B = FAS (alcohol exposure unknown); C = partial FAS (alcohol exposed); E–H indicate the remaining FASD categories (with confirmed alcohol exposure). Details for interpretation of the 4-Digit Diagnostic Code of FASD can be found in Astley (2004).

[a]Astley (2004). [b]$M = 10$, $SD = 3$. [c]$M = 100$, $SD = 15$.

involving children diagnosed with an FASD (Carmichael-Olson & Astley, 2005) and the second from a normative study of TD school-aged children (Coggins, 1995).

Procedures

All narratives from the two respective databases were elicited using *Frog Where Are You?* (Mayer, 1969). In both studies, participants were tested individually and received the same instructions. Each child was instructed to look through Mayer's book to become familiar with the story line. When the child completed previewing the story, the examiner exhorted the participant to tell the best story possible while using the picture book as a visual prompt. In each case, examiners were seated across the room from the child, with the storybook out of their line of sight.

Transcription and Coding

Narratives were recorded on audiocassette and orthographically transcribed by trained graduate students. The second author supervised the narrative collection and transcription process and then stripped all transcripts of identifying information while assigning each a random code so that relevant information could be retrieved for later data analysis.

Transcripts were coded by the first author using the Semantic Elaboration Coding System (Thorne, 2004). The system assigns codes along the parameters of (a) ambiguity, the consequence of inappropriate reference strategies, and (b) elaboration of concepts.

Ambiguity. Operationally, measurement of ambiguity involved coding references to concepts as either unambiguous or ambiguous. To reduce the number of coding categories, ambiguous anaphoric reference strategies for maintenance and reintroduction of concepts and ambiguous introduction strategies that make unwarranted presuppositions about listener knowledge and attention were collapsed into just two ambiguity categories (nominal and pronominal) because their use has similar impact on a listener's discourse processing (Cornish, 1999; van Hoek, 1997).

Elaboration. Measurement of elaboration involved core lexical items that unambiguously introduced concepts into the story that were coded as either schematic (i.e., minimally characterized) or elaborated. Additional words that helped elaborate concepts were also coded.

For this study, each word in a transcript was assigned 1 of 10 mutually exclusive scoring codes along

these two parameters, or a null code. The 10 scoring codes are presented later with a brief definition of each category. Further details can be found in the Semantic Elaboration Coding System (Thorne, 2004).

Ambiguity codes. Two codes identified unambiguous anaphoric reference to concepts and made a distinction between nominal forms and pronominal forms serving maintenance and reintroduction functions.

1. *Nominal reference (NR):* an unambiguous nominal form used to maintain or reintroduce a concept previously introduced into the discourse (e.g., *a dog* introduced into the narrative later referred to unambiguously as *the dog*).
2. *Pronoun reference (PR):* an unambiguous pronominal form used to maintain or reintroduce a concept previously introduced into the discourse (e.g., *a dog* later referred to unambiguously as *he* or *it*).

Two additional codes were used to identify cases in which reference was ambiguous.

3. *Ambiguous nominal reference (ANR):* an ambiguous use of a nominal form attempting to introduce, maintain, or reintroduce a concept.
4. *Ambiguous pronoun reference (APR):* an ambiguous use of a pronominal form attempting to introduce, maintain, or reintroduce a concept.

Semantic elaboration codes. Six codes were used to quantify semantic elaboration. Four of these codes dichotomized core lexical items as either schematic or elaborated. Two codes identified core lexical units as schematic.

5. *Schematic verb (SV):* a word that introduced basic information regarding an event into the discourse (i.e., the *fact* that something happened: *went, got, is, going*).
6. *Schematic nominal (SN):* a word that introduced basic information regarding an entity into the discourse (e.g., *boy, dog, frog, jar, animal, thing*).

Two additional codes identified those core lexical items that were relatively elaborated.

7. *Elaborated verb (EV):* a word that introduced elaborated information regarding an event into the discourse (i.e., the manner in which something happened: *ran, fell, chased, yelled*).
8. *Elaborated nominal (EN):* a word that introduced elaborated information regarding an entity unambiguously into the discourse (e.g., *Timmy, elk, bullfrog, wife, bumblebee*).

Two final codes identified word forms associated with these core lexical items that provided additional semantic elaboration. These two codes are the most frequent in the Semantic Elaboration Coding System, making up a significant portion of the information the system gathers.

9. *Verb satellite (VS):* a word providing elaborating information about a verb (e.g., went *away,* ran *quickly, in the morning when* he got *up*).
10. *Nominal modifier (NM):* a word providing elaborating information regarding a nominal (e.g., *big mad* owl, frog *that ran away*).

A null code was used to indicate that a word did not fit any of the 10 scoring categories.

Null code (null): a word not meeting operational definitions for any ambiguity or elaboration code category in the system.

Analysis

Intercoder agreement. A graduate student in speech and hearing sciences was recruited and trained to function as a secondary coder. Coder competence was established when intercoder agreement between the primary (the first author) and secondary coder reached a kappa of .7 or better for each code in the system on a set of five training narratives taken from the CHILDES databank (MacWhinney, 2000).

The primary coder then scored all 32 of the study narratives while the secondary coder independently scored 25% of the narratives (n = 8) randomly selected using SPSS for Windows (SPSS, 1998). Random selection and all coding were completed before either coder knew the diagnostic status, age, or gender of the storytellers. The resulting sample contained 5 narratives from the TD group and three from the FASD group.

For both training and study narratives, kappa was calculated as a measure of agreement between coders for each of the 10 Semantic Elaboration Coding System codes and for the null code. Calculation of kappa was conducted separately for each code, with agreement based on a binary decision—every word in the narratives was identified as carrying the designated code or not (following Kraemer, n.d.; see also Bakeman & Gottman, 1997). All words not coded by both judges with the designated code were treated as disagreements in the calculation of kappa for that code. Because it reveals performance for individual codes and avoids overly optimistic and difficult-to-interpret estimates of overall agreement that can occur in multicode calculations of kappa, this is a conservative method of estimating intercoder agreement (Acklin, McDowell, Verschell, & Chan, 2000; see also Kraemer, Periyakoil, & Noda, 2004). Results are presented in Table 2.

Eleven kappa statistics were computed. The precision of 10 kappa scores ranged from substantial (i.e., .6–.8) to almost perfect (i.e., >.8; Kraemer, Periyakoil, & Noda,

Table 2. Interrater agreement (kappa) for all Semantic Elaboration Coding System codes.

Code	κ
VS	.836
SV	.893
EV	.935
NM	.653
NR	.876
SN	.793
EN	.792
PR	.767
ANR	.764
APR	.540
Null (no code)	.836

Note. Calculation of the kappa was conducted separately for each code, with agreement based on a binary decision: Every word in the narratives was identified as carrying the designated code or not. All words not coded by both judges with the designated code were treated as disagreements in the calculation of the kappa for that code. VS = verb satellite; SV = schematic verb; EV = elaborated verb; NM = nominal modifier; NR = nominal reference; SN = schematic nominal; EN = elaborated nominal; PR = pronoun reference; ANR = ambiguous nominal reference; APR = ambiguous pronoun reference.

2004; Landis & Koch, 1977). The kappa statistic for the coding of ambiguous pronoun reference was in the moderate range of precision (i.e., .4–.6). Because it increases chances of Type II error, the moderate level of intercoder agreement on this single code might be considered insufficient for clinical application (cf. Bakeman & Gottman, 1997; Cicchetti & Sparrow, 1981), highlighting the need for attention to coder training and measurement stability in subsequent development of the system (see the Discussion section for more on pronouns and intercoder agreement).

Data preparation. Several preparatory steps were taken to ready the data for analysis. First, the total number of words (TW) was calculated for each narrative (excluding mazes, range: 154–796; M = 308) using SALT (Miller, 2004). Second, the raw frequencies of each of the 11 scoring codes in the 32 narratives were calculated also using SALT. Next, the raw frequencies of codes for APR and ANR were combined to create a summary ambiguity score, while the raw frequencies of codes for EV forms, EN forms, VS forms, and NM forms were combined to create a summary elaboration score.

Next, code and score rates were computed by dividing each measure by the TW in the narrative. Because the Semantic Elaboration Coding System examines narratives on a word-by-word basis, the TW in a story was considered to best represent the length of the story and thereby became the denominator used in the calculation of code and score rates. Using a common denominator for the calculation of all rates also facilitated comparison between rates.[2] This process resulted in 26 narrative measures for analysis: 11 code frequencies, 2 summary scores, and 13 associated rates as a function of narrative length. Table 3 presents all 26 measures.

Classification accuracy analysis. To explore the accuracy of classification for each of the 26 measures, empirical classification rates including sensitivity (true positive rate), specificity (true negative rate), and efficiency (overall accuracy rate) were examined. Methods from signal detection theory based on these three measurement parameters were implemented to judge the relative potential of each of the 26 measures to match the classification of participants provided by the appropriate reference standard (Kraemer, 1988, 1992; Kraemer, Noda, & O'Hara, 2004; McFall & Treat, 1999). The two classifications of particular interest were as follows: *Classification 1*—the accuracy of each measure in classifying participants as members of the FASD or TD group; *Classification 2*—the accuracy of each measure in classifying participants diagnosed with an FASD as a member of the group with average performance or low performance on the RS-TLC.

More specifically, for both classifications, each of the 26 measures was analyzed using an empirical receiver operating characteristics (ROC) curve based on values obtained from the 32 narratives (for recent applications of this method, see Dwolatzky et al., 2003; see also Heilmann, Weismer, Evans, & Hollar, 2005). This analysis compared the classification of each measure against the classification by the appropriate reference standard, and provided an ROC curve plotting the sensitivity against 1 minus the specificity of each measure for all obtained values. The ROC curve, the area under the ROC curve (AUC), and the asymptotic significance, standard error, and 95% AUC confidence intervals were all calculated using SPSS.

Results

Criteria for a Reasonable Measure

The AUC is a widely accepted measure of overall accuracy (McFall & Treat, 1999). An index of effect size, the AUC can distinguish between tests that are random (AUC = 0.5), poorly accurate (0.5–0.7), moderately

[2]It is common to calculate proportional rates for referential terms based on total number of referential opportunities rather than total words. In the case of the Semantic Elaboration Coding System, this would mean dividing each ambiguity code frequency by the total number of NRs + PRs + ANRs + APRs + SNs + ENs. To assure that results using total word rates were not substantially skewed when compared with those using total opportunity rates, correlations and ROC curves were run for ambiguity code rates calculated using both methods. Rates were substantially correlated ($r > .9$), and AUC results were not significantly different ($p > .4$). AUC data are reported using rates calculated with TW to facilitate comparison between elaboration rates and ambiguity rates.

Table 3. Semantic Elaboration Coding System measures evaluated for classification accuracy.

Raw Code Frequencies	Summary Scores and Formula	Rates as a Function of TW
Ambiguity measure		
NR		NR/TW
PR		PR/TW
ANR		ANR/TW
APR		APR/TW
	AS = ANR + APR	AR = AS/TW
Elaboration measure		
EV		EV/TW
EN		EN/TW
VS		VS/TW
NM		NM/TW
	ES = EV + EN + VS + NM	ER = ES/TW
Schematic code		
SV		SV/TW
SN		SN/TW
Null		Null/TW

Note. TW = total words; AS = ambiguity score; AR = ambiguity rate; ES = elaboration score; ER = elaborate rate; Null = no code.

accurate (0.7–0.9), and highly accurate (0.9–1.0; see Swets, 1988). To be considered reasonable in the current analysis, a measure required an AUC with an asymptotic significance better than .02 and an AUC 95% confidence interval with a lower bound above 0.7. These criteria assured not only that the AUC was significantly different from a random test (i.e., AUC = 0.5) but also that it had at least a moderate chance of accurately classifying cases.

Sensitivity, specificity, and efficiency values were calculated at the best possible cut-points for measures obtaining an AUC with an asymptotic significance better than .02. A "best cut-point" was defined as the obtained value along the ROC curve with the highest efficiency (overall accuracy rate). If multiple cut-points had equivalent efficiency, the one with the highest sensitivity was chosen.

Data Presentation

Figure 1 presents AUC data for both of the tested classifications. The top portion of Figure 1 displays results for Classification 1—FASD versus TD group membership. The lower portion of Figure 1 displays results for Classification 2—performance grouping for the FASD participants: low performance versus average performance on the RS-TLC. Figure 1 includes asymptotic significance levels, AUC values, and 95% confidence intervals for each measure (i.e., test) that achieved an asymptotic significance better than .02 for each classification. The shaded regions of Figure 1 indicate the range used to determine that a particular test's confidence interval indicated reasonable accuracy. The four measures that reached the criteria for a reasonable measure are indicated by a double asterisk. Those measures not included on Figure 1 were not statistically different from a random test.

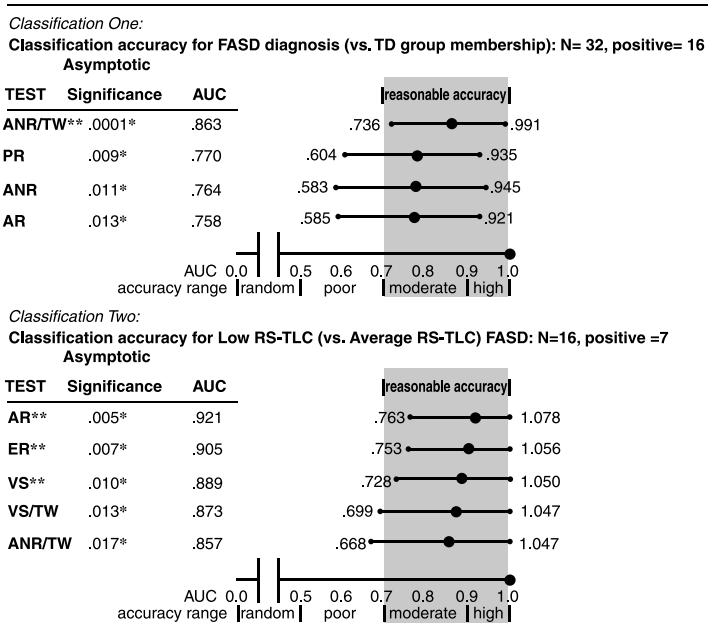
Table 4 displays information on the sensitivity, specificity, and efficiency at the best cut point for the most promising measures. These measures were chosen based on visual inspection of ROC curve shape (see Kraemer, 1992). The top of Table 4 includes data for Classification 1—TD versus FASD, while the lower portion displays data for Classification 2—RS-TLC performance group.

Accuracy for Classification 1—FASD Versus TD Group Membership

As can be seen in the top portion of Figure 1, the rate of ambiguous nominal reference (ANR/TW) obtained an AUC of .863, asymptotic significance = .0001. This AUC indicates classification accuracy solidly within the moderate-to-high accuracy range with a 95% confidence interval from .736 to .991.

As revealed in Table 4, the rate of ambiguous nominal reference (ANR/TW) achieves strong sensitivity, specificity, and efficiency for Classification 1. At the best possible cut point, >.0165 (i.e., greater than 1.65% of total words being ambiguous nominal references equals a positive test for FASD status), ANR/TW achieved a sensitivity of 87.5%, a specificity of 75%, and overall efficiency of 81.25%. At this particular cut point, it correctly

Figure 1. Area under the receiver operating characteristic (AUC) curve with 95% confidence intervals for measures asymptotically different than a random test. Analysis compares classification by Semantic Elaboration Coding System measures indicated and that by reference standard. For Classification 1, reference standard is diagnosis of an FASD by interdisciplinary team. For Classification 2, reference standard is based on average performance (within 1 *SD* of the mean) or low performance (< −2 *SD* below the mean) on the Re-Creating Sentences subtest of the Test of Language Competence (RS-TLC). FASD = fetal alcohol spectrum disorder; ANR = ambiguous nominal reference; TW = total words; PR = pronoun reference; AR = ambiguity rate; ER = elaboration rate; VS = verb satellite. *Asymptotic significance better than .02. **Reasonable test based on a lower bound of AUC confidence interval above 0.7. All values generated with SPSS.



classified 14 of 16 children from the FASD group and 12 of 16 from the TD group.

Post hoc analysis of ANR coding revealed that nominal references were most likely to be rated ambiguous when definite nominal forms were used to introduce or reintroduce concepts (>92% of 185 ambiguous nominal references). In a concordance search of all 32 stories, only 14 (<8%) nominals out of 185 that were rated ambiguous contained the indefinite articles *a* or *an*. Of these 14, 8 were in stories told by children with a diagnosis of FASD and 6 were in stories told by children in the TD group.

As seen in the top portion of Figure 1, the raw frequency of two codes, PR and ANR, achieved a significant point estimate of AUC in the moderately accurate range. However, both measures have AUC confidence intervals that fall below the criteria of .7 set for a reasonable measure. Because the calculation of the ROC curve is based on fewer values, the width of a confidence interval for AUC increases with smaller sample sizes and greater numbers of participants with tied scores. Both ANR and PR codes resulted in large numbers of tied scores relative to sample size. Twenty-nine participants shared their ANR frequency with at least 1 other participant, while 20 shared their PR frequency with at least 1 other participant. As a result, these measures had wide 95% confidence intervals for AUC that ranged below the criteria (see Figure 1). Notice in Table 4, however, that at its best cut-point, ANR was highly sensitive, specific, and efficient for Classification 1, correctly classifying 13 children from each group. While PR correctly classified an equal number from the FASD group, its relatively poor specificity makes it a less promising measure.

Accuracy for Classification 2—RS-TLC Performance for Participants With an FASD

AR, ER, and VS met study criteria for reasonable measures with high classification accuracy. As can be seen in the lower portion of Figure 1, a high AUC was

Table 4. Sensitivity, specificity, and efficiency of most promising measures at their best cut-point for both Classification 1 and Classification 2.

Measure	Cut-Point	Sensitivity(%)	Specificity(%)	Efficiency(%)
Classification 1: FASD vs. TD group membership				
ANR/TW	>.0165	87.50	75	81.25
PR	≤18.0	81.25	62.50	71.88
ANR	>5.0	81.25	81.25	81.25
Classification 2: RS-TLC performance group (FASD only)				
AR	>.0588	85.7	100	93.75
ER	≤0.4816	71.4	100	87.50
VS	≤89.0	100	66.7	81.25

Note. Best cut-point chosen as most efficient test weighing sensitivity over specificity for equally efficient tests. High sensitivity and a negative test help rule out diagnosis, which is useful for screening. High specificity and a positive test help to confirm a diagnosis. Higher efficiency indicates better overall diagnostic performance. RS-TLC = Re-Creating Sentences subtest of the Test of Language Competence.

achieved for the AR. The obtained value of .921, asymptotic significance = .005, places this result in the highly accurate range, with a 95% confidence interval ranging from .763 to 1.00. The lower portion of Table 4 shows that at the best cut-point, >.0588 (i.e., more than 5.88% of words being ambiguous indicates low RS-TLC performance group), this measure obtained a sensitivity of 85.7%, a specificity of 100%, and an efficiency of 93.75%. At this cut-point, the measure accurately classified 6 of 7 children in the low RS-TLC performance group and all 9 of those in the average RS-TLC performance group.

The AUC of the ER, as shown in the lower portion of Figure 1, is .905, asymptotic significance = .007. This AUC falls in the highly accurate range, with a 95% confidence interval ranging from .753 to 1.00. As seen in lower portion of Table 4, at the best cut-point, ≤.4816 (i.e., 48.16% or less of words being elaborators indicating low RS-TLC performance group), ER obtained a sensitivity of 71.4%, a specificity of 100%, and an efficiency of 87.5%. At this cut-point, the measure accurately classified 5 of 7 children in the low RS-TLC performance group and all 9 of those in the average RS-TLC performance group.

The total number of VS met study criteria for Classification 2. As can be seen in the lower portion of Figure 1, this measure obtained an AUC of .889, asymptotic significance = .01, placing it in the top of the moderately accurate range with a 95% confidence interval ranging from .728 to 1.00. The lower portion of Table 4 shows that at the best cut-point, ≤89 (89 or fewer VS indicating low RS-TLC performance group), this measure obtained a sensitivity of 100%, a specificity of 66.7%, and an efficiency of 81.25%. At this cut-point, the measure accurately classified 7 of 7 children in the low RS-TLC performance group and 6 of 9 children in the average RS-TLC performance group. This measure's high sensitivity but relatively modest specificity limits its diagnostic utility to that of a potential screening measure.

Combination of Classifiers

Based on their complementary distribution of classification errors, a combination of ER and AR was tested in a post hoc analysis to determine if combining these measures would improve classification accuracy for Classification 2. The two summary rates were combined using an *or* rule. A positive classification as belonging to the low RS-TLC performance group was obtained if a child had an ER less than or equal to 48.16% or an AR greater than 5.88%. This combination of measures perfectly predicted low RS-TLC performance group (vs. average RS-TLC performance group) with 100% sensitivity, specificity, and efficiency.

Discussion

This study investigated the classification accuracy of 26 measures generated using a new narrative analysis tool. The investigators explored ROC curves to identify the classification capabilities of the Semantic Elaboration Coding System as compared with two reference standards: (a) an interdisciplinary team diagnosis of an FASD and (b) performance grouping based on scores from a standardized expressive language measure, the RS-TLC (Wiig & Secord, 1989). The results are discussed for each topic in turn beginning with classification based on the performance of children with FASD on the RS-TLC.

Concurrent Validity of the Semantic Elaboration Coding System

The degree of elaboration a child uses in narrative discourse is a developmental skill (see Curenton & Justice, 2004; Eisenberg & Gillam, 2005; Loban, 1976; Scott, 1988) that is predictive of language impairment (see Greenhalgh & Strong, 2001; Johnston & Kamhi, 1984). Our results support these findings. The ER was a reasonable and highly accurate predictor of poor performance on the RS-TLC for school-aged children with FASD. At its best cut-point, ER was able to match classification based on the RS-TLC for 14 of 16 children (87.5%) into either low RS-TLC performance or average RS-TLC performance groups. In addition, we found that the summary AR was also a reasonable and highly accurate classifier of language performance group. At its best cut-point, AR matched the classification based on the RS-TLC for 15 of 16 children (93.75%). Post hoc analysis indicated that a logical combination of these two measures using

an *or* rule correctly classified all 16 children with respect to their performance on the RS-TLC.

These results support the notion that narrative analysis should play an important role in diagnostic decision making. Classification using information from a narrative analysis perfectly matched that based on performance on a standardized measure of expressive language. Testing of the Semantic Elaboration Coding System against a wider range of standardized language measures to establish a better understanding of its concurrent validity appears warranted.

Classification Accuracy for FASD Diagnosis

A second goal of this feasibility research was to determine whether the Semantic Elaboration Coding System would provide the information needed for a more accurate classification than the standardized measure to support the idea that narrative analysis provides a more ecologically valid description of a child's ability to produce meaningful language in socially integrated discourse. This is clearly shown with the results of our between-groups classification.

One ambiguity measure satisfied strict accuracy criteria in matching the reference standard classification of study participants into FASD and TD groups. The rate of ANR (calculated as a function of narrative length) accurately identified participants previously identified by an interdisciplinary team as having an FASD regardless of the participant's performance on a standardized expressive language task. At its best value, the rate of ANR matched the interdisciplinary team classification for 14 of 16 (87.5%) children with an FASD, and identified 12 of 16 (75%) children with typical development. Moreover, this measure achieved a substantially reliable kappa statistic (κ = .764).

This finding is arguably the most important from the current study. The data demonstrate a procedure for reliably quantifying meaningful performance differences in the use of reference strategies that has the potential to be diagnostically informative for a population of children who have resisted easy classification using standardized language tests. In spite of the FASD group's wide range of cognitive and linguistic abilities, a single narrative measure keyed to the rate at which a child used inappropriate nominal reference strategies was able to match an interdisciplinary team diagnosis of an FASD for all but 2 children.

Ambiguous Nominal Reference by Children in the FASD Group

A closer look at the post hoc analysis of ambiguous nominal reference sheds light on the behaviors children in the FASD group were using in their narratives that was captured by the ANR code. For a reference to be rated ambiguous in the Semantic Elaboration Coding System, an equivocal word choice must occur. In other words, the storyteller has selected a word that fails in its mission to either introduce or unambiguously reference a concept. There are three basic conditions under which a nominal reference may be considered ambiguous in the coding system.

In Condition 1, an existing concept (e.g., THE BOY) is treated as if it were new by using an indefinite nominal form (e.g., *a boy*) to maintain or reintroduce it. Condition 1 involves pragmatically inappropriate use of an indefinite nominal. Post hoc analysis found this type of error to be rare (<8%) and evenly distributed between the TD and FASD groups. In Condition 2, ambiguity results during reintroduction or maintenance of a concept when the storyteller treats a nominal form new to the discourse as referentially equivalent to a form used previously in the discourse when, in fact, the two are not referentially equivalent. In Condition 3, ambiguity results when a new concept is treated as if it were familiar or already existing in the discourse by using a definite nominal to introduce it into the discourse (e.g., *the boy* used to introduce THE BOY or *the barking* used to introduce an event, BARKING). Conditions 2 and 3 both involve pragmatically inappropriate use of a definite nominal form. It was this inappropriate use of definite nominal forms for introduction, maintenance, or reintroduction of concepts that most commonly (>92%) led to a nominal reference being judged as ambiguous. Condition 2 is considered in detail first.

When children use a particular reference word, they are, in essence, making a categorical decision. That is, they are deciding that a particular entity (e.g., the glass container holding the boy's frog in Mayer's, 1969, story) is a member of a category that can be named with a particular nominal form, for example, *jar*. Certainly, *jar* is not the only possible name that could be used to reference the concept GLASS CONTAINER HOLDING FROG. It could reasonably be referred to as a *glass container* or a *glass frog holder,* for example. If the form *jar* is chosen, however, it will be the form used by listeners as the basis for their understanding of the concept GLASS CONTAINER HOLDING FROG.

Decontextualized narratives obligate the storyteller to find linguistic strategies for keeping entities and events distinct. Heim (as cited by van Hoek, 1997) likened each initial reference within a story to a file card that is introduced into a file catalogue (the narrative discourse). In this scheme, subsequent references to a particular event or entity access and potentially update the information on the appropriate file card (cf. Fauconnier, 2004; Levine & Klin, 2001). The pragmatics of English allow specific linguistic strategies to introduce new file cards

into decontextualized discourse (indefinite forms) that are distinct from those for accessing (i.e., maintaining or reintroducing) file cards already present in the discourse (definite nominals and pronouns; see Croft, 2001; Klin et al., 2004; Langacker, 1991; Maratsos, 1976; van Hoek, 1997; Wong & Johnston, 2004).

Applying this analogy, if *jar* is used to introduce the entity concept GLASS CONTAINER, it will be the nominal form listed first on the listener's file card for that concept. It is not the only lexical form available on the file card, but it will be the one that most effectively refers to the concept. When storytellers who have introduced the concept into the story with the nominal complex *a jar* decide to maintain or reintroduce that same concept using a different nominal form, let's say *the bottle,* they are acting ostensively as if their listener will recognize the overlapping nature of JAR and BOTTLE (both are glass containers) and will assign reference appropriately. However, context plays a significant role in when and how the quite distinct categories JAR and BOTTLE are equivalent and when they are not.

In a shared visual context in which only one item fitting in the category GLASS CONTAINER is seen, visual information aids the listener in disambiguating a reference to that glass container whether the term *jar* or *bottle* is used. In a decontextualized discourse, however, that visual information is unavailable to the listener (despite being available to the storyteller). With only their developing conception of the entities involved in the story to support inferences about the referent, listeners may not be able to quickly and easily determine if *the bottle* being referred to is the same GLASS CONTAINER as *the jar* introduced into the story earlier.

When this occurs, a storyteller who has visual support has not recognized the potential increase in processing demands that a switch in reference forms causes for the listener who does not have access to that visual support (Wong & Johnston, 2004). This increased processing effort may or may not lead to an equivalent understanding of the concepts in the story as listeners attempt to find the most efficient way to resolve the ambiguity. Because this switching of reference forms would not create an equivalent difficulty for a listener who shared the visual context, we refer to this reference strategy as *picture-bound reference* (following Shapiro & Hudson, 1991).

A picture-bound reference strategy is even more apparent in Condition 3, in which new concepts are introduced as if they already existed in the discourse. When there is a shared visual context, picture-bound reference is a reasonable and pragmatically appropriate strategy for introducing concepts because visual information will support listeners as they quickly and easily disambiguate the reference. There is not an obligation to verbally introduce concepts into the discourse if they can be introduced visually.

In decontextualized narrative discourse, the visual information is not available to the listener. So, storytellers who use picture-bound reference strategies to introduce concepts are not recognizing the increased processing demands they are placing on their listeners and are risking that their listeners will not develop an equivalent understanding of the concepts in the story. By identifying this picture-bound reference strategy, the Semantic Elaboration Coding System was able to substantially match interdisciplinary team classification of children into the group with an FASD independent of the child's performance on a standardized expressive language task.

Pronouns and Picture-Bound Referencing

As a definite form, pronouns have the potential to be markers of picture-bound reference. Our results, however, do not show ambiguous pronoun reference to be a reasonable measure for accurately classifying children. It may be that pronouns represent a more complex reference form providing for more fine-grained manipulation of listener attention than full nominal phrases (Gundel, Hedberg, & Zacharski, 2001). As relatively complex forms, it is more likely that pronominal forms will be used in error by children in this age group (cf. Schelletter & Leinonen, 2003; van Der Lely, 1997; Wigglesworth, 1997; Wong & Johnston, 2004). This may be seen in the relatively poor specificity of PR in Table 4. Results indicate that despite the fact that the children in the FASD group tended to use relatively few unambiguous pronoun references, the same can be said for many of their TD peers, leading to a relatively high rate of false-positive classifications. The poor classification accuracy of APR may also reflect the fact that, unlike PR ($\kappa = .767$), APR was relatively difficult for judges to agree upon ($\kappa = .540$). Lower precision in a measure results in a higher chance of a Type II error and potentially masks the utility of the underlying construct. Given the uncertainties, this study highlights the need to consider nominal and pronominal lexical forms separately in narrative research but does not diminish the need for continued study of children's development and use of pronominal forms of reference in discourse.

Conclusion

Whether they exhibited average or low performance on a standardized language measure, children in this study who had an existing interdisciplinary team diagnosis of a disorder on the fetal alcohol spectrum (FASD) were more likely than were their typically developing peers to use a picture-bound reference strategy during storytelling. This strategy could be identified with reasonable accuracy using the rate of ANR calculated as a function of narrative length as defined in the Semantic Elaboration Coding System. If this result can be replicated in a

well-designed validation study, the rate of ANR has the potential to provide useful diagnostic information to clinicians trying to identify clinical populations independent of their performance on standardized measures of expressive language.

As measured by the Semantic Elaboration Coding System, both pragmatically inappropriate reference strategies and semantic elaboration demonstrated the potential to play a role in the diagnosis of FASD by identifying languages behaviors that may be quite prevalent in this population (i.e., picture-bound referencing and unelaborated concepts in decontextualized narratives). It is unlikely that these impairments are specific to FASD (see Bates, 2004). Given that both semantic and pragmatic language ability are frequently compromised in children with complex clinical profiles of diverse etiology, these results also point to the possibility that narrative analysis using the Semantic Elaboration Coding System may have utility in other contexts. In particular, the rate of ANR in a narrative, which is easy to compute and has excellent reliability, may be a potential tool for reliably identifying pragmatic deficits in children who perform well on standardized language tasks despite poor performance during the socially integrated discourse of everyday communication.

Limitations of the Current Study

The TD participants in this study did not undergo the same interdisciplinary assessment as did the children with an FASD. TD participants were chosen because records indicated unremarkable behavior and adequate school achievement—a profile that would not, in a clinical setting, trigger such an assessment. This is not the same as undergoing the comprehensive assessment but provides a reasonable basis for contrasting the two groups in the context of a feasibility study. The lack of objective measures confirming that these children were indeed "typically developing" and not subject to a prenatal alcohol exposure increases the risk of Type II errors (potentially masking reasonable measures). The lack of objective language and cognitive measures on these children increases the chances of Type I errors in the unlikely event that as a group, their ability was significantly above average along the parameters of interest (potentially enhancing the apparent differences between the groups). Both of these limitations enhance the need for the results of this initial feasibility research to be confirmed with validation research.

Also, although strict criteria were used to screen out potentially useless test measures in this feasibility study, numerous measures were examined, so our results may be overfitted to the study population. Consequently, any measure and, particularly, any specific cutoff value reported here will need to be confirmed and validated in subsequent research. Results of this feasibility research can point to potentially useful diagnostic or screening measures, but until these measures have been shown to perform similarly in a well-designed validation study, their utility remains potential but unproven.

Responding to the Challenge of Early Intervention for Fetal Alcohol Spectrum Disorders

Heather Carmichael Olson, PhD; Tracy Jirikowic, PhD; Deborah Kartin, PhD; Susan Astley, PhD

Prenatal alcohol exposure can lead to significant neurodevelopmental disabilities, now recognized as fetal alcohol spectrum disorders (FASD). This includes both fetal alcohol syndrome, a lifelong birth defect, and a wider range of enduring learning and behavior deficits often called alcohol-related neurodevelopmental disorder (ARND). Diagnostic classification systems have been developed to identify children with FASD, and early interventionists from multiple disciplines can be central in identification and referral for diagnosis, and in providing the known protective influence of intervention early in life. With the recent federal mandates to better address needs of children born prenatally affected by substances, or those impacted by abuse and/or neglect, by referring them for screening and possible early intervention services, there is heightened need for providers to understand FASD. There is a growing body of research data describing the teratogenic effects of alcohol on central nervous system function and physical development, the diversity of children with prenatal alcohol exposure and their families, and the developmental and behavioral characteristics of this clinical population. This article reviews the latest research evidence, bearing in mind what is important to early intervention. This article also gives practical guidance on FASD prevention, methods for early screening, and referral of young children for diagnosis of FASD (and referral for needed services once diagnosed), and how to provide education, support, advocacy assistance, and anticipatory guidance for families raising children with FASD. **Key words:** *early diagnosis and intervention*, *fetal alcohol syndrome, alcohol-induced disorders (nervous systems)*, *maternal exposure*, *teratogen*

PRENATAL ALCOHOL EXPOSURE can lead to significant developmental disabilities, now recognized under the umbrella term of "fetal alcohol spectrum disorders" (FASD) (National Organization on Fetal Alcohol Syndrome, 2004). The number of children with the full "fetal alcohol syndrome" (FAS) has been estimated to be 0.5 to 3 per 1000 live births, with higher rates in some communities (Stratton, Howe, & Battaglia, 1996). But FAS is found in only a fairly small proportion of children affected by prenatal alcohol exposure. Many children have alcohol-induced impairments that can be just as serious, or more so, than those seen in FAS (Mattson, Riley, Gramling, Delis, & Jones, 1998). The term "alcohol-related neurodevelopmental disorder" (ARND) has been applied to this condition (National Institute on Alcohol Abuse and Alcoholism [NIAAA],

2000). Prevalence rates of the full range of FASD beyond FAS, including ARND and other alcohol-related birth defects, are believed to occur about 3 times as often as FAS. A rate of 2 to 6 per 1000 (Centers for Disease Control and Prevention [CDC], 2007), and approach the latest estimated prevalence of autism spectrum disorders. New regulations at the federal level, under both the Keeping Children and Families Safe Act of 2003, which amended and reauthorized the Child Abuse Prevention and Treatment Act (CAPTA), and the Individuals with Disabilities Education Improvement Act of 2004, require that children involved in substantiated cases of child abuse and neglect be referred to early intervention systems. IDEA further requires early intervention referral for children whose development is impacted by prenatal substance exposure. These regulations are certain to result in increased numbers of children in early intervention systems who need referral for FASD diagnosis followed by tailored early intervention.

Clearly, FASD is an important problem that every early interventionist will encounter—now more than ever—and potentially play a key therapeutic role. To help guide practice in early intervention, this article summarizes current research on FASD and provides practical ideas about prevention, qualifying children for services, supporting families, anticipatory guidance, and a developmental systems model useful in thinking about assessment and intervention for young children with FASD.

ALCOHOL AS A TERATOGEN AND FASD PREVENTION

As a neurobehavioral teratogen, alcohol interferes with normal fetal growth and development through multiple actions at different sites. Researchers are now studying the biochemical mechanisms underlying alcohol's effects, in hopes that pharmacologic treatments might eventually be used to intervene with (or prevent) alcohol-related fetal injury. Researchers are also looking at neuroimaging and physical measures (such as EEGs) to understand more precisely how alcohol damages the brain (NIAAA, 2000). Most important to early interventionists is the fact that prenatal alcohol exposure can significantly compromise central nervous system (CNS) function, leading to a wide range of developmental, learning, and behavior problems. These problems can affect later life success. Indeed, natural history data so far show that individuals with FASD have a very high likelihood of suffering secondary disabilities of lifestyle and daily function in adolescence and adulthood (Streissguth et al., 2004).

Fetal effects of alcohol exposure differ depending on the amount, timing, and pattern of maternal drinking, so deficits are highly variable from one child to another. In general, the more a pregnant woman drinks, the greater the severity of persistent neurobehavioral deficits. Episodic (or binge) drinking that creates higher maternal peak blood alcohol concentrations is associated with greater fetal damage. On an individual basis, however, *any* amount of drinking during pregnancy can cause harm, and alcohol use *at any time* during gestation is associated with a higher risk of CNS dysfunction. Figure 1 provides highlights from the 2005 U.S. Surgeon General's Advisory on Drinking and Pregnancy (2005). Early interventionists can advance the important goal of FASD prevention by providing this information to the many women with whom they work who are thinking about pregnancy or are already pregnant, and to women's partners.

IDENTIFYING THE PROBLEM AND QUALIFYING CHILDREN FOR SERVICES

Table 1 defines diagnoses on the fetal alcohol spectrum, and Figure 2 shows the "face" of FAS. These diagnoses are medical conditions. Current practice guidelines suggest that diagnosing physicians work with a multidisciplinary team and follow well-defined FASD diagnostic guidelines. National diagnostic guidelines have been published in the United States for FAS (National Center

- Alcohol consumed during pregnancy increases the risk of alcohol-related birth defects, including growth deficiencies, facial abnormalities, central nervous system impairment, behavioral disorders, and intellectual development.
- No amount of alcohol consumption can be considered safe during pregnancy.
- Alcohol can damage a fetus at any stage of pregnancy. Damage can occur in the earliest weeks of pregnancy, even before a woman knows that she is pregnant.
- The cognitive deficits and behavioral problems resulting from prenatal alcohol exposure are lifelong.
- Alcohol-related birth defects are completely preventable.
- For these reasons:

1. A pregnant woman should not drink alcohol during pregnancy.
2. A pregnant woman who has already consumed alcohol during her pregnancy should stop in order to minimize further risk.
3. A woman who is considering becoming pregnant should abstain from alcohol.
4. Recognizing that nearly half of all births in the United States are unplanned, women of childbearing age should consult their physician and take steps to reduce the possibility of prenatal alcohol exposure.
5. Health professionals should inquire routinely about alcohol consumption by women of childbearing age, inform them of the risks of alcohol consumption during pregnancy, and advise them not to drink alcoholic beverages during pregnancy.

Figure 1. Highlights of the 2005 surgeon general's advisory on drinking and pregnancy. From http://www.surgeongeneral.gov/pressreleases/sg02222005.html.

on Birth Defects and Developmental Disabilities [NCBDD], 2004) and in Canada for the broader spectrum (Chudley et al., 2005). More specific FASD diagnostic systems have been developed for clinical and research use which provide a method for diagnosing the full range of conditions that make up the fetal alcohol spectrum.

FASD diagnoses commonly co-occur with developmental delays or deficits arising from other genetic or medical causes, psychiatric disorders (such as ADHD), and/or academic problems. A full understanding of an individual child's problems requires taking all co-occurring conditions into consideration. Diagnoses on the fetal alcohol spectrum typically add an important dimension to the description of a child's problems as classified by other medical and psychiatric diagnoses generated through the use of diagnostic systems such as *ICD-10* (World Health Organization, 2005), DC:0-3-R (Zero to Three, 2005), or *DSM-IV* (American Psychiatric Association, 1994). Knowing that a child has ADHD in the presence of FASD, for example, can mean that commonly used interventions for ADHD will not have expected effects, and that a different combination of treatment techniques may be required. Indeed, an understanding that a child has neurological unpairment arising from alcohol exposure can fundamentally change a parent's or provider's perception of the child's behavior.

Current FASD diagnostic guidelines usually require evidence of structural, neurologic, and/or functional damage of the CNS. Evidence of structural/neurologic damage may include such findings as microcephaly (small head size), abnormal neuroimaging, or seizure disorders. These can sometimes be identified early in life. Evidence of CNS dysfunction includes standardized test scores that document significant global delays or, more commonly, variability revealed in significant gaps in skills, atypical patterns of development, or uneven profiles of learning strengths and weaknesses. Unfortunately, it is often difficult to gather clear evidence of CNS dysfunction at a young age. Early developmental deficits of alcohol-exposed children may be subtle and yet important precursors of later problems. Tests used with young children often cannot detect variability in learning profiles or subtle problems, so young children

Table 1. Criteria for diagnosing fetal alcohol spectrum disorders*,†

Diagnosis	Diagnostic features
Fetal alcohol syndrome (FAS)	Growth deficiency: *Height or weight less than 10th percentile* Cluster of characteristic minor facial anomalies: *Small palpebral fissures (eyeslits), thin upper lip, smooth philtrum (groove above the upper lip)* Central nervous system damage (evidence of structural and/or functional brain impairment) Reliable evidence of confirmed prenatal alcohol exposure: Not necessary if the cluster of characteristic facial features is fully present
Partial FAS (PFAS)	Some of the characteristic minor facial anomalies Growth deficiency: *Height or weight less than 10th percentile* Central nervous system damage (evidence of structural and/or functional brain impairment) Reliable evidence of confirmed prenatal alcohol exposure
Alcohol-related neurodevelopmental disorder (ARND)	Central nervous system damage (evidence of structural and/or functional brain impairment) Reliable evidence of confirmed prenatal alcohol exposure

*Adapted from the Astley (2004).

†The 4-Digit Diagnostic Code (Astley, 2004) is a system used by clinicians and researchers to evaluate the effects of prenatal alcohol exposure. While the 4-Digit Code maps onto these widely known diagnoses, the system actually uses different descriptive terms to more precisely describe *how* children manifest PFAS and ARND. There are other diagnostic guidelines that also include a category called "Alcohol-Related Birth Defects" (ARBD). ARBD exist in the presence of confirmed prenatal alcohol exposure, but children who have ARBD do not necessarily show the characteristic facial features. ARBD are defined as follows: "Any of a number of anomalies (such as heart or kidney defects) present at birth that are associated with maternal alcohol consumption during pregnancy" (NIAAA, 2000, p. 286).

will less often meet FASD diagnostic criteria. In addition, because alcohol effects may often emerge most clearly as deficits in higher level cognitive functions, children's problems may not even become evident until well past the window for early intervention, around second to fourth grades (Olson, Morse, & Huffine, 1998b). Yet there is growing knowledge about the plasticity of the CNS, and intriguing findings on the positive developmental effects of enriching the motor and learning environment with alcohol-exposed animals (eg, Klintsova, Goodlet, & Greenough, 1999; Miura, Whinery, Dominguez, Riley, & Thomas, 2005). These strongly imply that early identification and intervention for children who are alcohol-exposed may be especially important, because CNS function might potentially be improved.

Some states recognize the full FAS as a diagnosed condition with a high probability of developmental delay, thus deserving early intervention. But there are many additional children impacted by prenatal alcohol exposure, and new diagnostic guidelines recognize conditions across the full fetal alcohol spectrum. Literature review later in this article strongly indicates that children affected by prenatal alcohol, but without the full syndrome, have diagnosable conditions that also carry a high likelihood of developmental delay and later significant problems in adaptive function. Because of this, providing early intervention services for all children diagnosed with FASD should be strongly encouraged. An even broader approach to qualifying developmentally vulnerable young children for early intervention is to classify them "at-risk"

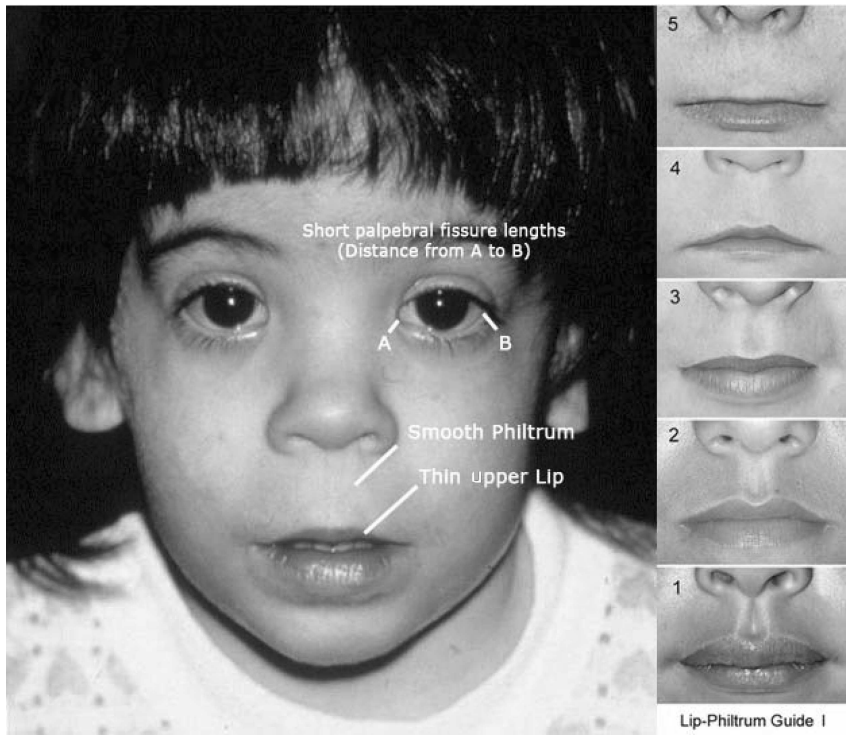

Figure 2. The 3 diagnostic facial features of fetal alcohol syndrome are as follows: (1) palpebral fissure length (eyeslit length) of 2 or more SD below the mean; (2) smooth philtrum (the vertical groove between the nose and the upper lip) (rank 4 or 5 on Lip-Philtrum Guide); (3) thin upper lip (rank 4 or 5 on Lip-Philtrum Guide). Used with permission from Susan Astley.

because of prenatal alcohol exposure coupled with evidence of emerging learning problems and/or environmental risk if this approach fits into IDEA implementation in the state where the child resides. One strategy that does *not* fit with current evidence is assuming that an alcohol-exposed child will "grow out of" apparently mild early delays, and therefore not providing services or developmental monitoring. Instead, if an exposed child does not qualify for early intervention, or improves after intervention and then no longer qualifies, a better approach lies in careful monitoring and reevaluation at key developmental transitions. This will address the possible emergence of later cognitive, language, and social difficulties.

YOUNG CHILDREN WITH PRENATAL ALCOHOL EXPOSURE AND THEIR FAMILIES

What does current scientific evidence say about young children with prenatal alcohol exposure, and what are the implications for early intervention? At present, data for young children born prenatally exposed to alcohol come from several well-designed prospective longitudinal studies of the impact of moderate or higher levels of prenatal alcohol exposure conducted in various locations in the United States, Canada, and selected other countries (with varying ethnic compositions and levels of environmental risk). There are also a few small but carefully investigated clinical

samples of young children with FASD. Just now emerging are data from larger clinical samples composed of patients seen in FASD diagnostic clinics. All these studies are the source of research findings reviewed here, given the focus of this article on the direct impact of prenatal alcohol exposure, a proven neurobehavioral teratogen, on child and family outcome. Also available in the literature are longitudinal studies of young children born polydrug-exposed, including alcohol, who typically have lives characterized by high levels of postnatal environmental risk. Findings from these latter studies are referred to briefly but not reviewed here, because these studies primarily provide insight into the impact of illicit drug exposure coupled with the larger issues of very high risk families and the impact of chemical dependency, rather than the impact of alcohol exposure before birth.

To begin, we briefly summarize new data on a large number of young children, aged birth to 8, and their families ($N = 781$), from the Washington State FAS Diagnostic and Prevention Network (FAS DPN). The FAS DPN is a statewide clinic network operating since 1993 that uses an interdisciplinary team diagnostic process and a carefully developed diagnostic system called the "4-Digit Diagnostic Code" (Astley, 2004; Astley & Clarren, 2000). The FAS DPN data discussed here come from the largest clinical database of children born prenatally alcohol-exposed believed to be in existence at this time, and includes a large number of young children. There are *no* national data on this set of neurodevelopmental disabilities, so the FAS DPN database is an excellent source of information useful to early interventionists even though conclusions are somewhat limited by geographical context. Compared to the population of Washington State, the overall FAS DPN database includes somewhat fewer females and, in terms of ethnicity, slightly underrepresents Caucasians (including those of Hispanic origin) and slightly overrepresents African Americans. Largely because of referral patterns (perhaps because of cultural differences in recognition of the problem and willingness to refer), the FAS DPN database includes somewhat more Native Americans and fewer Asians than in the larger population of Washington State. It should be noted that the FAS DPN database likely underrepresents the subset of children with FASD still living with parents grappling with chemical dependency. Research is needed on the prevalence of FASD in this high-need group.

Age of identification and important demographic characteristics

FAS DPN data show that the average age of referral for FASD diagnosis overall is $9\frac{1}{2}$ years. This means that identification of problems related to alcohol exposure often occurs rather late in children's lives. Younger children, aged birth to 8, comprise only half of those referred. Of these, the average age of identification is just more than 5, with only about a third brought in before age 4. This indicates that two thirds of younger children missed the chance for true early intervention. Improved recognition of FASD by early interventionists could bring more young children in for early diagnosis. Early diagnosis has been identified as a crucial protective factor in this population, because it is associated with more positive outcomes in adolescence and adulthood (Streissguth et al., 2004).

Many children referred for FASD diagnosis are not in the care of their birth parents. In the FAS DPN database, more than 70% of those referred for FASD diagnosis are in foster/adoptive homes. Interestingly, almost half of young children referred (and those diagnosed with FAS or Partial FAS [PFAS]) are at least third born (or later), which fits with observations that the impact of prenatal alcohol exposure may be greater for later borns. Children referred for FASD diagnosis have various racial and ethnic backgrounds. Half of those referred (and those diagnosed with FAS/PFAS) are considered Caucasian, fewer than expected given Washington State demographics, while the others come from a variety of ethnic backgrounds.

Need for referral for FASD diagnosis and advocacy by early interventionists

Surprisingly, in the FAS DPN database, very few families (4.7%) of young children are referred for FASD diagnosis from school or early intervention settings, but instead come from other referral sources such as medical, psychological, or social service providers. This low referral rate could be raised by increased awareness among early intervention providers of referral signs and the hazards of alcohol exposure, and by recognizing the importance of subtle early deficits when prenatal alcohol exposure is present (which even the children's parents may not fully appreciate).

Young children in this database receive FASD diagnoses across the whole spectrum, at rates consistent with population-based studies. This fits with wide variation in prenatal alcohol exposure seen in this population, ranging from maternal consumption of a single glass of wine once in pregnancy to daily intoxication throughout pregnancy. Of children aged birth to 8, only 7.4% receive an FAS or a PFAS diagnosis. It is this surprisingly small group who has the "face" of FAS and who is most likely to be recognized and qualify for early intervention. This is true even though their CNS dysfunction is often no more severe than that of children with ARND. A larger percentage (25.0%) of young children are diagnosed with the equivalent of "severe" ARND. While these young children are clearly in need of intervention, their families may not be able to access help without strong advocacy from early interventionists. An even larger percentage (43.4%) are diagnosed with the equivalent of "mild" ARND. These youngsters may very well show significant problems later on. Yet they are far less likely to receive any early intervention unless providers are very well informed, and have the chance to serve these children within an "at-risk" category.

Early indicators suggesting referral for an FASD diagnosis

FAS DPN data suggest that the simple presence of prenatal alcohol exposure may be the most important reason to refer for diagnosis, with higher levels of exposure especially worrisome. Behavior problems in the presence of prenatal alcohol exposure are also an important referral sign. FAS DPN data also reveal that some indicators commonly used by providers to prompt early identification of problems may *not* be as useful in signaling the need to refer for FASD diagnosis. For example, the average gestational age for children referred to FAS DPN clinics is very close to full term at 37.3 weeks. As another, very striking example, only just over half of the children show marked developmental delay in the first 3 years of life—even among those who receive an FAS/PFAS diagnosis. Indeed, more than one fourth of referred children have developmental profiles well within normal limits, with an additional third who show only mildly abnormal developmental scores. Some familiar indicators of early risk do characterize this group. Data from the FAS DPN show that most of these young children (84.5%) are also exposed to cigarettes or illicit drugs, and most (82.6%) have experienced some degree of postnatal environmental risk.

FAS DPN data reveal that some important early signs for referral for FASD diagnosis that providers could use, with training, are often being missed. It was surprisingly rare for young children to be referred for concerns about facial anomalies or growth. Indeed, diagnostic referral because of FAS-like facial features occurred for only about a tenth of these young children. Yet with careful diagnostic measurement about three quarters of young children referred showed at least 1 or more of the "sentinel" physical features. If early interventionists were more aware of these characteristic features, and/or if facial features were regularly screened as part of an early intervention intake process, diagnostic referral might occur more often. FAS DPN data do suggest that it remains important to pay close attention to even mild impairments of body growth and, especially, to small head size ($\geq$2 SD below the mean). Children with microcephaly show more developmental problems than the general population (Dolk, 1991), and over

two thirds of young children diagnosed with FAS/PFAS had microcephaly.

THE EFFECTS OF PRENATAL ALCOHOL EXPOSURE ON DEVELOPMENT IN YOUNG CHILDREN

An overview, including problems in sensory processing

What is known about the effects of prenatal alcohol exposure on development in young children? It is well established that heavy levels of prenatal alcohol exposure lead to neurobehavioral deficits, but the effects of lower levels of alcohol exposure are less clear (NIAAA, 2000). Neurobehavioral deficits arising from alcohol exposure are lifelong, but their impact on adaptive function emerges more clearly over time—and can likely be improved or made worse by postnatal experiences.

A good overview of clinically relevant findings is provided by a recent, careful study using FAS DPN data that compare a clinical sample of twenty-five 5- to 8-year-olds to an age-, gender-, and ethnicity-comparable group of 26 typically developing peers (Jirikowic, 2003). Children with FASD performed significantly more poorly than comparison peers across measures of IQ, adaptive behavior, academic performance, and sensory-motor development. A main contribution of this study was findings of sensory processing problems in the children with FASD, which validated and extended findings of an older nonstandardized questionnaire study (Morse, Miller, & Cermak, 1995). Using a standardized parent questionnaire coupled with direct testing, Jirikowic (2003) found clinically significant difficulties among children with FASD in tactile, auditory, and visual sensitivity, underresponsiveness to sensory information and sensation-seeking behaviors, and auditory filtering. Although as a group overall motor performance was in the low average range, specific difficulties were seen in sensory-motor tasks involving eye-hand coordination and timed responses, and on tests revealing persistent minor neurologic soft signs. Children with FASD showed generally lowered early academic performance (though still in the average range), with significantly low mathematics skills and early spelling skills. Overall adaptive level was lower than among children with typical development, but quite variable across alcohol-exposed individuals. For children with FASD, relative strengths in adaptive behavior were seen in ratings of motor function, and poorer performance in socialization and ability to follow the rules of daily living. Both teachers and caregivers also endorsed significantly more behavior problems among children with FASD than among typically developing peers. Interestingly, analysis of this carefully constructed and diagnosed sample revealed *no* differences in performance between girls and boys in the group with FASD. Gender differences have almost never been assessed in other studies.

Problems in early cognitive skills and learning, and sleep

Although there is a wide variety in the type and extent of deficits, problems in cognition, learning and memory, attention, and academic achievement have consistently been found among preschool (eg, Janzen, Nanson, & Block, 1995; Jirikowic, 2003) and older children with FASD (eg, Coles et al., 1997; Howell, Lynch, Platzman, Smith, & Coles, 2006; Mattson & Riley, 1998). In clinical samples with FASD, there are consistent findings of deficits in attention, wide-ranging difficulties in higher order cognitive processes called "executive functions," visual-spatial processing deficits and other problems in information processing speed and efficiency, and difficulties with mathematical problem-solving and achievement (NIAAA, 2000). Also of special interest are newer findings of alcohol effects on basic conditioned learning and other cognitive functions that reveal an impact on specific brain regions (such as the cerebellum) (eg, Jacobson et al., 2005). An interesting emerging area is potential alcohol effects on sleep, with likely sleep difficulties in respiratory control and/or circadian rhythms related to problems in brain development, and also to physical problems in midface development

leading to possible breathing obstruction (M. Chen, personal communication, January 3, 2006).

Prenatal alcohol exposure has been associated with cognitive and learning difficulties into adolescence (eg, Goldschmidt, Richardson, Cornelius, & Day, 2004; Streissguth, Barr, Sampson, & Bookstein, 1994) and beyond, though not all longitudinal studies find effects (Greene et al., 1991). Prenatal alcohol has been associated with mildly decreased performance on the Bayley Mental Scale in infancy (eg, Jacobson et al., 1993) and with mildly lowered IQ scores in preschoolers (eg, Streissguth, Barr, Sampson, Darby, & Martin, 1989). Newer longitudinal research with wider ethnic diversity and somewhat more highly exposed samples (using more sensitive measures) has found an association between alcohol exposure and early, specific cognitive and achievement difficulties. For example, infants prenatally exposed to alcohol have shown deficits in information processing and efficiency (Jacobson, Jacobson, & Sokol, 1994). These persist into the early elementary years, with additional findings of a distinctive prenatal alcohol effect on number processing (Burden, Jacobson, & Jacobson, 2005).

Deficits in speech, language, and communication

A variety of speech, language, and communication problems have been described for clinical samples of school-aged children with heavy prenatal alcohol exposure, including delays in speech acquisition, impaired receptive and expressive language, and problems in speech production (Church & Kaltenbach, 1997). Some school-aged children with FASD show discrepancies between relatively better verbal abilities (eg, vocabulary, basic syntax), and diminished capacity to use these skills effectively in social communication (which is an important foundation for developing social relationships and exchanging information) (Coggins, Friet, & Morgan, 1998). There has so far been limited clinical or longitudinal study of language and communication in infants and young children with prenatal alcohol exposure, although this is an area of intense research interest. Current clinical thinking is that young children with FASD can often acquire basic linguistic skills in a typical manner, but have difficulty becoming socially competent communicators later on and, as they grow older, show deficits in higher order language skills. These include difficulties in the more complex syntax, metacognitive abilities, and narrative skills that are tied to their cognitive difficulties in executive functions (eg, Coggins, Olswang, Carmichael Olson, & Timler, 2003).

Problems in motor development and neurologic soft signs

Alcohol-exposed individuals consistently show impairments in the development of motor control (NIAAA, 2000). In infancy, clinical studies reveal motor delays occurring more often and/or with increased severity in the presence of heavy alcohol exposure (eg, Autti-Ramo & Granstrom, 1991). Among younger children with FASD, delays in motor skills are generally mild to moderate in extent, and poor movement quality (decreased speed, efficiency, and control; abnormal balance) is often seen (eg, Osborn, Harris, & Weinberg, 1993). Significant deficits in visual-motor development (but not in motor-free visual perception), and in fine motor coordination, have been described in samples of younger children with FAS in comparison to that of typically developing peers (Adnams et al., 2001; Janzen et al., 1995).

Some longitudinal researchers have found no discernable impact of more moderate levels of social drinking on motor development in infancy (eg, Richardson, Day, & Goldschmidt, 1995) or early childhood (eg, Chandler, Richardson, Gallagher, & Day, 1996; Fried & Watkinson, 1990; Larrouque & Kaminski, 1998). Other long-term studies have found clinically significant effects, but only among infants at high exposure levels—with qualitative differences in motor behaviors (eg, deficits in imitating movements, standing, and walking) noted in infants

with lower exposure levels when compared to those with no exposure (Jacobson et al., 1993). In early childhood, longitudinal research has identified increased levels of minor neurologic soft signs among alcohol-exposed preschoolers (Larrouque et al., 1995), and a positive association between greater alcohol exposure and increased deficits in fine motor steadiness and balance (Barr, Streissguth, Darby, & Sampson, 1990).

Difficulties in adaptive behavior and social-emotional development

Difficult behaviors and social skill deficits that persist across time are an overarching concern among individuals of all ages with prenatal alcohol exposure in both clinical and longitudinal samples (eg, Olson et al., 1997; Olson, Feldman, Streissguth, Sampson, & Bookstein, 1998a; Spohr & Steinhausen, 1996). Mental health problems have been reported for a very large majority of individuals with FASD in natural history research (Streissguth, Barr, Kogan, & Bookstein, 1996), and elevated rates of psychiatric disorders are a concern (eg, Fryer, McGee, Matt, Riley, & Mattson, 2005; Murray, Olson, & Montague, 2005; O'Connor, Kogan, & Findlay, 2002a). For school-aged children with FASD, studies using questionnaires and child behavior checklists often show clinically elevated attention, social, and sometimes internalizing problems (eg, Mattson & Riley, 2000; Roebuck & Riley, 1999), and sometimes also problems with externalizing behavior and aggression (eg, Olson, Brooks, Davis, & Astley, 2004). Adaptive behavior and social skills among pre–school-aged and young school-aged children with FASD are reported as lower than expected for age and intellectual level (Mattson, Lee, Hayden, & Riley, 2005; Thomas, Kelly, Mattson, & Riley, 1998). It appears that children exposed to alcohol show relatively greater deficits in adaptive function than do clinic-referred peers after the age of 8 (Whaley et al., 2001). Clinical studies of children with FASD use terms such as impulsive, distractible, and "always on the go" to describe behavior in the preschool and elementary years (Janzen et al., 1995). In addition, while younger children with FASD have been described as engaging, verbal, apparently alert, and "bright-eyed" (Streissguth, 1997), and appear more functional than they actually are, they seem to lack social boundaries (Olson, 1994). There is wide variability in the level of these deficits, ranging from subtle to severe.

Longitudinal studies focused on infancy report early problems in behavioral regulation associated with prenatal alcohol exposure, including mild to moderate irritability, poor habituation, sleep problems, and feeding difficulties (Eyler & Behnke, 1999; Streissguth, Barr, Martin, & Herman, 1980). Among preschoolers, limited longitudinal data suggest that prenatal alcohol exposure has been associated with functional compromise that includes mild to moderate inattention and hyperactivity, and subtle to moderate impulsivity, and behavior problems (eg, Streissguth, Bookstein, Sampson, & Barr, 1993, 1995).

Developmental systems thinking adds to our understanding of the direct "main" effects of alcohol on child outcome, to better explain the reverberating impact of prenatal alcohol exposure and maternal drinking on social-emotional development across infancy and early childhood. O'Connor and her colleagues (eg, O'Connor et al., 2002b) described a transactional process in which alcohol-exposed infants show increased negative affect, their mothers have difficulty responding to these babies (perhaps because of their own depression that may be associated with a tendency to drink, and/or because of difficulties presented by the child), attachment security is compromised, and these alcohol-exposed children grow into preschoolers who show increased levels of depression at around 4 to 5 years of age. This has been shown in middle-income families, and even more clearly in low-income families who have additional risk factors that increase severity of this negative cycle. Additional analyses of middle-income families through age 6 revealed this process as most important for girls, but also found

separate trends or significant direct effects of prenatal alcohol exposure on outcome in both boys and girls (O'Connor, 2001). Further research taking a developmental systems approach, and examining issues such as gender and socioeconomic differences, is crucial to creating targeted, empirically based early intervention for children who are alcohol-exposed or have FASD diagnoses.

Cumulative risk and FASD

The impact of prenatal alcohol exposure is often coupled with that of other prenatal drug exposures, poor prenatal care, and life with parents who struggle with chemical dependency. Children may live in environments with health and safety concerns, relationship problems, and chaotic lifestyles. Longitudinal studies (eg, Arendt et al., 2004; Butz, Pulsifer, Leppert, Rimrodt, & Belcher, 2003; Singer et al., 2004) have tracked the often negative developmental outcomes of children with prenatal substance exposures in these high-risk situations. Clinical studies have examined the difficult lives of children and the potential impact of intensive interventions through comprehensive chemical dependency treatment programs serving women with children (eg, Division of Alcohol & Substance Abuse, 1999), long-term and very intensive family support programs for the highest risk mothers (eg, Grant, Ernst, Streissguth, & Stark, 2005), and intensive early intervention with family support (eg, Butz et al., 2001; Nair, Schuler, Black, Kettinger, & Harrington, 2003; Schuler, Nair, & Kettinger, 2003). These studies are sharp reminders that children with FASD may often spend at least some of their early years in an environment of cumulative risk. A developmental systems approach emphasizes that cumulative risk could be especially harmful for a child made biologically vulnerable by prenatal alcohol exposure. With the implementation of CAPTA amendments and the IDEA Improvement Act of 2004, early intervention providers will more often be linked with the child welfare system and see children who not only experience cumulative risk but also have prenatal exposures. As a result, the need to refer children for FASD diagnosis or to refer those children who are diagnosed for appropriate supplementary services will increase—and specialized training and systematic linkages with service systems that work specifically with these families will be needed.

TAKING ON THE CHALLENGE OF FASD IN EARLY INTERVENTION

A developmental systems model and its usefulness in guiding practice and research

Developmental systems thinking can guide practice for young children with FASD or with prenatal alcohol exposure, and makes clear why early intervention for this population is especially important. A useful developmental systems model was created for early intervention with children who have special needs (Guralnick, 2001). Applying this model to FASD, prenatal alcohol exposure can be seen as placing a child at risk for (or creating) biological vulnerability and "disabling child characteristics," such as sensory sensitivities or unusual learning deficits. Such deficits are individually variable and arise in multiple domains of development (perhaps in subtle ways), and may emerge more clearly or become more debilitating over time, and these child deficits (and compensatory strengths) must be comprehensively assessed.

Disabling child characteristics can disrupt existing family interaction patterns, creating information and resource needs for parents, threats to parenting confidence, and both caregiver and family stress. Comprehensive assessment of these "environmental risk factors," and risks uniquely important in this population, are also essential. One unique risk factor identified through clinical experience centers around inappropriate caregiver reactions to deficits of the child with FASD—deficits caregivers may not easily recognize as a result of alcohol-induced CNS dysfunction, but see as willful disobedience. Other pivotal family risk factors have been documented in natural history research. For this population,

past or current parental substance use, and poor quality of attachment security or poor quality of the childhood caregiving environment, is significantly associated with poor life outcomes (Streissguth et al., 2004). Protective factors hypothesized as important to this target population, such as the parent's level of optimism and parenting efficacy, use of specialized parenting practices, advocacy skill, and knowledge of FASD, or appropriate linkage to community resources (Olson et al., 2005), must also be assessed.

Early intervention should then aim to concurrently reduce the impact of disabling child characteristics and cumulative environmental risk, while at the same time enhancing protective factors. For the diagnosed child, a comprehensive intervention program can be developed and implemented, providing resource, social, and information supports, and direct intervention to enhance family interaction patterns, adjusted to the family's unique needs and targeted to the disability. For example, if a child with FASD has sensory sensitivities and processing speed deficits arising from prenatal alcohol exposure, then environmental modification and supportive OT services, caregiver education, and advocacy for later special education, might be necessary. Home visiting or clinical services to help caregivers understand alcohol-related brain damage, modify attitudes, learn specialized parenting skills, and learn effective advocacy to access existing community supports may be required when children with FASD have especially difficult behavior problems. Intervention models for such services have been developed and show promising findings in systematic research with somewhat older children with FASD (eg, Olson et al., 2005). For "at-risk" young children with prenatal alcohol exposure who may or may not yet show clinically concerning behaviors, preventative interventions are needed. For example, if attachment security is compromised in a very young child, intervention focused on enhancing secure attachment may be helpful—but may have to be adjusted for a biologically vulnerable child and the family structure (eg, foster, birth) in which the child is being raised. Early intervention models are being developed that incorporate a variety of child- and family-focused intervention strategies as needed (eg, Coles, Kable, Dent, & Lee, 2003; Gurwitch, Mulvihill, & Chaffin, 2003).

Of course, research on FASD prevention and on biological methods to ameliorate the impact of prenatal alcohol exposure on child development (such as nutritional supplements) is important. But many children are born exposed to, and affected by, prenatal alcohol, so intervention research is essential. Developmental systems thinking can also guide intervention research. Specific "disabling child characteristics" of children with FASD (or prenatal alcohol exposure) must be identified. For deficits amenable to change, targeted intervention strategies must be studied. For example, young children with FASD or prenatal exposure likely have behavior regulation problems, and targeted interventions might involve teaching caregivers specialized techniques to calm their alcohol-exposed child or help the child self-sooth. It is also imperative to conduct research on the effectiveness of more comprehensive early intervention services. These reduce "environmental risk factors" that have already been identified and increase hypothesized protective parenting and family factors. Such research is already under way through, for example, collaborative research by several research groups funded by the Centers for Disease Control and Prevention (eg, Bertrand, Sidhu, & Floyd, 2003).

Educating early intervention professionals about FASD and improving service delivery

To best serve children with FASD or prenatal substance exposure, what training is recommended for all early intervention professionals? As a start, this article presents important information about the disability. But there are additional needs for specialized preservice education and continuing education in the field, with training recommendations presented in Table 2. Training

Table 2. Suggested training topics for early intervention providers working with children affected by parental substance abuse, including alcohol*,†

How to ask questions about prenatal exposure
The process of addiction and recovery; harm reduction and relapse prevention
How to provide FASD prevention information
How to recognize and screen for the characteristic facial features of FAS, small head size, and mild or greater growth impairment
Key behavioral symptoms signaling need for diagnostic referral when in the presence of alcohol exposure
Advocacy skills to help children at risk continue to be monitored or qualify for services even with subtle deficits, and to promote services in the next intervention setting
Neurodevelopmental disabilities, and specifics about FASD; how brain development and function are affected by prenatal alcohol exposure
How to provide appropriate early intervention given current data on FASD, with a focus on environmental modification and antecedent-based positive behavior support planning
The family experience of raising children with FASD, and differences between different family structures
How parental substance abuse affects children's lives
CAPTA and IDEA regulations, and interagency efforts to improve services for children affected by parental substance abuse
Systems of care for chemical dependency treatment, FASD diagnosis, child welfare, crisis placement, foster care, adoption, adult corrections, and adult developmental disabilities service.

*Contact Drs Carmichael Olson and Jirikowic for more information on training program.
†FASD indicates fetal alcohol spectrum disorders; FAS, fetal alcohol syndrome; CAPTA, Child Abuse Prevention and Treatment Act; and IDEA, Individuals with Disabilities Education Act.

is an essential foundation to help providers develop skills to screen for FASD, guide families in obtaining a diagnosis, and effectively support the children with a diagnosis and their caregivers. Such training programs are under development and continuing education about some of these topics already exists. Beyond training, early intervention providers can build working relationships and formal connections with service provider systems that specialize in this area, such as woman-oriented chemical dependency treatment centers, FASD diagnostic clinics, FASD intervention programs, FASD parent support/advocacy organizations, and the child welfare system. At the state and local levels, interagency efforts can set up methods to raise awareness and train providers, facilitate smooth diagnostic and service referrals, modify categorical service requirements as needed, enhance collaborative care, and strengthen supports for these children and families.

Screening for FASD

Using a developmental systems approach, screening is an essential first step to identify children who should be referred for FASD diagnosis as young as possible. Screening should take place in all early intervention settings. The most efficient and effective screening method for FAS is to look for the characteristic facial features. Inexpensive and user-friendly tools are available (Lip-Philtrum Guides and FAS Facial Photographic Analysis Software) and have been used to effectively screen high-risk populations for FAS such as children in foster care (Astley, Stachowiak, Clarren, & Clausen, 2002). Screening for ARND requires effective and appropriate inquiry about prenatal alcohol exposure because, unlike the FAS facial features, there

is no pattern or type of CNS dysfunction that is specific to prenatal alcohol exposure and can clearly identify ARND. Providers should obtain training on how to ask about women's drinking and drug use, know their own agency guidelines before talking with caregivers about prenatal exposures, and remember that alcohol use at times other than pregnancy can suggest only the possibility of gestational alcohol exposure. Providers should also screen for behavior problems and growth impairment that occur in the presence of alcohol exposure.

Helping families obtain an FASD diagnostic workup

Early interventionists are well-placed to help families find a diagnostic center and obtain a workup for an identified child. Diagnostic services are most likely to be available in child guidance or child development centers, hospitals specializing in children's services, or the growing number of specialized FASD diagnostic clinics. The Substance Abuse and Mental Health Services Administration, a governmental agency, through its FASD Center for Excellence, has sponsored a Web site that as of 2007 collates all available information on diagnostic services, intervention, prevention efforts, screening programs, and research literature: http://fascenter.samhsa.gov/about/index.cfm.

Understanding and supporting families through FASD diagnosis

Early interventionists can play a key role in helping families adjust to the possibility that a child may have (or does have) FASD. Caregivers raising a child with FASD and behavior problems almost all experience high levels of child-related parenting stress (Olson et al., 2004). Perhaps more than with other neurodevelopmental disabilities, FASD carries with it an emotional overlay, because it is a birth defect that could have been prevented—and the disruptive influence of addiction will, in some way, be part of the family history. Parents' emotional reactions to the diagnosis can range from anger, to refusal to believe or listen, to acceptance—but almost always include grief, and often a firm (but likely mistaken) conviction that all problems can be dealt with by nurturing parenting or extraordinary efforts at early intervention.

Reactions of birth parents are also influenced by whether parent(s) are currently drinking or involved in the recovery process. The emotions of guilt and shame, or the psychological defense of denial, can create barriers to problem recognition or offers of intervention. Continued drinking and/or accompanying illicit drug use can mean ineffective communication and unpredictable lives, and even raise ethical and legal dilemmas for providers. Working with birth parents requires interpersonal sensitivity, and at least some specialized training (or access to consultation with providers who understand the issues of addiction and recovery). But a basic precept is that meeting families where they are, with a respectful, open, nonjudgmental, and supportive stance, is the best response by providers to the feelings of families. To maintain such a stance, however, requires that an early intervention provider think through their emotional reactions to their own and others' substance use, and to the stark reality that parental alcohol use can compromise an affected child's lifelong development.

Foster families in many states often receive training on issues related to children's special needs, and even specifically about FASD. But a child's foster placement may be temporary, so early intervention providers often must support both foster parents and caregivers who may then receive the child, including birth parents in recovery. Adoption agencies now typically openly disclose to adoptive families what is known about a child's prenatal and postnatal risks and any special needs, and families may have specifically chosen to adopt a child with FASD. But because alcohol effects may reveal themselves over time, adoptive families often find themselves struggling as they realize what is really meant by a lifelong birth defect. Therefore, they

may need intensive support from early interventionists. Furthermore, kinship adoptive placements may differ quite dramatically from nonrelative adoptive placements. Children in kinship placements are living in families touched directly by addiction. A maternal grandmother raising her grandson, for instance, might also be contending with her daughter's ongoing addiction, and the grief and shame (or anger) that arises from both the ongoing addictive behavior and its consequences that impact the child.

Providing anticipatory guidance and a model for future intervention

Early interventionists individualize and set up appropriate, clear structure and routines, promoting strengths and accommodating each child's particular deficits. Early intervention settings ideally aim to provide family-centered, integrated services that are based on a developmental framework and attempt to achieve inclusion (Guralnick, 2001). Such settings are, perhaps, a model for how children with FASD would best be served even *after* the early intervention period. It is a major challenge when a child with FASD transitions out of the early intervention system to the schools, and the child and family must then deal with the expectations of more independent function and reduced access to individualized programming that come with age. Early interventionists can smooth this transition. They can be the first to grasp the real hazards of prenatal alcohol exposure, referring children for diagnosis with FASD as early as possible, alerting caregivers to the growing child's likely emerging neurobehavioral deficits and increasing struggles with relationships, connecting families with needed additional services (such as alcohol treatment for parents)—and showing the family and the child's set of care providers what intervention strategies can really work. Early intervention providers can be proactive and essential gatekeepers and guides to the future.

Children With Fetal Alcohol Spectrum Disorders: Problem Behaviors and Sensory Processing

Laureen Franklin, Jean Deitz, Tracy Jirikowic, Susan Astley

KEY WORDS
- fetal alcohol spectrum disorders
- pediatrics
- prenatal alcohol exposure
- sensory integration

OBJECTIVE. This study describes the sensory-processing and behavior profiles of a clinic-referred sample of children with fetal alcohol spectrum disorders (FASD) and examines the relationship between sensory processing and behavior.

METHODS. Outcomes on the Short Sensory Profile (SSP) and Child Behavior Checklist (CBCL) for 44 children, ages 5 to 10 years, were assessed and compared using retrospective data analysis.

RESULTS. A high proportion of the children demonstrated deficits in sensory processing and problem behaviors as measured by the SSP and the CBCL. Moreover, the correlation between the SSP and CBCL total scores ($r = -.72$) was significant.

CONCLUSION. Results provide evidence that children with FASD demonstrate problem behaviors and sensory-processing impairments as reported by parents and that sensory-processing deficits co-occur with problem behaviors at a high rate in this population. This finding suggests that deficits in sensory processing may affect the ability of children with FASD to respond adaptively to their environments.

Laureen Franklin, MS, OTR/L, is Occupational Therapist, Anacortes Children's Therapy, Inc., Anacortes, WA. At the time of this study, she was Graduate Student, Master of Science Program, Department of Rehabilitation Medicine, University of Washington, Seattle; franklinlr@gmail.com

Jean Deitz, PhD, OTR/L, FAOTA, is Professor, Department of Rehabilitation Medicine, University of Washington, Seattle.

Tracy Jirikowic, PhD, OTR/L, is Occupational Therapist, Washington State Fetal Alcohol Syndrome Diagnostic and Prevention Network (FAS DPN), and Clinical Instructor, Department of Rehabilitation Medicine, University of Washington, Seattle.

Susan Astley, PhD, is Professor of Epidemiology and Director of the Washington State Fetal Alcohol Syndrome Diagnostic and Prevention Network (FAS DPN), the University of Washington, Seattle.

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy (Jones & Smith, 1973). FAS is characterized by growth deficiency, a specific cluster of minor facial anomalies, and central nervous system damage and dysfunction (Astley & Clarren, 2000). Not all children subjected to prenatal alcohol exposure have FAS. The adverse impact of prenatal alcohol exposure presents along a continuum called *fetal alcohol spectrum disorders* (*FASD;* Bertrand et al., 2004). Clinical diagnoses that fall under the umbrella of FASD include FAS, partial FAS, static encephalopathy–alcohol exposed, and neurobehavioral disorder–alcohol exposed. The teratogenic impact of alcohol on the developing brain can lead to deficiencies in cognitive functioning, attention, memory, learning, language, auditory processing, motor skills, and problem solving (Connor & Streissguth, 1996; Mattson & Riley, 1998). Secondary disabilities affecting work, school, and social functioning may also result, which may include deficits in adaptive behavior, social competence, communication, and daily living skills (Roebuck, Mattson, & Riley, 1999; Streissguth et al., 2004; Whaley, O'Connor, & Gunderson, 2001).

Although cognitive and behavioral deficits associated with FASD have been extensively reported in the literature, sensory-processing deficits have received less attention. *Sensory processing* is a general term based on Dunn's (1999) conceptual model, which hypothesizes that a continuum of interaction exists between neurological processing of sensory input and behavioral responses. Daily activities and skills are believed to be negatively affected by sensory-processing deficits (Ayres,

1979). Sensory-processing impairments have been theoretically linked to a wide range of neurobehavioral difficulties, including problems with motor coordination, language, visual–perceptual skills, behavior, attention, learning, and emotional regulation (Ayres, 1972, 1979). Some of the documented manifestations of sensory-processing deficits include hyperactivity, distractibility, social difficulties, learning difficulties, poor organizational skills, and behavioral difficulties (Ayres, 1979). These characteristics also have been consistently reported in children with FASD (Mattson, Goodman, Caine, Delis, & Riley, 1999; Mattson & Riley, 1998).

Unfortunately, little research examines the relationship between sensory-processing and behavioral impairments in children with FASD. Findings from two studies that explored sensory processing in children with prenatal alcohol exposure suggest that children with FASD do present with sensory-processing difficulties and that these deficits co-occur with other behavioral and adaptive deficits (Jirikowic, Olson, & Kartin, in press; Morse, Miller, & Cermak, 1995). Although both studies found significantly more sensory-processing problems in children with FASD compared with typically developing children, findings were considered preliminary with limitations in instrumentation, sample size, and the depth of concurrent problem behaviors examined. More investigation of the impact prenatal alcohol exposure has on a child's ability to process and respond to sensory stimuli in his or her environment and how this relates to the child's behavioral responses to the environment is an important step that may lead to more effective intervention.

Two assessments typically administered to children in the Fetal Alcohol Syndrome Diagnostic and Prevention Network (FAS DPN) at the University of Washington are the Short Sensory Profile (SSP; Dunn, 1999), which is used to measure sensory-processing impairments, and the Child Behavior Checklist (CBCL; Achenbach, 1991; Achenbach & Rescorla, 2001), which is used to measure problem behaviors. Children's total and section scores on the SSP are classified into three categories (definite difference, probable difference, and typical performance) on the basis of parent-reported sensory-processing behaviors. Similarly, parent-reported problem behaviors on the CBCL syndrome scales, internalizing scale, externalizing scale, and total problems scores are classified into three categories (clinical, borderline, and normal).

Because of the paucity of research related to sensory processing and potential association with problem behaviors in children with FASD, this study had two purposes. The first purpose was to describe the sensory-processing characteristics and problem behaviors of 5- through 10-year-old children with FASD. The second was to explore the relationship between sensory-processing deficits and problem behaviors in children with FASD by testing the following hypotheses.

1. A significant negative correlation will exist between the CBCL total score (high scores document impaired outcome) and the SSP total score (low scores document impaired outcome).

2. Children with FASD in the SSP definite or probable group will score significantly different from children with FASD in the SSP typical group on the CBCL in the following areas: two of the syndrome scales (attention problems and social problems), the total problems score, and the externalizing problem score.

3. Children with FASD in the CBCL clinical or borderline group will score significantly different than children with FASD in the CBCL normal group on the SSP total score and five of the seven section scores (i.e., tactile sensitivity, movement sensitivity, underresponsive/seeks sensation, auditory filtering, and visual/auditory sensitivity).

4. Children with FASD who have scores that fall within the categories of definite or probable differences on the SSP will be more likely to demonstrate borderline or clinical ranges on the CBCL than children who demonstrate SSP scores within the typical performance category.

Methods

Research Design

A retrospective study was conducted using data from the Washington State FAS DPN clinical database. This database contains more than 2,000 fields of exposure and outcome data on each child with prenatal alcohol exposure who received FASD diagnostic evaluations at one of the six network clinics. Approximately half of the children are seen at the University of Washington FAS DPN clinic. Although the FAS DPN database is a clinic-referred sample, the only requirement for obtaining a FASD diagnostic evaluation at a FAS DPN clinic is a confirmed prenatal alcohol exposure at any quantity, frequency, or duration.

All children in this database received an interdisciplinary FASD diagnostic evaluation (Clarren, Carmichael Olson, Clarren, & Astley, 2000) using the FASD 4-Digit Diagnostic Code developed by Astley and Clarren (1997, 2000). The four digits of the code reflect the magnitude of expression of the four key diagnostic features of FASD in the following order: (1) growth deficiency, (2) FAS facial features, (3) central nervous system damage–dysfunction, and (4) prenatal alcohol exposure. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4

reflecting strong presence of the FAS feature. Diagnoses were updated and coded according to the 2004 version of the 4-Digit Diagnostic Code (Astley, 2004).

Data were used in this study from all children in the FAS DPN database who met the following inclusion criteria: (1) being 5 through 10 years of age at the time of diagnosis, (2) being male or female of any race or ethnicity, (3) having one of the FASD diagnoses using the 2004 FASD 4-Digit Diagnostic Code (FAS, partial FAS, static encephalopathy–alcohol exposed, or neurobehavioral disorder–alcohol exposed); and (4) having complete data available in the database for the SSP and the CBCL. The CBCL has been administered at the FAS DPN since it first opened in 1993. The SSP was not available until 1999; thus, it was not administered in the FAS DPN until 2000. Because administration of both the CBCL and the SSP was an inclusion criterion for this study, the study population was restricted to only those diagnosed since 2000 who had data for both measures.

Instruments

SSP. Sensory-processing behaviors were measured using the SSP. The SSP is a 38-item, judgment-based caregiver questionnaire that serves as a tool for identifying a child's sensory-processing behaviors; it links these behaviors with the child's functional performance in daily activities (Dunn, 1999). The SSP, a shorter version of the Sensory Profile, was developed as a screening tool to identify children with sensory difficulties more quickly and for use as a sensory-processing measure for research purposes. The SSP is a standardized behavioral checklist with normative data. A 5-point Likert scale ranging from *always* to *never* is used to record caregiver responses. Low raw scores reflect sensory-processing problems. Moreover, the SSP includes a classification system made up of three categories (normal, probable difference, and definite difference). Psychometric properties, including reliability and validity, for the SSP are generally strong (Dunn, 1999; Dunn & Brown, 1997; Dunn & Westman, 1997; Ermer & Dunn, 1998; Watling, Deitz, & White, 2001). Internal reliability of the section scores, for a sample of 117 children, ages 3 to 17, ranged from .82 to .89 (Cronbach's alphas; Dunn, 1999). Internal reliability for the total score was .96 (Cronbach's alpha; Dunn, 1999). Intercorrelations among the SSP sections scores ranged from .25 to .76 ($p < .01$; Dunn, 1999). This finding implies that the sections are measuring differing but overlapping constructs.

Achenbach CBCL. Functional behaviors were measured using the CBCL (Achenbach, 1991) for ages 4 to 18 years and the Achenbach System of Empirically Based Assessment CBCL for ages 6 to 18 years (Achenbach & Rescorla, 2001). These are standardized tools used to assess behavioral and emotional problems that have occurred during the past 6 months.

Both versions of the CBCL are questionnaires on which a caregiver rates a child's problem behaviors. The response format is 0 (*not true*), 1 (*somewhat or sometimes true*), or 2 (*very true or often true*). Scoring provides eight syndrome scales that measure behavioral and emotional problems. These scales are anxious/depressed, withdrawn/depressed, somatic complaints, social problems, thought problems, attention problems, rule-breaking behavior, and aggressive behavior. The eight syndrome scales are summarized into three broader scales: internalizing (anxious/depressed, withdrawn/depressed, somatic complaints), externalizing (rule-breaking behavior, aggressive behavior), and total problems score. Moreover, the CBCL includes a classification system made up of three categories (normal, borderline, and clinical ranges). High *T* scores reflect the presence of problem behaviors. Both versions of the Achenbach CBCL are based on a careful review of the literature and empirical studies. Test–retest reliabilities and the majority of the internal consistency reliabilities were adequate to excellent for both the 1991 and 2001 CBCL scales used in this study. For the 1991 CBCL scales reported in this study, using a mean Pearson *r,* test–retest reliabilities ranged from .82 to .95, and internal consistency reliabilities (coefficient alphas) for males ranged from .62 to .96 and for females ranged from .66 to .96 (Achenbach, 1991). For the 2001 CBCL scales reported in this study, using the Pearson *r,* test–retest reliabilities ranged from .82 to .94 and internal consistency reliabilities (coefficient alphas) ranged from .82 to .97 (Achenbach & Rescorla, 2001). For both versions of the CBCL (Achenbach, 1991; Achenbach & Rescorla, 2001), content validity, criterion-related validity, and construct validity were studied extensively with one of the key findings being that both of these measures discriminate significantly between children who are referred for evaluation and those who are not referred.

Data Analysis

Descriptive statistics (e.g., means, standard deviations) were used to summarize the sociodemographic profile of the study population and outcomes from the SSP and CBCL. Because the data met the assumptions for the use of parametric statistics, the Pearson *r* correlation coefficient was used to address Hypothesis 1 regarding the linear associations between sensory processing and functional behaviors, and *t* tests were used to compare mean outcomes between the two groups. The chi-square and the Fisher exact tests were used to test for significant contrasts in proportions between groups for the test classification categories. The alpha level was set at $p \leq .05$. Because of the increased risk of Type I errors with

multiple comparisons, specific hypotheses were declared a priori. The *p* values across the CBCL and SSP subtests should be interpreted with caution and regarded as exploratory.

Results

Child Demographic and Child Development Information

Forty-four children met the study's inclusion criteria. A summary of the sociodemographic and clinical profiles of the study population is presented in Table 1. The diagnostic classifications of these 44 children spanned the full continuum under the umbrella of FASD. Eighteen children reportedly had concomitant mental health or psychiatric diagnoses, including oppositional defiant disorder (n = 6), posttraumatic stress disorder (n = 5), adjustment disorder (n = 4), conduct disorder (n = 2), and bipolar disorder (n = 1). In addition, 23 children were reported to have a diagnosis of attention deficit disorder (ADD) or attention deficit/hyperactivity disorder (ADHD).

Analyses confirmed that the 44 children included in the study population were a representative subset of all 205 children (5–10 years of age) who received a FASD diagnosis at a FAS DPN clinic since 2000. They were comparable across all variables presented in Table 1. Of the 205 children in the target population, only 44 had both a CBCL and an SSP administered. The primary reason a child did not receive a CBCL or SSP was because he or she was seen at a clinic site that did not routinely administer that assessment. The CBCL and SSP are most routinely administered at the University of Washington FAS DPN clinic site.

Because the effects of multiple home placements and short time durations in foster placement or with current caregivers were factors that also could negatively affect behavioral outcomes in this sample of children, these factors were further examined in a post hoc analysis. Findings revealed no significant correlations between the number of home placements or the duration of home placements and behavioral problems.

Table 1. Child Demographic and Development Information Gathered at Time of FASD Diagnostic Evaluation

	Children With FASD	
Variables	*n*	%
Age (years, months) at time of diagnosis (*n* = 44)		
5,0 through 6,11	14	31.8
7,0 through 8,11	17	38.6
9,0 through 10,11	13	29.5
Gender (*n* = 44)		
Male	30	68.2

Note. The sample sizes vary because data were not available for all variables for all children. Summed percentages may not equal 100 because of rounding error. FASD = fetal alcohol spectrum disorders; FAS = fetal alcohol syndrome.

SSP and CBCL Profiles

The distributions of outcomes for the SSP and the Achenbach CBCL, as reported by the primary caregivers for children with FASD, are presented in Tables 2 and 3.

Correlation Between the SSP and CBCL: Hypothesis 1

A statistically significant negative correlation between SSP and CBCL total scores (r = –.72, $p \leq .05$) was found. The relationship is a negative correlation because as the SSP total score becomes lower (indicating more sensory-processing difficulties), the CBCL score becomes higher (indicating more problem behaviors).

Associations Between Clinical Categorizations of the SSP and CBCL

Hypothesis 2. As hypothesized, relative to children with SSP total scores in the typical performance range, children with SSP total scores in the definite or probable difference clinical range had significantly higher mean *T* scores for the CBCL total problems score, externalizing problem score, and

Note. FASD = fetal alcohol spectrum disorders.

two syndrome scale scores (attention problems and social problems). In addition, significant differences were found for the syndrome scale scores of rule-breaking behavior and thought problems (Table 4).

Hypothesis 3. Relative to children with normal CBCL total scores, children with clinical or borderline CBCL total scores had significantly lower mean scores for the SSP total score, underresponsive/seeks sensation section score, and auditory filtering section score (Table 5).

Concordance Between CBCL and SSP Category Classifications: Hypothesis 4

Table 6 presents percentages of children falling into each test category. Thirty-seven of the children in this sample (84%) demonstrated deficits in both sensory processing (definite or probable) and problem behaviors (clinical or borderline) on the CBCL. Only 2 children demonstrated no problems on either measure. Children who demonstrated deficits in sensory-processing abilities appeared more likely to also demonstrate problem behaviors. Several analyses document this concordance. When the three clinical classification groups were maintained, a significant linear-by-linear trend was observed ($\chi^2[1, N = 44] = 8.8$, $p = .003$). Because of the small sample size, some cells had expected counts less than five. When the SSP categories of "definite" and "probable" and the CBCL categories of "clinical" and "borderline" were combined to overcome the small expected cell counts, a near significant association between SSP and CBCL outcomes was observed (Fisher exact test, $p = .057$).

Discussion

This study supports previous findings indicating that sensory-processing dysfunction and problem behaviors co-occur in children with FASD (Jirikowic, Olson, et al., in press; Morse et al., 1995). A high percentage of children in this sample demonstrated both problem behaviors and sensory-processing deficits as indicated by caregiver report. Children who were

classified in clinically concerning categories on measures of sensory processing or problem behaviors also showed significant differences in specific sensory or behavioral test domains when compared with children in normal classification categories on either measure. A statistically significant correlation between SSP and CBCL total scores ($r = -.72$) was found, indicating that children with FASD who demonstrated sensory-processing deficits were more likely to demonstrate functional behavioral deficits.

The behavioral problems in children with FASD who demonstrated sensory-processing deficits were consistent with those described in previous sensory-processing literature (Ayres, 1972, 1979; Bundy, Lane, & Murray, 2002; Livingston, 1978), as well as those described in other studies on children affected by prenatal alcohol exposure (Jirikowic, Kartin, & Olson, in press; Mattson & Riley, 2000; Whaley et al., 2001). Children with FASD who demonstrated sensory-processing deficits demonstrated significantly more externalizing behavior problems and problems in the specific domains of socialization, attention, rule breaking, and thought problems. More specifically, findings parallel those of Miller, Reisman, McIntosh, and Simon (2001), who compared 46 typically developing children (ages 3 to 13 years) with 32 children with sensory modulation dysfunction (ages 3 to 9 years). They found that children with sensory modulation dysfunction, as measured by the SSP, demonstrated more thought problems, aggressive behaviors, social problems, and attention problems as measured by the CBCL.

Normal	1 (3.1%)	1 (14.3%)	2 (40.0%)

Note. SSP = Short Sensory Profile; CBCL = Child Behavior Checklist.

Although aggressive behaviors were reported by Miller and colleagues (2001) in children with sensory modulation disorder, as well as by Mattson and Riley (2000) in children with prenatal alcohol exposure, in the current study, significant differences were not found for this domain. However, trends were in the hypothesized direction.

Moreover, results indicated that children with behavioral problems also demonstrated significant differences in their abilities to process sensory stimuli as measured by caregiver report. Children who had impairments in behavior also had specific difficulty processing auditory stimuli and difficulty modulating sensory input from their surroundings as indicated by more sensation-seeking behaviors or underresponsiveness to environmental stimuli. However, the hypothesis that children with impairments in behavior would also have difficulty with tactile, visual/auditory, and movement sensitivities was not supported. These findings suggest that deficits in sensory modulation and auditory processing may result in an increased prevalence of behavioral impairments because of poor adaptive behavioral responses.

Because the majority of children (84%) demonstrating impairments in behaviors also displayed sensory-processing deficits, this study supports the notion that deficits with sensory modulation interfere with the child's abilities to demonstrate adaptive behavioral responses, leading to problem behaviors or impairments in behavioral regulation (Dunn, 1999). The strong correlation between sensory-processing impairments and behavioral problems further supports this relationship. Although concordance between those in clinically concerning categories on the both the CBCL and the SSP only approached significance statistically, possibly because of small numbers in some cells resulting in a reduction of power, the trend was in the hypothesized direction.

Finally, it is of note that children in this study also had a high prevalence of reported mental health and psychiatric diagnoses. Comorbid psychiatric conditions, such as ADD and ADHD or anxiety, mood, conduct, and explosive disorders, also have been reported in previous studies of people with prenatal alcohol exposure (Brown et al., 1991; Coles, 2001; O'Malley & Nanson, 2002). Symptoms associated with prenatal alcohol exposure, sensory-processing deficits, and mental health or psychiatric disorders warrant further exploration in terms of discerning their specific or collective impact on functional behaviors. Further research is warranted to examine the possible effects of other environmental factors (e.g., abuse, neglect) that may influence the relationship between sensory-processing impairments and functional behaviors.

Clinical Implications

This study supports the idea that a link exists between deficits in sensory processing and deficits in problem behaviors in children with FASD. Therefore, occupational therapists working with children with FASD should consider addressing sensory-processing concerns, both in the evaluation process and during intervention. The possibility of decreasing problem behaviors with sensory-based interventions and environmental modifications needs to be considered when serving a child with FASD. Perhaps occupational therapists could intervene for a child with FASD by adapting environments and educating care providers and teachers on how the child's responses to sensory stimuli may negatively influence the child's behavior.

Limitations

The following potential limitations of this study should be considered. First, the study sample was drawn from a clinical population of people referred for diagnostic evaluation. Thus, participants do not necessarily represent all people with FASD. Second, the sample was small, limiting power in some of the analyses, and the possibility of a Type I error is increased for analyses involving multiple comparisons. Third, the SSP and CBCL are standardized measures based on caregiver report. Outcomes can vary depending on which caregiver completes the report.

Direction for Future Research

Further studies should explore and clarify the relationship between sensory processing and problem behaviors in children with FASD. For example, the same hypothesis could be explored using a larger, more diverse sample of children, which would allow examination of subgroups within the population of children with FASD, such as those also diagnosed with ADHD. Gaining a better understanding of the impact prenatal alcohol exposure has on a child's ability to process and respond to sensory stimuli in his or her environment and how this relates to the child's behavioral responses to the environment is an important step in understanding this population of children. With an improved understanding of sensory processing in children with FASD, early intervention and support services could be implemented to assist with problem behaviors, potentially preventing secondary disabilities.

The relationship between problem behaviors and sensory-processing deficits in children with FASD identifies a need for research focused on the effectiveness of interventions for sensory-processing dysfunction and behavioral problems. Future results may help therapists, educators, and caregivers better understand and accommodate these children within their homes, schools, and communities.

Conclusion

Results of this study support previous research that children with FASD demonstrate significant impairments in problem behaviors (Jirikowic, Kartin, et al., in press; Mattson & Riley, 2000) and sensory processing (Jirikowic, Olson, et al., in press; Morse et al., 1995), as reported by parents. Findings further strengthen the idea that deficits in sensory processing co-occur with problem behaviors at a high rate in this population. Deficits in sensory processing, which may contribute to a range of behavioral problems, may thus affect the ability of children with FASD to demonstrate adaptive responses to their environments. ▲

Acknowledgments

We express our deepest gratitude to all the people who supported this endeavor and to the families and children who continue to be our teachers. This work was facilitated, in part, through support from the Center on Human Development and Disability (National Institute of Child Health and Human Development) and the Washington State FAS DPN (Division of Alcohol and Substance Abuse, Department of Social and Health Services).

ABSTRACT

Background
Clinical and research advancements in the field of fetal alcohol spectrum disorders (FASD) require accurate and valid identification of FASD clinical subgroups.

Objectives
A comprehensive neuropsychological battery, coupled with magnetic resonance imaging, (MRI), MR spectroscopy (MRS), and functional MRI (fMRI) were administered to children with fetal alcohol spectrum disorders (FASD) to determine if global and/or focal abnormalities could be identified across the spectrum, and distinguish diagnostic subclassifications within the spectrum. The neuropsychological outcomes of the comprehensive neuroimaging study are presented here.

Methods
The study groups included: 1) FAS/Partial FAS; 2) Static Encephalopathy/Alcohol Exposed (SE/AE); 3) Neurobehavioral Disorder/Alcohol Exposed (ND/AE) as diagnosed by an interdisciplinary team using the FASD 4-Digit Code; and 4) healthy peers with no prenatal alcohol. A standardized neuropsychological battery was administered to each child and their primary caregiver by a psychologist.

Results
Use of the 4-Digit Code produced three clinically and statistically distinct FASD clinical subgroups. The three subgroups (ND/AE, SE/AE and FAS/PFAS) reflected a linear continuum of increasing neuropsychological impairment and physical abnormality, representing the full continuum of FASD. Behavioral and psychiatric disorders were comparably prevalent across the three FASD groups, and significantly more prevalent than among the Controls. All three FASD subgroups had comparably high levels of prenatal alcohol exposure.

Conclusions
Although ND/AE, SE/AE, and FAS/PFAS are distinct FASD subgroups, these groups are not distinguishable solely by their neuropsychological profiles. While all children within a group shared the same *magnitude* of neuropsychological impairment, the patterns of impairment showed considerable individual variability. MRI, MRS and fMRI further distinguished these FASD subgroups.

Key Words: *Fetal alcohol spectrum disorder (FASD), magnetic resonance (MR), FASD 4-Digit Diagnostic Code, neuropsychological*

While the focus of this report is to assess the neuropsychological, behavioral, and physical features that distinguish three FASD clinical subgroups, these data are the product of a larger, recently completed magnetic resonance imaging (MRI) (submitted for publication), MR spectroscopy (MRS)[1], and functional MRI (fMRI)[2] study of children with FASD. The key objective of the neuroimaging study was to determine if brain abnormalities could be detected between clinical subgroups along the full continuum of FASD. To conduct such a study, one must be able to *establish* distinct FASD clinical subgroups, empirically *confirm* they are distinct, and specifically *describe* how they are distinct. To establish these groups, the FASD 4-Digit Diagnostic Code[2] was employed. Thus, the primary question, and focus of this report—Were three distinct FASD subgroups successfully established, and how are they distinct? The establishment of these distinct groups was integral to the design and interpretation of the separately reported MRI, MRS, and fMRI components of this study. Presented below is the clinical rationale for the larger neuroimaging study and the essential role of this neuropsychological component.

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal alcohol consumption during pregnancy. FAS is defined by growth deficiency, a unique cluster of minor facial anomalies, and central nervous system (CNS) dysfunction and/or structural brain abnormalities.[4] Not all individuals with prenatal alcohol exposure present with CNS abnormalities, and not all who present with CNS abnormalities have FAS. Recently, the term FASD was coined to depict the full spectrum of outcomes observed among individuals with prenatal alcohol exposure. FASD is not a medical diagnosis. Rather, medical diagnoses like FAS, Partial FAS, Static Encephalopathy/Alcohol Exposed (SE/AE), Neurobehavioral Disorder/Alcohol Exposed (ND/AE), Alcohol Related Neurodevelopmental Disorder (ARND)[3,5,6] fall under the umbrella of FASD.

The degree of brain damage among individuals with prenatal alcohol exposure may vary from microcellular and neurochemical aberrations to gross structural anomalies. Similarly, neuropsychological/behavioral dysfunction varies along the full continuum from mild developmental delay or learning disabilities to global developmental disability.

The neuropsychological/behavioral problems in this condition *stem from* the prenatal brain damage. The specificity of the FAS facial phenotype to prenatal alcohol exposure lends credence to the clinical judgment that the neuropsychological and behavioral dysfunction observed in individuals with FAS is due, at least in part, to brain damage caused by prenatal alcohol exposure.[7-9] Unfortunately without the unique facial phenotype of FAS or at least a severe or clinically obvious expression of brain damage, the neurodevelopmental disabilities of an individual with prenatal alcohol exposure often go unrecognized and inappropriately served.[10]

Many individuals with prenatal alcohol exposure exhibit cognitive difficulties and significant maladaptation that prevent them from leading productive, independent lives.[11,12] Prior literature finds that regardless of overall intellectual level, most individuals show a range of identifiable cognitive deficits—at a rate greater than that expected given their IQ.[13] Executive functioning deficits have consistently been identified.[14-17] Deficiencies in attention are often viewed as hallmark features of prenatal alcohol exposure.[18] Deficits in complex visual-spatial skills, learning and memory, and a high prevalence and wide variety of speech/language deficits have been documented.[19] Difficulties in adaptive behavior have consistently been noted [10, 20-22] and risk of increased psychiatric disorders.[12] The profile of cognitive dysfunction among these individuals is highly variable, though there are some commonalities in functional compromise among subgroups, and conceptual models of overarching deficits have been proposed.[23] However, no single behavioral phenotype specific to alcohol teratogenicity has been described. Without a specific behavioral phenotype, attributing an alcohol-exposed child's dysfunction to brain damage is often questionable at a clinical level.[9] If indisputable evidence of brain damage (e.g., alterations in neurostructure, neurometabolites, and/or neuroactivation) could be found in alcohol-exposed individuals who present with neuropsychological deficits, but no

physical features of FAS, the "disability" of these individuals would be more clearly established, and could help them qualify for needed services.

MRI, MRS, and fMRI offer non-invasive methods for in vivo assessment of neuroabnormalities. An extensive FASD MRI research literature exists.[24-27] A few FASD studies utilizing fMRI and MRS have also been published.[28-30] In general, many of these FASD neuroimaging studies have found evidence of brain alterations among individuals with full FAS, regardless of FASD diagnostic system used, but have not always found clear evidence of brain alterations among nondysmorphic FASD subgroups. The majority of FASD neuroimaging studies have enrolled study groups diagnosed or classified as FAS, Fetal Alcohol Effects (FAE), Alcohol Related Neurodevelopmental Disorders (ARND), or Prenatal Alcohol Exposed (PEA) prior to the establishment of comprehensive, case-defined FASD diagnostic guidelines that are quickly becoming best practice.[3,5,6] The specific diagnostic criteria used to establish the FASD study groups (e.g., level of growth deficiency; type, number and severity of facial anomalies; breadth and magnitude of neuropsychological deficit; type of neurostructural anomaly present), were typically not reported. Absence of rigorous diagnostic methods can lead to diagnostic misclassification and obscure distinctions between FASD subgroups. Astley and Clarren[31] and Hoyme et al[32] have both confirmed, using two large clinical datasets, that the majority of individuals diagnosed with FAS by a gestalt approach lose that diagnostic classification when more rigorous diagnostic guidelines are applied. Misclassification error impacts study validity and reduces the power of a study to detect clinically meaningful differences between FASD subgroups.[33] If specific diagnostic features that define the FASD study groups are not reported, this limits the ability to compare outcomes across studies.

The recently completed MRI (submitted for publication), MRS[1], and fMRI[2] study was designed to overcome these limitations by using a comprehensive, case-defined diagnostic system. For this study, the FASD 4-Digit Diagnostic Code was used to establish three distinct FASD clinical subgroups (FAS/PFAS, SE/AE, and ND/AE). The focus of this report is to confirm and describe how these three FASD subgroups are clinically distinct. In describing these three clinically distinct groups, their complex neuropsychological, behavioral, and psychiatric profiles are revealed. This information is integral to the design and interpretation of the separately reported MRI, MRS[1], and fMRI[2] components of this study.

METHODS

Subjects and Study Groups

The protocol was approved by the University of Washington Human Subjects Review Board. The three FASD groups were selected from among 1,200 patients previously diagnosed by an interdisciplinary team in the WA State FAS Diagnostic & Prevention Network (FAS DPN) of clinics using a practical, comprehensive diagnostic system called the FASD 4-Digit Code.[3] Briefly, the 4 digits of the FASD 4-Digit Code[3,31] reflect the magnitude of expression of the 4 key diagnostic features of FASD, in the following order:

1. growth deficiency,
2. FAS facial phenotype,
3. CNS structural/functional abnormalities, and
4. prenatal alcohol exposure (Figure 1).

The magnitude of expression of each feature is ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong "classic" presence of the FASD feature. Each Likert rank is specifically case defined. There are 256 possible 4-digit diagnostic codes, ranging from 1111 to 4444. Each 4-digit diagnostic code falls into 1 of 22 unique clinical diagnostic categories (labeled A through V). Seven of the 22 diagnostic categories (4-Digit Categories A–C and E–H) fall broadly under the designation of FASD (A. FAS/Alcohol Exposed, B. FAS/Alcohol Exposure Unknown, C. Partial FAS/Alcohol Exposed, E-F. Static Encephalopathy/Alcohol Exposed, and G-H. Neurobehavioral Disorder/Alcohol Exposed). The three FASD study groups in this neuroimaging study represent these FASD diagnostic categories. This diagnostic system is currently being used by a wide variety of diagnostic teams in the USA and other countries.

The control population for this study was selected primarily from a large cohort of children

enrolled at birth in a University of Washington study of typical development conducted through the Department of Speech and Hearing Sciences. This registry has been maintained over the years to serve as a source of healthy controls for studies throughout the University. With the enrollment of each child in the FAS/PFAS group, a child matched on age (within 6 months), gender, and race was randomly identified and invited to enroll from the eligible SE/AE, ND/AE and Control populations. The enrollment goal was 80 subjects (20 per group).

The study enrollment procedure produced a sample of 81 children of diverse ethnicity, though with 60% Caucasian (Table 1). The age range (8 to 15.9 years) included the broadest age range of children that could be administered a comparable psychometric assessment battery and be reasonably capable of participating in the MR scanning. Each of the four study groups had 16-24 subjects successfully balanced on age, gender, and race. The 61 children with FASD were highly representative of the entire clinic sample of 1,200 from which they were drawn.

The diagnostic features specific to each group were as follows:

1. *Children in Group 1* had a 4-Digit diagnosis of **FAS or Partial FAS (FAS/PFAS)** (e.g., 4-Digit Diagnostic Categories A,B,C: with Growth Ranks 1-4, Face Ranks 3-4, CNS Ranks 3 and/or 4, Alcohol Ranks 2-4) (Figure 1). Alcohol Rank 2 (unknown exposure) could only be present if the child had a diagnosis of full FAS because the Rank 4 FAS facial features are so specific to prenatal alcohol exposure.[8,34] Since the only clinical difference between FAS and PFAS in this study was the presence of growth deficiency in the former, the two groups were combined. In summary, children in Group 1 had severe cognitive/behavioral dysfunction and the FAS facial phenotype.

2. *Children in Group 2* had a 4-Digit diagnosis of **Static Encephalopathy / Alcohol Exposed (SE/AE)** (e.g., 4-Digit Diagnostic Categories E,F: with Growth Ranks 1-4, Face Ranks 1-2, CNS Ranks 3 and/or 4, Alcohol Ranks 3-4). In summary, children in Group 2 had severe cognitive/behavioral dysfunction, comparable to Group 1, but did not have the FAS facial phenotype.

3. *Children in Group 3* had a 4-Digit diagnosis of **Neurobehavioral Disorder / Alcohol Exposed (ND/AE)** (e.g. 4-Digit Diagnostic Categories G, H: with Growth Ranks 1-4, Face Ranks 1-2, CNS Rank 2, Alcohol Ranks 3-4). In summary, children in Group 3 had prenatal alcohol exposure comparable to Groups 1 and 2, but in comparison to Groups 1 and 2 had only mild to moderate cognitive/behavioral dysfunction, and did not have the FAS facial phenotype.

4. *Children in Group 4* (**Healthy Controls / No Alcohol Exposure**) were selected based on parental report that the child was healthy, had no academic concerns, and no prenatal alcohol exposure (e.g., 4-Digit Diagnostic Category V: with Growth Ranks 1-2, FAS Face Ranks (no restrictions), CNS Rank 1, Alcohol Rank 1). In summary, these were non-exposed, healthy, average to high-functioning controls.

Using the FASD terminology introduced by the Stratton et al[11], the SE/AE group most closely reflects 'severe ARND' and the ND/AE group most closely reflects 'mild ARND'.

Abbreviations: Chi^2: chi-square test across the four study groups, unless otherwise specified. Duncan: The Duncan multiple comparison range test is reported if the overall ANOVA is statistically significant; commas separate groups with homogeneous means at $p < 0.05$. F: F statistic. FAS/PFAS: FAS/partial FAS. L: left. LT: ANOVA unweighted linear trend. ND/AE: Neurodevelopmental Disorder/Alcohol Exposed. OFC: occipital frontal circumference. Overall: Overall assessment of between-group means using ANOVA. p: p-value. PFL: palpebral fissure length. R: right. SD: standard deviation. SE/AE: Static Encephalopathy/Alcohol Exposed. Unk: unknown. Z-score: number of standard deviations above/below the population-based mean. $: United States dollars.

Notations: A. Six of the 20 subjects in the FAS/PFAS group had full FAS using the 4-Digit Code. Ten of the 14 PFAS had Rank 4 Faces, but received a diagnosis of PFAS because they had no growth deficiency (Growth Rank 1). B. Two subjects had agenesis (PFAS) or hypogenesis (FAS) of the corpus callosum. C. Between groups degrees of freedom = 3; within groups df = total sample size minus 4. D. Between groups linear term degrees of freedom = 1; within groups df = total sample size minus 4. E. Caucasian versus not Caucasian. F. No growth deficiency versus mild to severe growth deficiency. G. All 4 subjects with Rank 3 faces had palpebral fissure lengths more than 2 SDs below the norm. The philtrum-lip Ranks for each subject were 3-4, 3-4, 5-3, and 4-3. H. Definition of Rank 4 FAS Face: palpebral fissure lengths 2 or more SDs below the norm, and lip and philtrum are Rank 4 or 5 on Lip-Philtrum Guide [3]. I. No child had hypo-or hypertelorism that could impact the validity of the D-score. J. All 3 children with moderate functional impairment had structural evidence of brain abnormality (microcephaly). K. Chi-square for FAS/PFAS versus SE/AE (7.1, p = .008). L. Chi-square for FAS/PFAS versus SE/AE (9.6, p = .002). M. The one child with unknown prenatal alcohol exposure had full FAS. N. The 4 digits represent the rank for growth, face, brain and alcohol, in that order [3].

Can J Clin Pharmacol Vol 16 (1) Winter 2009:e178-e201; March 27, 2009

Study Participation
Participation in the study involved five visits over a 4 to 6 week study period. The neuropsychological and sociodemographic data were collected during visits 1 and 2. The neuroimaging data were collected during visits 3 and 4. The outcomes of the neuropsychological assessments were shared with the caregivers on visit 5, and submitted to the child's medical record with caregiver consent.

Sociodemographic and Clinical Assessment
A comprehensive sociodemographic and health/medication history of each child was obtained by parent interview and record review. Information included birth data, growth, and all prenatal and lifetime exposures and adverse events. For subjects with FASD, most information was obtained at the time of their FASD diagnostic evaluation. The following measures of maternal alcohol consumption were collected retrospectively, with a focus on two time points (just before pregnancy and during pregnancy): a) average and maximum number of drinks per drinking occasion, b) average number of drinking days per week, c) type of alcohol consumed (beer, wine, liquor), and d) trimester(s) during which drinking occurred. Although presence or absence of prenatal alcohol exposure was reliably documented for all subjects; more detailed information such as quantity, frequency, and duration of use was only available on 53 of the 65 alcohol-exposed subjects. This is not atypical, as accurate, detailed alcohol histories are frequently unavailable on patients presenting to a FASD diagnostic clinic. All controls had a reported absence of prenatal alcohol exposure per birth mother report.

All children had a standardized digital facial photograph taken at the time of enrollment. The facial photographs were analyzed using the FAS Facial Analysis Software[35] to generate two measures of the magnitude of expression of the FAS facial phenotype: 1) the ordinal 4-Digit Code Facial Rank (1 to 4) and 2) the continuous FAS facial D-score.[7] The D-score documents the severity of the FAS facial phenotype on a continuous scale. The higher the D-score, the more FAS-like the facial features. A D-score ≥ 0.8 is equivalent to a Rank 4 FAS facial phenotype.[7]

Neuropsychological / Psychiatric Assessments
A comprehensive, standardized assessment battery was administered to each child and their primary caregiver by a psychologist masked to group assignment (Table 2). Based on an extensive review of the prior literature, the assessment battery was designed to capture the domains of potential neuropsychological deficit seen as the result of the typically diffuse brain damage arising from alcohol teratogenesis.[5,6,23,36-39]

Magnetic Resonance Evaluation
The MRI, MRS, and fMRI components of this study are reported separately.[1,2] Briefly, all scans were acquired using a General Electric 1.5 Tesla scanner in the Diagnostic Imaging Sciences Center (DISC) at the University of Washington. MRI was used to measure the size of the following structures: total brain, frontal lobe, caudate, hippocampus, putamen; corpus callosum, and cerebellar vermis.

MRS[1] was used to measure the concentrations of neurometabolites including:

1. choline, a marker of cell membrane stability and myelination,
2. N-acetyl aspartate, a neuronal or axonal marker, and
3. creatine, a marker of metabolic activity;

in three brain regions (frontal/parietal white matter, hippocampus, and an axial slice at the level of the thalamus).

fMRI[2] was used to assess neuroactivation in seven brain regions (anterior cingulate; anterior and posterior parietal lobe; and the dorsolateral prefrontal, inferior frontal, middle frontal, and precentral regions of the frontal lobe) during performance of N-back working memory tasks. A brief summary of findings from the MRI, MRS and fMRI portions of the study is presented in the Discussion section, with citations for readers interested in further detail.

Predicted FASD Subgroup Contrasts

The following clinical distinctions should exist between the subgroups enrolled in this study based on: 1) the use of the FASD 4-Digit Code[3] to classify each alcohol-exposed child into one of three FASD clinical subgroups (FAS/PFAS, SE/AE, and ND/AE), and 2) prior studies assessing the performance of the 4-Digit Code.[7,31]

Growth: The FAS/PFAS group should have the highest prevalence of growth deficiency.

Face: The magnitude of expression of the FAS facial phenotype should be greatest in the FAS/PFAS group, but will also increase linearly as one progresses from Controls to FAS/PFAS.

CNS: Structural Abnormality. Head circumference should be smallest in the FAS/PFAS group, but will also decrease linearly as one progresses from the Control group to the FAS/PFAS group.

CNS: Magnitude of Neuropsychological Impairment. The FAS/PFAS and SE/AE groups should be comparably impaired, and significantly more impaired than the ND/AE and Control groups. The ND/AE group should be significantly less impaired than the FAS/PFAS and SE/AE groups and significantly more impaired than the Control group.

It is important to point out that the 4-Digit Code criteria used to rank brain dysfunction (CNS Rank 1: no dysfunction; Rank 2: moderate dysfunction; Rank 3: severe dysfunction) focus strictly on *magnitude* of dysfunction, not *pattern* of dysfunction. For example, a Rank 3 classification is defined by the presence of three or more domains of brain function, two or more standard deviations below the population mean. The diagnostic criteria do not specify *which* domains of function must be impaired. It is also important to note that the diagnostic criteria for FAS/PFAS, SE/AE, and ND/AE do not specify how much prenatal alcohol exposure must be reported. This follows a basic epidemiologic tenet; exposures and outcomes should be documented independently to validly assess the relationship(s) between the two. Thus the pattern of neuropsychological dysfunction and level of prenatal alcohol exposure will vary independent of the diagnostic criteria imposed on the FASD subgroups.

Statistical Analyses

Descriptive statistics (means, SDs, proportions) were used to summarize the sociodemographic and clinical profiles of the four study groups (Tables 1, 3, 4). For comparisons between groups, chi-square was used for categorical variables and ANOVA was used for continuous variables. When ANOVA was employed, the overall f- statistic was used to test if differences existed among the four group means. When the overall f-statistic was statistically significant, the Duncan post hoc range test was used to identify which group means differed. The Duncan test makes pairwise comparisons using a stepwise procedure. Means are ordered from highest to lowest, and extreme differences are tested first. The Duncan test sets a protection level for the error rate for the collection of tests. The Duncan test identifies homogeneous subsets of means that are not different from one another. An a priori test for linear trend was included in the ANOVA to determine if performance on the neuropsychological assessments (mean standardized score) became increasingly more impaired progressing across the four study groups from Control, to ND/AE, to SE/AE, to FAS/PFAS. This trend would be anticipated based on the 4-Digit Code diagnostic criteria. Two-tailed p-values of 0.05 were used throughout the analyses. Due to multiple comparison, p-values should be interpreted accordingly.[40,41] This study had 80% power or greater to detect the following effect sizes at a two-tailed alpha level of 0.05; 1) A difference in means equal to or greater than the standard deviation of the mean difference; 2) A 35-point or greater difference in proportions between two groups.

RESULTS

The 4-Digit Code produced four clinically and statistically distinct study groups. The three FASD clinical subgroups reflect a linear continuum of increasing neuropsychological deficit and physical abnormality (e.g., growth deficiency and FAS facial features) across the full continuum of FASD (Tables 1, 3, and 4). All three FASD subgroups had comparably high levels of prenatal alcohol exposure.

Group Differences in Key FASD Diagnostic Features (growth, face, CNS, alcohol)

Growth

The prevalence and severity of growth deficiency generally increased as one advanced across the four study groups from Controls to FAS/PFAS (Table 1). Height was more impaired than weight.

Face

The FASD Facial D-Score revealed that the magnitude of the FAS facial phenotype increased linearly across the four study groups demonstrating that the FAS facial phenotype is not simply present or absent (Table 1). This was further illustrated by the Duncan post hoc group comparisons. The magnitude of expression of the FAS facial phenotype was significantly highest among the FAS/PFAS group. The magnitude of expression was significantly lower in the SE/AE and ND/AE groups relative to the FAS/PFAS group, but significantly higher than the Control group. It is also interesting to note that although the 4-Digit Code criteria for the FAS facial phenotype requires the palpebral fissure length (PFL) to be 2 or more standard deviations below the population mean, the mean PFL for the FAS/PFAS group is 3 SD's below the mean.

CNS

By design, all subjects in the control group were without evidence of central nervous system dysfunction (CNS Rank 1). However, all those in the ND/AE group had mild to moderate dysfunction (CNS Rank 2) and all subjects in the SE/AE and FAS/PFAS groups had evidence of severe CNS dysfunction / damage (CNS Ranks 3 and 4) (Table 1). Severe dysfunction (CNS Rank 3) is defined by the presence of three or more domains (e.g., cognition, executive function, language, memory, attention, etc.) of brain function, two or more standard deviations below the norm, as measured on standardized neuropsychological tests, administered and interpreted by professionals. A Rank 3 classification does NOT dictate which domains of function must be impaired. CNS Rank 4 signifies the presence of structural brain abnormalities or frank neurological abnormality as determined by a clinical neuroradiologist or neurologist. The CNS Rank 4 classifications in Table 1 reflect the Rank 4 classifications the children received at the time of their FASD diagnostic evaluation. They do not reflect the new findings from this neuroimaging study. Nineteen subjects with FASD (13 with FAS/PFAS and 6 with SE/AE) had a CNS Rank 4 classification at the time of their FASD diagnostic evaluation. These clinical abnormalities were known prior to their enrollment into the study. Of the 13 subjects with FAS/PFAS and CNS Rank 4: 11 had microcephaly, 1 had hypogenesis of the corpus callosum (HCC), and 1 had microcephaly, agenesis of the corpus callosum (ACC), and petit mal seizures. Of the 6 subjects with SE/AE and CNS Rank 4: 4 had microcephaly, 1 had a seizure disorder and 1 had an abnormal clinical MRI (heterotopias in the left temporal lobe as interpreted by a neuroradiologist).

Within our FASD participants, one subject with PFAS had agenesis of the corpus callosum (ACC) and one subject with FAS had hypogenesis of the corpus callosum (HCC). That these subjects had callosal abnormalities were known prior to study enrollment. Interestingly, these two subjects with ACC/HCC are the only documented cases of ACC/HCC in the 2,040 patients with prenatal alcohol exposure diagnosed to date at the WA State FAS DPN clinics. In a clinical database such as the FAS DPN, MRIs are typically only available when clinically indicated (e.g., evidence of neurological abnormalities). Therefore, only 204 (10%) of the 2,040 patients evaluated at the FAS DPN had a previous MRI evaluation summarized in their medical record and 76% of the 204 MRI evaluations were interpreted as normal by the patient's neuroradiologist. Although ACC/HCC has been observed in individuals with FASD[42], ACC/HCC is not specific to prenatal alcohol exposure. The prevalence of ACC among developmentally disabled populations is estimated to be 2-3 per 100.[43] Thus, a causal link between ACC/HCC and prenatal alcohol exposure in these two individuals should not be assumed; nor can it be ruled-out.

Alcohol

Of the 65 alcohol-exposed subjects, 64 had confirmed prenatal alcohol exposure and one with full FAS had an unknown exposure (Table 1). All controls had reported absence of prenatal alcohol exposure by birth mother report. More detailed information on quantity, frequency, and/or

trimester of alcohol use was available on 53 of the 65 alcohol-exposed subjects. Reported exposure ranged from 1 to 26 drinks per drinking occasion, 1 to 7 days per week, first trimester only to all three trimesters. The mean number of days per week of drinking during pregnancy (4 to 5 days), and the maximum number of drinks per drinking occasion during pregnancy (12 to 14 drinks) were statistically comparable across the three alcohol-exposed groups (Table 1). A significantly higher proportion of subjects reported drinking all three trimesters as one advanced from the Controls to ND/AE to SE/AE to FAS/PFAS.

Maternal use of illicit drugs during pregnancy was reportedly present in 45%, 58%, 67%, and 0% of the FAS/PFAS, SE/AE, ND/AE and Control groups respectively. Use of illicit drugs was not an exclusion criteria for enrollment into this study because of its very high co-occurrence with prenatal alcohol exposure. Over 70% of the Washington State FAS DPN diagnostic clinic population has documented prenatal exposure to illicit drugs. The three FASD groups were also significantly more likely than the Control group to have other risk factors, in addition to prenatal alcohol exposure, that could adversely impact their growth and development (Table 1).

Group Differences in Neuropsychological, Behavioral and Psychiatric Outcomes

Key neuropsychological, behavioral, and psychiatric outcomes across the four study groups are presented in Tables 3 and 4. Table 3 presents mean scores on each measure for each group, reported as standard scores (or scaling appropriate for the instrument; e.g., T-scores on the CVLT-C). Table 4 presents the proportion of subjects within each group who performed in the impaired range on each measure. The "impaired range" was defined as 2 or more standard deviations below the age-appropriate population mean.

Group Mean Differences

Performance did not vary significantly with age, gender, or race. Inclusion of these covariates in between-group analyses confirmed they did not modify the outcomes. Mean performance on all assessments decreased significantly and incrementally as one advanced across the four groups from Controls, to ND/AE, to SE/AE, to FAS/PFAS (Table 3). As anticipated given the diagnostic criteria, multiple comparison tests confirmed that neuropsychological performance among the FAS/PFAS and SE/AE groups was comparably impaired—but significantly more impaired than the ND/AE and Control groups. The ND/AE group was almost always significantly less impaired than the FAS/PFAS and SE/AE groups, and significantly more impaired than the Control group on most standardized neuropsychological measures administered by the psychologists. However, the ND/AE group did not show significant differences from the Control group on direct testing measures of executive function. This was true even though caregiver report on measures of adaptation, behavior problems, and behavior rating inventory of executive functioning revealed comparable impairments in the ND/AE, SE/AE and FAS/PFAS groups, in the clinically significant range, with significantly more impairment than seen in the Control group. Psychiatric disorders were comparably prevalent across the three FASD groups, and significantly more prevalent than among the Controls. ADD/ADHD occurred most frequently. In interpreting these data, it is essential to remember that the subjects with FASD had originally sought help in a diagnostic clinic, so this high prevalence of psychiatric outcomes may not fully represent the population of all children with FASD.

The healthy, non-alcohol-exposed Control subjects showed significantly better performance on most measures when compared to the three FASD study groups. The mean full scale IQ of the healthy control group (123 + 7 SD) was higher than the population-based mean of 100 $\pm$ 15 SD. This was not surprising since children with prenatal and postnatal risk factors were screened out. Other population-based MRI and FASD-MRI studies enrolling healthy controls have reported mean full scale IQs ranging from 110 to 127.[44-46] Most FASD-MRI studies do not report the IQ or neuropsychological profile of their healthy control population. Interestingly, in spite of the Control group's relatively high IQ, many of their scores in the areas of memory, executive function, language, and adaptive behavior were, on average, solidly within normal limits compared to age peers. It is also interesting to note that the ND/AE group had a mean FSIQ (99.2 + 11.3 SD)

equivalent to the population-based mean, despite multiple prenatal/postnatal risk factors and parent-reported, significant adaptive/behavioral deficits.

Prevalence of Impairment

When the data are examined by looking at the prevalence of significant impairment on the various neuropsychological measures, compared across the diagnostic groups, a somewhat different picture emerges than that seen by comparison of group means alone (Table 4). For example, typically 20% to 50% of the children with FAS/PFAS performed significantly below the population mean in any single domain of function. A comparable prevalence of impairment was observed among the children in the SE/AE group. The prevalence was markedly less in the ND/AE group and essentially absent in the Control group. Of importance, the pattern of functional impairment varied among participants, even when they were in the same FASD subgroup diagnostic classification. While there was no consistent 'profile' of neuropsychological deficits, it was interesting to note that children with prenatal alcohol exposure (including those in the ND/AE group), had the greatest percentage of participants in the clinically impaired range on the following specific scores: Rey Complex Figure Test–Copy and Delayed Recall; the IVA Response Control Quotient; and the California Verbal Learning Test -Trial 1 Immediate Recall. Children with prenatal alcohol exposure were more likely to score in the impaired range on these tasks than on many of the more common executive function measures such as DKEFS, Tower Trail Making, Verbal Fluency, and/or Sorting Test- or the Wisconsin Card Sorting test.

Most children in the FASD groups had full scale IQs within or above the borderline range (standard score > 70), but adaptive function was well below that expected for their level of IQ (Table 4). Parent data from the Behavior Rating Inventory of Executive Function (BRIEF) questionnaire reflect that parents of alcohol-exposed children on average rate their children as falling in the range of clinical concern (>2 standard deviations from the population mean) on everyday tasks requiring executive functioning, in contrast to direct testing of executive functions on which many fewer children scored in the impaired range (90% of the children with FASD fell in the impaired range based on parent report, while only 34% were in the impaired range on the direct EF measure that had the highest percentage of impaired scores (D-KEFS:Trails).

DISCUSSION

Three clinically and statistically distinct FASD study groups were successfully established using a comprehensive diagnostic system. Use of the FASD 4-Digit Code revealed three FASD study groups (ND/AE, SE/AE and FAS/PFAS) that reflect a linear continuum of increasing neuropsychological impairment and physical abnormality (e.g., growth deficiency and FAS facial anomalies). This represents the full spectrum of FASD. Although ND/AE, SE/AE, and FAS/PFAS are distinct FASD subgroups, a central finding of this study is that they are not distinguishable solely by their neuropsychological profiles. While all children within a group shared the same *magnitude* of neuropsychological impairment, no two children necessarily shared the same *pattern* of impairment. The creation of these three distinct FASD subgroups played a vital role in the interpretation of the MRI, MRS[1], and fMRI[2] outcomes of this study. Concurrently, the MRI, MRS, and fMRI outcomes played a vital role in further confirming the three FASD subgroups were clinically distinct.

While the neuropsychological, behavioral, and psychiatric profiles of the current FASD group closely parallel those presented in the FASD literature[23,47], the FASD literature presents a somewhat mixed picture on whether significant neuropsychological differences exist between FASD subgroups with and without the physical features of FAS or between nondysmorphic FASD groups and healthy controls.[17,48,49] The current study found clear neuropsychological differences between these various groups. Most of the differences observed between FASD subgroups, however, would not have been identified if the SE/AE and ND/AE groups had been combined into one nondysmorphic FASD group (typically referred to as ARND, FAE, or PEA in other studies).

Findings from the larger neuroimaging study further confirmed the distinction between these three FASD subgroups, and the notion that children with FASD differ in important ways from healthy, non-alcohol-exposed peers. The larger neuroimaging study also served to further validate[7,8,31,34] the measurement scales and procedures for diagnostic classification used in the FASD 4-Digit Diagnostic Code. Data from the larger study revealed significant, neurostructural neurometabolite[1] and neuroactivation[2] differences between FASD diagnostic subgroups, and between nondysmorphic FASD subgroups and controls. For example MRI data from the larger study reveal that the frontal lobe was disproportionately smaller only in the FAS/PFAS group (the only group with the FAS facial phenotype as defined by the 4-Digit Code) (Figure 1B). The frontal lobe and FAS facial features share the same embryologic origin (the frontal nasal prominence.[50] The caudate was disproportionately smaller only in the FAS/PFAS and SE/AE groups (the only two groups with severe neuropsychological impairment). Neurostructural abnormalities were also observed in the ND/AE group. The prevalence of participants in the ND/AE, SE/AE and FAS/PFAS groups with one or more brain regions found to be 2 or more standard deviations below the mean size observed in the control group increased significantly and incrementally from 43% to 58% to 75%. In addition, the prevalence/severity of structural brain abnormality increased significantly as one progressed from CNS Rank 1 (no dysfunction) to Rank 2 (mild-moderate dysfunction) to Rank 3 (severe dysfunction). Indeed, when these CNS Ranks were first defined in 1997 [31] the underlying principle was that as the magnitude and breadth of functional impairment increased, the probability of underlying structural abnormality would increase. It is for this reason that the 4-Digit CNS Ranks 1, 2, and 3 were labeled “unlikely”, “possible”, and “probable” underlying CNS abnormality respectively (Figure 1A). MRS[1] data from the larger study reveal the choline concentration (a marker of cell membrane stability and myelination) in a frontal/parietal white matter region was significantly lower only in the FAS/PFAS group. Finally, fMRI[2] data reveal that neuroactivation during a difficult “2-back” working memory task decreased significantly and incrementally progressing across the four groups from Controls, to ND/AE, to SD/AE, to FAS/PFAS. These neuroimaging reports and previous studies[7,31] demonstrate that these subgroup differences would not have been identified if the SE/AE and ND/AE groups had been combined into one nondysmorphic FASD group, or if less rigorous diagnostic methods and

allowed the FAS/PFAS and SE/AE groups to be intermixed.

It is clear from the comprehensive neuroimaging study that MRI, MRS[1], and fMRI[2] can illuminate underlying brain abnormality across the full spectrum of FASD in new and important ways. What is learned about the teratogenic effects of alcohol on neurostructure, neurometabolites, and neuroactivation may help to clarify why individuals exposed to prenatal alcohol perform as they do on standardized neuropsychological measures. Certainly these neuroimaging technologies also provide convincing evidence that cognitive and behavioral deficits among those prenatally alcohol-exposed are, to an important extent, "brain-based." These physical findings validate the importance of detecting and diagnosing the medical condition (and developmental disability) of FASD so that medication and behavioral interventions can be appropriately employed

If we can improve our ability to physically identify the presence of CNS abnormality across the full spectrum of FASD, this may facilitate access to essential social and educational services for those with FASD. In truth, in the absence of definitive physical evidence of underlying organic CNS damage, it is often questioned whether individuals along the spectrum are really impacted by their prenatal exposure. As Stratton et al.[11] note in the landmark Institute of Medicine report, not all individuals with FASD meet eligibility criteria for educational, developmental disability or mental health services. This is because FAS, and especially ARND, are typically not recognized as diagnostic labels in many existing service systems. This is also because children with FASD often have neuropsychological profiles that do not make them eligible for the services they actually need. The deficit patterns of children with FASD are characterized by deficits across multiple domains, and IQ scores may not reflect their full range of deficits or extent of functional compromise. Children with FASD often do not receive test scores that are low enough to qualify for services until their later elementary school (or even middle school) years, so many do not qualify for intervention that occurs sufficiently early. Indeed, children with FASD may receive services targeting disruptive or antisocial behavior, rather than services that more appropriately address the complex cognitive and learning deficits that comprise the foundation for their behavioral difficulties and problems in adaptive function. The clinical literature suggests that these deficits have an increasingly debilitating effect as children move into the elementary school years and beyond, interfering with successful daily function.[51]

FIG. 1 A) FASD 4-Digit Diagnostic Code grid. FASD is defined by growth deficiency, specific FAS facial features, evidence of CNS damage and prenatal alcohol exposure. The 4-Digit Code ranks each of these areas on 4-point, case-defined, Likert scales. The 4-Digit Code (3444) inserted in the grid is 1 of 12 codes that meet the diagnostic criteria for FAS.[3] **B)** FASD 4-Digit Code FAS facial phenotype (view image). The Rank 4 FAS facial phenotype determined with the 4-Digit Diagnostic Code requires the presence of all 3 of the following anomalies: (1) palpebral fissure length 2 or more standard deviations below the norm; (2) smooth philtrum (Rank 4 or 5 on the Lip-Philtrum Guide), an (3) thin upper lip (Rank 4 or 5 on the Lip-Philtrum Guide). Examples of the full Rank 4 FAS facial phenotype for Caucasian, Native American, African American and Asian American children are shown.

Magnetic Resonance Imaging Outcomes From a Comprehensive Magnetic Resonance Study of Children With Fetal Alcohol Spectrum Disorders

Susan J. Astley, Elizabeth H. Aylward, Heather Carmichael Olson, Kimberly Kerns, Allison Brooks, Truman E. Coggins, Julian Davies, Susan Dorn, Beth Gendler, Tracy Jirikowic, Paul Kraegel, Kenneth Maravilla, and Todd Richards

Background: Magnetic resonance (MR) technology offers noninvasive methods for in vivo assessment of neuroabnormalities.

Methods: A comprehensive neuropsychological/psychiatric battery, coupled with MR imaging, (MRI), MR spectroscopy (MRS), and functional MRI (fMRI) assessments, were administered to children with fetal alcohol spectrum disorders (FASD) to determine if global and/or focal abnormalities could be identified, and distinguish diagnostic subclassifications across the spectrum. The 4 study groups included: (i) fetal alcohol syndrome (FAS)/partial FAS (PFAS); (ii) static encephalopathy/alcohol exposed (SE/AE); (iii) neurobehavioral disorder/alcohol exposed (ND/AE) as diagnosed with the FASD 4-Digit Code; and (iv) healthy peers with no prenatal alcohol exposure. Presented here are the MRI assessments that were used to compare the sizes of brain regions between the 4 groups. The neuropsychological/behavioral, MRS, and fMRI outcomes are reported separately.

Results: Progressing across the 4 study groups from Controls to ND/AE to SE/AE to FAS/PFAS, the mean absolute size of the total brain, frontal lobe, caudate, putamen, hippocampus, cerebellar vermis, and corpus callosum length decreased incrementally and significantly. The FAS/PFAS group (the only group with the 4-Digit FAS facial phenotype) had disproportionately smaller frontal lobes relative to all other groups. The FAS/PFAS and SE/AE groups [the 2 groups with the most severe central nervous system (CNS) dysfunction] had disproportionately smaller caudate regions relative to the ND/AE and Control groups. The prevalence of subjects in the FAS/PFAS, SE/AE, and ND/AE groups that had 1 or more brain regions, 2 or more SDs below the mean size observed in the Control group was 78, 58, and 43%, respectively. Significant correlations were observed between size of brain regions and level of prenatal alcohol exposure, magnitude of FAS facial phenotype, and level of CNS dysfunction.

Conclusions: Magnetic resonance imaging provided further validation that ND/AE, SE/AE, and FAS/PFAS as defined by the FASD 4-Digit Code are 3 clinically distinct and increasingly more affected diagnostic subclassifications under the umbrella of FASD. Neurostructural abnormalities are present across the spectrum. MRI could importantly augment diagnosis of conditions under the umbrella of FASD, once population-based norms for structural development of the human brain are established.

Key Words: Fetal Alcohol Spectrum Disorder, Magnetic Resonance Imaging, FASD 4-Digit Diagnostic Code.

FETAL ALCOHOL SYNDROME (FAS) is a permanent birth defect syndrome caused by maternal alcohol consumption during pregnancy. FAS is defined by growth deficiency, a unique cluster of minor facial anomalies, and central nervous system (CNS) dysfunction and/or structural brain abnormalities (Smith, 1979). The cognitive/behavioral problems in this condition stem from prenatal brain damage. Not all individuals with prenatal alcohol exposure present with measurable CNS dysfunction or structural brain abnormalities, and not all who present with measurable CNS dysfunction or structural brain abnormalities have FAS. Recently, the term fetal alcohol spectrum disorders (FASD) was coined to depict the spectrum of outcomes observed

among individuals with prenatal alcohol exposure. The degree of brain damage among individuals with prenatal alcohol exposure may vary from microcellular and neurochemical aberrations to gross structural anomalies. Similarly, cognitive/behavioral dysfunction varies along the full continuum from mild developmental delay or learning disabilities to global developmental disability (Astley et al., 2009b). The specificity of the FAS facial phenotype to prenatal alcohol exposure lends credence to the clinical judgment that the cognitive and behavioral dysfunction observed in individuals with FAS is due, at least in part, to brain damage caused by a teratogen (Aase et al., 1995; Astley and Clarren, 2001; Astley et al., 2002). Unfortunately, without the unique facial phenotype of FAS or at least a severe or clinically obvious expression of brain damage, the neurodevelopmental disabilities of an individual affected by prenatal alcohol exposure often go unrecognized and inappropriately served (Streissguth et al., 1993).

Many individuals with prenatal alcohol exposure exhibit cognitive difficulties and significant maladaptation that prevent them from leading productive, independent lives (Stratton et al., 1996; Streissguth et al., 2004). Across the population, the profile of cognitive dysfunction among individuals with prenatal alcohol exposure is highly variable, although there are some commonalities in functional compromise among subgroups, and conceptual models of overarching deficits have been proposed (Kodituwakku, 2007). However, no single behavioral phenotype specific to alcohol teratogenicity has been described. Without a behavioral phenotype specific to the teratogen alcohol, attributing an alcohol-exposed child's dysfunction to brain damage is often questionable at a clinical level (Aase et al., 1995). If indisputable evidence of brain damage (e.g., alterations in neurostructure, neurometabolites, and/or neuroactivation) could be found in these individuals, and linked to behavioral deficit, diagnostic efforts could be improved. The "disability" of these alcohol-exposed children would be clearly established, and help facilitate eligibility for needed services. Further, if specific alterations in neurostructure, neurometabolites, and/or neuroactivation could be linked to clinically meaningful, discrete neuropsychological deficits, development of appropriate intervention programs could be accelerated.

The overall goal of this research study was to determine if magnetic resonance (MR) imaging (MRI), MR spectroscopy (MRS), and/or functional MRI (fMRI) could serve as noninvasive methods for definitively identifying global and/or focal brain abnormality across the full continuum of FASD, and distinguish diagnostic subclassifications within the spectrum. The results of this comprehensive study are presented in 4 separate reports: MRI (presented here) and the neuropsychological/behavioral (Astley et al., 2009b), MRS (Astley et al., 2009c), and fMRI (Astley et al., 2009a) outcomes reported separately. The focus on FASD diagnostic methodology in this report directly responds to the following Research Recommendations for Diagnostic Criteria published in the Institute of Medicine report on FASD (Stratton et al., 1996) research: (i) to evaluate the utility, reliability, and validity of schemes for classification and diagnosis, (ii) to identify potential structural or functional brain abnormalities and other neurobiological indices that may be associated with or distinguish FAS, alcohol-related neurodevelopmental disorder (ARND), or alcohol-related birth defect, and to relate these abnormalities and indices to cognitive and behavioral correlates.

Magnetic resonance imaging allows for very sensitive assessment of size, shape, spatial orientation, and even tissue composition of selected brain regions. Numerous FASD MRI studies have been conducted to date (Archibald et al., 2001; Bookstein et al., 2002b; Mattson et al., 2001; Miller et al., 1999; Riley et al., 1995; Sowell et al., 2001b, 2002a,b). Documented abnormalities include reduction in overall brain size, reduction in absolute size of selected brain regions (basal ganglia, caudate, cerebellum, and anterior/posterior regions of the corpus callosum), disproportionate reduction of the caudate, alterations in shape and spatial orientation of the corpus callosum, and white matter hypoplasia in the parietal and temporal lobes.

The majority of FASD MRI studies published to date have enrolled study groups diagnosed or classified as FAS, fetal alcohol effects (FAE), ARND, or prenatal exposure to alcohol (PEA) prior to the establishment of comprehensive, case-defined FASD diagnostic guidelines that are quickly becoming best practice (Astley, 2004; Bertrand et al., 2004; Chudley et al., 2005). The specific diagnostic criteria used to establish the FASD study groups (e.g., level of growth deficiency; type, number and severity of facial anomalies; breadth and magnitude of neuropsychological impairment; type of neurostructural anomaly present), providing confirmation that FASD diagnostic subgroups are clinically and statistically distinct from each other, are typically not reported. Absence of rigorous diagnostic methods can lead to diagnostic misclassification. Astley and Clarren (2000) and Hoyme and colleagues (2005) have both demonstrated that individuals diagnosed with FAS by a gestalt approach often lose that diagnostic classification when more rigorous diagnostic guidelines are applied. Misclassification impacts study validity and reduces the power of a study to detect clinically meaningful differences between FASD subgroups. If specific diagnostic features that define the FASD study groups are not clearly reported, this limits the ability to compare outcomes across studies.

In general, most FASD MRI studies have found significant differences between FAS and control groups, regardless of diagnostic system used; but have not always found differences between clinical subgroups on the fetal alcohol spectrum. In the current study, the sizes of brain regions were compared between 3 FASD diagnostic subgroups and a healthy control group with no prenatal alcohol exposure. An important goal of this MRI study was to determine if meaningful neurostructural differences do exist between FASD subgroups when the subgroups, including FAS, are rigorously case-defined (Astley, 2004) and confirmed to be clinically and statistically distinct from one another (Astley et al., 2009b).

MATERIALS AND METHODS

Subjects and Study Groups

The protocol was approved by the University of Washington Human Subjects Review Board. The goal of the study was to create 3 clinically distinct and increasingly less affected FASD study groups and 1 healthy unexposed control group that fell along the following ordinal scale: (i) significant brain damage/dysfunction with the FAS facial phenotype; (ii) significant brain damage/dysfunction without the FAS facial phenotype; (iii) mild to moderate brain dysfunction without the FAS facial phenotype, and (iv) healthy with no prenatal alcohol exposure. The 3 FASD groups were selected from among 1,200 patients previously diagnosed by an interdisciplinary team in the WA State FAS Diagnostic & Prevention Network (FAS DPN) of clinics using a practical, comprehensive diagnostic system called the FASD 4-Digit Code (Astley, 2004; Astley and Clarren, 2000). Briefly, the 4 digits of the FASD 4-Digit Code reflect the magnitude of expression of the 4 key diagnostic features of FASD, in the following order: (i) growth deficiency, (ii) characteristic FAS facial phenotype, (iii) CNS structural/functional abnormalities, and (iv) prenatal alcohol exposure (Fig. 1). The magnitude of expression of each feature was ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong "classic" presence of the FASD feature. Each Likert rank is specifically case-defined. There are 256 possible 4-digit diagnostic codes ranging from 1111 to 4444. Each 4-digit diagnostic code falls into 1 of 22 unique clinical diagnostic categories (labeled A through V). Seven of the 22 diagnostic categories (4-Digit Categories A–C and E–H) fall under the umbrella of FASD [A, FAS/alcohol exposed; B, FAS/alcohol exposure unknown; C, PFAS/alcohol exposed; E and F, static encephalopathy/alcohol exposed (SE/AE); and G and H, neurobehavioral disorder/alcohol exposed (ND/AE)]. The 3 FASD study groups in the current study represent these FASD diagnostic categories. This diagnostic system is currently being used

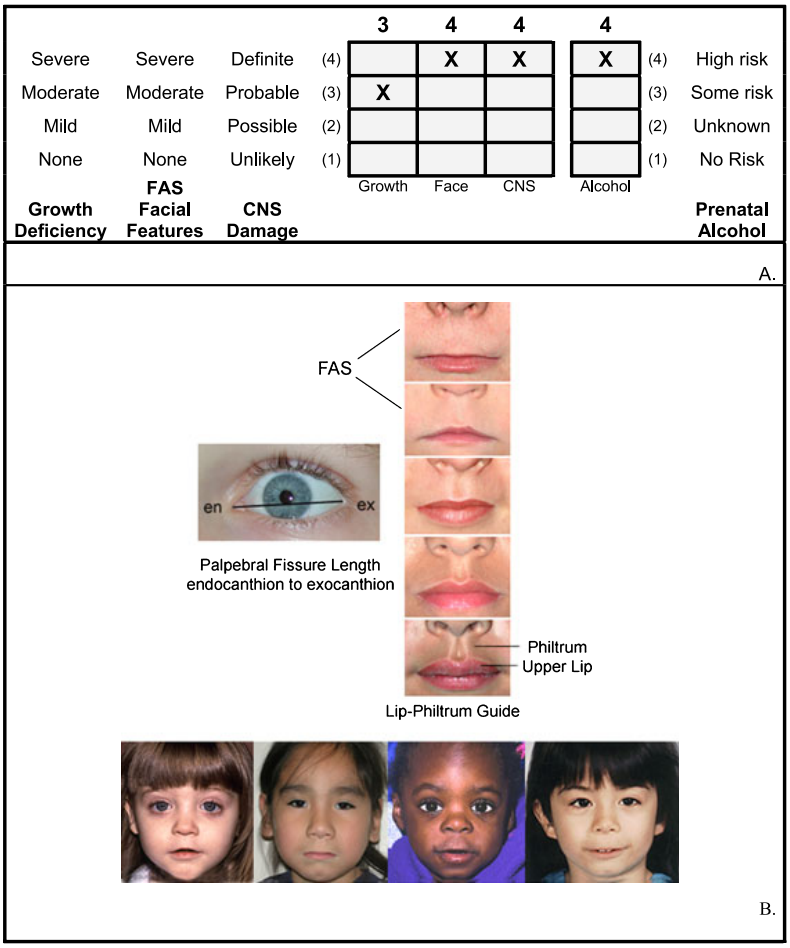

Fig. 1. (**A**) FASD 4-Digit Diagnostic Code grid. FASD is defined by growth deficiency, specific FAS facial features, evidence of CNS damage and prenatal alcohol exposure. The 4-Digit Code ranks each of these areas on 4-point, case-defined Likert scales. The 4-Digit Code (3444) inserted in the grid is 1 of 12 codes that meet the diagnostic criteria for FAS (Astley, 2004). (**B**) FASD 4-Digit Code FAS facial phenotype. The Rank 4 FAS facial phenotype determined with the 4-Digit Diagnostic Code requires the presence of all three of the following anomalies: (i) palpebral fissure length 2 or more SDs below the norm; (ii) smooth philtrum (Rank 4 or 5 on the Lip-Philtrum Guide), an (iii) thin upper lip (Rank 4 or 5 on the Lip-Philtrum Guide). Examples of the Rank 4 FAS facial phenotype for Caucasian, Native American, African American, and Asian American children are shown. © Susan Astley. FASD, fetal alcohol spectrum disorder; FAS, fetal alcohol syndrome; CNS, central nervous system.

by a wide variety of diagnostic teams in United States and other countries. The control population for this study was selected primarily from a large cohort of children enrolled at birth in a University of Washington study of typical development conducted through the Department of Speech and Hearing Sciences. With the enrollment of each child in the FAS/partial FAS (PFAS) group, a child matched on age (within 6 months), gender, and race was randomly identified and invited to enroll from the eligible SE/AE, ND/AE, and Control populations. The enrollment goal was 80 subjects (20 per group).

The study enrollment procedure produced a sample of 81 children of diverse ethnicity. The age range (8 to 15.9 years) included the broadest age range of children that could be administered a comparable psychometric assessment battery and be reasonably capable of participating in the MR scanning. Each of the 4 study groups had 16 to 24 subjects successfully balanced on age, gender, and race. The 61 children with FASD were highly representative of the entire clinic sample of 1,200 from which they were drawn. The clinic population of 1,200 was 43% female, 51% Caucasian, with 40% between 8 and 15.9 years of age. The 4-Digit Codes of all 81 children were presented in the neuropsychological/behavioral report for this study (Astley et al., 2009b). The diagnostic features specific to each group are as follows:

1. Children in Group 1 had a 4-Digit diagnosis of FAS/PFAS (e.g., 4-Digit Diagnostic Categories A, B, C: with Growth Ranks 1–4, Face Ranks 3–4, CNS Ranks 3 and/or 4, and Alcohol Ranks 2–4) (Fig. 1). Alcohol Rank 2 (unknown exposure) could only be present if the child had a diagnosis of full FAS because the Rank 4 FAS facial features are so specific to prenatal alcohol exposure (Astley and Clarren, 1996; Astley et al., 2002). As the only clinical difference between FAS and PFAS in this study was the presence of growth deficiency in the former, FAS and PFAS were combined. In summary, children in Group 1 had severe cognitive/behavioral dysfunction and the FAS facial phenotype.
2. Children in Group 2 had a 4-Digit diagnosis of SE/AE (e.g., 4-Digit Diagnostic Categories E and F: with Growth Ranks 1–4, Face Ranks 1–2, CNS Ranks 3 and/or 4, and Alcohol Ranks 3–4). In summary, children in Group 2 had severe cognitive/behavioral dysfunction, comparable with Group 1, but did not have the FAS facial phenotype.
3. Children in Group 3 had a 4-Digit diagnosis of ND/AE (e.g., 4-Digit Diagnostic Categories G and H: with Growth Ranks 1–4, Face Ranks 1–2, CNS Rank 2, and Alcohol Ranks 3–4). In summary, children in Group 3 had prenatal alcohol exposure like Groups 1 and 2, but had only mild to moderate cognitive/behavioral dysfunction, and did not have the FAS facial phenotype.
4. Children in Group 4 (Healthy Controls/No Alcohol Exposure) were selected based on parental report that the child was healthy, had no academic concerns, and no prenatal alcohol exposure (e.g., 4-Digit Diagnostic Category V: with Growth Ranks 1–2, FAS Face Ranks [no restrictions], CNS Rank 1, Alcohol Rank 1). In summary, these were nonexposed, healthy, average to high-functioning controls.

Using the FASD terminology introduced by Stratton and colleagues (1996), the SE/AE and ND/AE groups most closely reflected the severe and mild expressions of ARND, respectively. A comprehensive analysis of the between-group differences of these diagnostic features is presented in the neuropsychological/psychiatric report for this study (Astley et al., 2009b).

Within our FASD participants, 1 subject with PFAS had agenesis of the corpus callosum (ACC) and 1 subject with FAS had hypogenesis of the corpus callosum (HCC). That these subjects had callosal abnormalities was known prior to study enrollment. Indeed these 2 subjects with ACC/HCC were the only documented cases of ACC/HCC in the 2,040 patients with prenatal alcohol exposure diagnosed to date at the WA State FAS DPN clinics. MRIs were typically only available when clinically indicated (e.g., evidence of neurological abnormalities). As such, only 204 (10%) of the 2,040 patients evaluated at the FAS DPN had a previous MRI evaluation summarized in their medical record and 76% of the 204 MRI evaluations were interpreted as normal by the patient's neuroradiologist. Although ACC/HCC has been observed in individuals with FASD (Riley et al., 1995), ACC/HCC is not specific to prenatal alcohol exposure. The prevalence of ACC among developmentally disabled populations is estimated to be 2 to 3 per 100 (Jeret et al., 1986). Thus, a causal link between ACC/HCC and prenatal alcohol exposure in these 2 individuals should not be assumed nor can it be ruled out. As all current FASD diagnostic guidelines (Astley, 2004; Bertrand et al., 2004; Chudley et al., 2005; Hoyme et al., 2005) list ACC/HCC as one of the many types of structural abnormalities that meet the CNS criteria for a FAS/PFAS diagnosis, it would be clinically invalid to exclude ACC/HCC from the FAS/PFAS study group. While they might represent a very small fraction of all alcohol-exposed patients evaluated in the FAS DPN clinic, they represent 2 of all 41 patients with FAS/PFAS from the FAS DPN clinic who met the 8- to 15-year-old eligibility criteria for enrollment into this study.

Study Participation

Participation in the study involved 5 visits over a 4- to 6-week study period. The psychological and sociodemographic data were collected during visits 1 and 2. The MR data were collected during visits 3 and 4. Outcomes of the psychological assessments were shared with the caregivers on visit 5, and submitted to the child's medical record with caregiver consent.

Sociodemographic and Clinical Assessments

A comprehensive sociodemographic and health/medication history of each child was obtained by parent interview and record review. Information included birth data, growth, and all prenatal and lifetime exposures and adverse events. For subjects with FASD, most information was obtained at the time of their FASD diagnostic evaluation. All controls had a reported absence of prenatal alcohol exposure. All children had a standardized digital facial photograph taken at the time of enrollment. The facial photographs were analyzed using the FAS Facial Analysis Software (Astley, 2003) to document the magnitude of expression of the FAS facial phenotype (Astley and Clarren, 1996). A more detailed methodology and analysis of the sociodemographic and FASD diagnostic outcomes, including prenatal alcohol exposure histories, were presented in the neuropsychological/behavioral report from this study (Astley et al., 2009b).

Neuropsychological and Psychiatric Assessments

A detailed description of the assessment battery and a comprehensive analysis of the between-group differences in neuropsychological outcome were presented in the neuropsychological/behavioral report for this study (Astley et al., 2009b). Briefly, a comprehensive, standardized assessment battery was administered to each child and their primary caregiver by a psychologist masked to group assignment. The assessment battery was designed to capture the domains of potential neuropsychological impairment seen as the result of the typically diffuse brain damage arising from alcohol teratogenesis (Bertrand et al., 2004; Chudley et al., 2005; Kodituwakku, 2007; Mattson and Riley, 1998; Olson et al., 1998; Roebuck et al., 1999). The neuropsychological/behavioral outcomes served to profile the study groups and confirm the groups were clinically and statistically distinct from one another; fundamental to the interpretation of the MR outcomes. The neuropsychological data will also be used to

assess correlations between brain structure and function. These correlations will be reported separately.

It is important to note that the mean full scale IQ of the healthy Control group (123 ± 7 SD) was higher than the population-based mean of 100 ± 15 SD. This was anticipated as children with potential threats to brain development were screened out and recruitment was through a University community. Other population-based MRI and FASD-MRI studies enrolling healthy controls have reported mean FSIQs ranging from 110 to 127 (Bookstein et al., 2002b; Haier et al., 2004; Sowell et al., 2008; Waber et al., 2007). Most FASD-MRI studies do not report the IQ or neuropsychological profile of their healthy control population. In spite of the Control group's relatively high IQ, however, many of the memory, executive function, language, and adaptive behavior scores assessed for this Control group were, on average, solidly within normal limits compared with age peers (Table 1) (Astley et al., 2009b). The ND/AE group had a mean FSIQ (99.2 ± 11.3 SD) equivalent to the population-based mean, despite their multiple prenatal/postnatal risk factors and significant adaptive/behavioral deficits.

MR Scanner

All scans (MRI, MRS, and fMRI) were acquired using a General Electric 1.5 Tesla scanner in the Diagnostic Imaging Sciences Center at the University of Washington.

MRS and fMRI

The MRS (Astley et al., 2009c) and fMRI (Astley et al., 2009a) components of this study were reported separately. Briefly, MRS was used to measure the concentrations of neurometabolites, including: (i) choline, a marker of cell membrane stability and myelination, (ii) *N*-acetyl aspartate, a neuronal or axonal marker, and (iii) creatine, a marker of metabolic activity, in selected brain regions. fMRI was used to assess neuroactivation in selected brain regions during performance of N-back working memory tasks.

Structural MRI Acquisition

An initial sagittal series was obtained first for orientation of subsequent series (Echo Time (TE) = 8, Time to Repetition (TR) = 400, flip angle = 25°, Field of View (FOV) = 24 × 24, matrix = 256 × 160, thickness = 4.0 mm, gap = 1.0 mm]. A high resolution 3-D T1-weighted fast gradient echo image of the whole brain was then performed in the axial plane [TE = 3, TR = 18, FOV = 24 × 18, matrix = 256 × 256, number of excitations (NEX) = 2, thickness = 1.5 mm, no gap]. This acquisition allowed images to be reformatted into any plane, which, in turn, allowed measurement of each structure in the plane that was optimal for its visualization. This also allowed brain scans to be realigned to ensure that all scans were measured in a standardized format. An exact midsagittal slice was reconstructed, allowing for area measures of corpus callosum and cerebellar vermis. Total scanning time for the structural series was approximately 15 minutes. Each scan was clinically reviewed by the neuroradiologist (masked to group assignment) to determine if there were any gross structural abnormalities.

Structural MRI Image Processing

Magnetic resonance imaging measures were performed on a PC workstation using the MEASURE program (The Johns Hopkins University, Baltimore, MD) (Barta et al., 1997). Each scan was rotated in 3-D space so that the axial images were parallel to the line connecting the anterior and posterior commissures and perpendicular to the interhemispheric fissure (ac–pc plane). Coronal slices were reconstructed with a thickness of 0.9375 mm and positioned perpendicular to the ac–pc plane. Based on prior FASD MRI literature (Archibald et al., 2001; Mattson et al., 2001; Miller et al., 1999; Sowell et al., 2001b), volume measurements focused on the hippocampus, caudate, putamen, frontal lobe, gray matter and white matter of the frontal lobe, and total brain volume from the 1.5 mm spoiled gradient recalled echo in steady state (SPGR). Area measures included cerebellar vermis and its subregions, corpus callosum and its subregions, and total brain area in the midsagittal slice. For the hippocampus, caudate, putamen, and frontal lobe volume measures, area of each structure was outlined manually, using a mouse-controlled cursor, in each slice. Areas within each slice were calculated, summed across slices, and multiplied by slice thickness, resulting in approximate structure volumes. Semi-automated methods were used to measure total brain volume and a stereology point-counting method was used to measure gray and white matter within the frontal lobe. Specific methods of measurement for each structure are mentioned below.

Hippocampus. The rules for defining boundaries of the hippocampus were developed by Aylward and colleagues (1999). Briefly, measurement was made on the reconstructed coronal slices, began in the most posterior coronal slice in which the hippocampus was viewed. Boundaries of the hippocampus were traced manually, with the choroid fissure as the superior boundary, the inferior temporal horn of the lateral ventricle as the lateral boundary, and the white matter of the parahippocampal gyrus as the inferior boundary. The hippocampus formed a natural boundary around the edge of the medial temporal lobe. Both the alveus and the subiculum were included in hippocampal measurements. Anteriorly, when a clear demarcation between the hippocampus and amygdala was not seen coronally, the sagittal view was consulted to determine the border between the hippocampus and amygdala. Interrater reliability for the hippocampus yielded an intraclass correlation of 0.92.

Basal Ganglia. Volumes of putamen and caudate were obtained on the axial images using rules previously described (Aylward et al., 1997a). Briefly, measurement of putamen and caudate began in the most inferior slice in which these structures were clearly separated by the internal capsule. Measurement continued in a superior direction until the body of the caudate was no longer observed. The borders of the caudate were defined laterally by the anterior limb of the internal capsule and medially by the frontal horn or body of the lateral ventricle. The borders of the putamen were defined laterally by the external capsule. At more inferior levels, the medial borders of the putamen were defined by the globus pallidus; at more superior levels, the medial borders were defined by the internal capsule. Intrarater reliability yielded intraclass correlations of 0.99 for both caudate and putamen. Interrater reliability yielded intraclass correlations of 0.97 for caudate and 0.94 for putamen.

Frontal Lobe Volume. The procedure used to measure the volume of the frontal lobes (Aylward et al., 1997b) and of the gray and white matter within the frontal lobes was based on the identification of sulcal-gyral landmarks on the surface of a 3-D reconstruction of the 1.5 mm coronal slices. For frontal lobe measures, this 3-D reconstruction which could be viewed in any orientation, was used to identify the precentral gyrus and sylvian fissure. Using the MEASURE software, the surfaces of these regions were "painted" on the 3-D reconstruction. The brain imaging data were then resliced in the axial plane, starting at the most superior level, and the paint (which remains on the surface of the recreated slices) was used to guide as the rater cut away portions of the brain posterior to the paint. Interrater reliability yielded an intraclass correlation of 0.99 for frontal lobe volume. After the frontal lobe was thus identified, a stereological point-counting method was used to measure gray and white volumes within the frontal lobe, as described by Aylward and colleagues (1995). Interrater reliability yielded an intraclass correlation of 0.92 for the frontal cortex.

Chi2: chi-square test across four study groups, unless otherwise specified. D-KEFS: Delis-Kaplan Executive Function System, Tower, Total Achievement (Delis et al., 2000). Duncan: Multiple comparison range test. Reported if the overall ANOVA is statistically significant. Commas separate groups with homogeneous means at $p < 0.05$. F: *F* statistic. LT: ANOVA unweighted linear trend. OFC: occipital frontal circumference. Overall: Overall assessment of between-group means using ANOVA. *p*: *p* value. SD: standard deviation. Unk: unknown. VABS: Vineland Adaptive Behavior Scales, Adaptive Behavior Composite (Sparrow et al., 1984). VMI: Beery Buktenica Developmental Test of Visual-Motor Integration (Beery, 1997). WISC-III Full Scale IQ (Wechsler, 1996).

[a]Six of the 20 subjects in Group 1 had full FAS using the 4-Digit Code. Ten of the 14 PFAS had Rank 4 Faces but received a diagnosis of PFAS because they had no growth deficiency (Growth Rank 1).

[b]Between-groups, df = 3; within-groups, df = total sample size − 4.

[c]Between-groups linear term df = 1; within-groups df = total sample size − 4.

[d]Caucasian versus not Caucasian.

[e]No growth deficiency versus mild to severe growth deficiency.

[F]All 3 children with moderate functional impairment had structural evidence of brain abnormality (microcephaly).

[G]FAS/PFAS versus SE/AE ($\chi^2 = 7.1$, $p = 0.008$).

[H]FAS/PFAS versus SE/AE ($\chi^2 = 9.6$, $p = 0.002$).

Total Brain Volumes. Regional volumes were divided by total brain volume to allow correction for overall brain size. Total brain volume was measured using semi-automated thresholding procedures for segmenting brain tissue from cerebral spinal fluid (CSF) on the 1.5 mm axial images. Briefly, this procedure allowed the user to set the contrast such that all pixels above a certain value were highlighted, thus eliminating CSF (which in these images was black). A mask of this region was saved, and a command of "erode" was executed that "shrunk" the highlighted areas by a specified number of pixels. This performed automatic cutting of "bridges" between highlighted brain and nonbrain (e.g., dura and muscle) tissue regions. The cursor was then placed inside the brain region, and an "isolate blob" command then identified only those pixels that were connected (in any plane) with the pixel at the cursor location. This allowed the brain to be isolated from nonbrain tissue. Finally, a "dilate" command was executed, which restored pixels that were eroded previously, but no further than the original mask. Raters modified the procedure to ensure that only nonbrain tissue was removed. Intrarater reliability for obtaining brain volumes with this procedure yielded an intraclass correlation of 0.99. At each step, modifications were made manually to ensure inclusion of all brain tissue and exclusion of nonbrain regions.

Midsagittal Area Measures. The 3-D brain was rotated so that the interhemispheric fissure was perfectly positioned in the vertical plane. As described above, the slices were reformatted from the 1.5 mm axial series, yielding sagittal slices that were 0.9375 mm thick. The sagittal slice yielding the clearest visualization of the cerebral aqueduct was selected for the midsagittal measures. Midsagittal area measures were performed for cerebellar vermis and its 3 subsections (Lobules I–V, Lobules VI–VII, and Lobules VIII–X), corpus callosum and 5 subregions, and total brain (Aylward and Reiss, 1991; Aylward et al., 1994; Reiss et al., 1991). Interrater reliability for obtaining midsagittal areas yielded intraclass correlations ranging from 0.87 to 0.94. Midsagittal area of the total brain was also measured to allow correction of the corpus callosum and cerebellar vermis measures for overall brain size. The corpus callosum (CC) length (cm) was the distance from the most anterior and posterior borders of the CC that intersected with a line perpendicular to the ac–pc plane. The CC was transected into 5 equiangular regions: (i) genu, (ii) anterior body, (iii) posterior body, (iv) isthmus, and (v) splenium, using the mammillary body as a reference point (Riley et al., 1995).

MRI Hypotheses

In this report the analyses focus on the MRI comparisons between the 4 study groups. The following primary hypotheses were derived from the current MRI FASD literature (Archibald et al., 2001; Astley and Clarren, 2001; Bookstein et al., 2002b; Mattson et al., 2001; Miller et al., 1999; Sowell et al., 2001b). Note again that the neuropsychological/psychiatric report for this study (Astley et al., 2009b) confirmed that the 4 study groups were clinically distinct and increasingly more affected progressing across the 4 groups from the Controls to the FAS/PFAS.

1. The mean absolute and/or relative size of the brain as a whole and its regions would become increasingly smaller progressing across the 4 study groups from Controls to ND/AE to SE/AE to FAS/PFAS.
2. The mean absolute and/or relative size of the brain as a whole and its regions would be significantly smaller in the FAS/PFAS group (with the FAS facial phenotype) compared with the SE/AE group (without the FAS facial phenotype). This hypothesis specifically addressed a common clinical question: did individuals with FASD and the FAS facial phenotype have more severe brain abnormality than individuals with FASD and no FAS facial phenotype?
3. The prevalence of subjects with 1 or more brain regions 2 or more SDs below the mean size of the Control group would increase significantly progressing from the ND/AE group to the SE/AE group and to the FAS/PFAS group.

Statistical Analysis

The statistical analyses used to confirm the 4 study groups, effectively balanced on age, gender, and race, were described and presented in the neuropsychological/psychiatric report (Astley et al., 2009b).

Primary Analyses. ANOVA was used to determine if differences in mean size of brain regions existed among the 4 study groups. If significant differences existed, the Duncan post hoc range test was used to identify which group mean differed. The Duncan test makes pairwise comparisons using a stepwise procedure. Mean was ordered from highest to lowest, and extreme differences were tested first. The Duncan test sets a protection level for the error rate for the collection of tests and identifies homogeneous subsets of mean that are not different from one another at the $p = 0.05$ level. To specifically test primary hypothesis 1, an a priori test for linear trend was included in the ANOVA to determine if the mean size of selected brain regions became increasingly smaller progressing across the 4 study groups from Control to ND/AE to SE/AE to FAS/PFAS. To test primary hypothesis 2, an a priori contrast (*t*-test) between the FAS/PFAS and SE/AE groups was specified in the ANOVA. To test primary hypothesis 3, a chi-squared test for trend was used to compare the prevalence of structural anomalies across the 3 FASD groups relative to the Control group. Two-tailed *p* values of 0.05 were used throughout the analyses.

Secondary Analyses. Secondary analyses using Pearson Correlations coefficients and ANOVA tests for linear trends were conducted to determine if the size of brain regions decreased with increasing quantity, frequency, and/or duration of reported prenatal alcohol exposure between the 3 FASD groups. Two adjustments were used throughout the analysis of the MRI data: (1) adjustment for total brain volume (or midsagittal area) and (2) inclusion or exclusion of the 2 subjects in the FAS/PFAS group with ACC/HCC (Fig. 2*A* and 2*B*). Adjustment 1: to determine if some brain regions were disproportionately reduced in size. Given that overall brain size was often reduced among individuals with prenatal alcohol exposure, relative measures of brain regions were computed by dividing the volume of the region by total brain volume, or the midsagittal area of the brain region by the midsagittal area of the total brain. The terms "relative" and "absolute" were used to distinguish the 2 types of measures. Adjustment 2: the 2 subjects with ACC/HCC in FAS/PFAS group had CCs that were substantially smaller than the CCs of the other members of that group. The midsagittal area of the CC was 0.3 cm^2 in the subject with agenesis and 1.95 cm^2 in the subject with hypogenesis (Figs. 2*A* and 2*B*). These are 6 and 42%, respectively, of the mean midsagittal area of the CC (4.64 cm^2) for the remaining 18 members of the FAS/PFAS group. Inclusion of these 2 subjects in the FAS/PFAS group could influence some between-group differences (particularly differences in the mean midsagittal area of the CC). As such, it was important to confirm statistically significant group differences were not driven primarily by these 2 lowest measures (which represent outliers in the FASD sample). Although the size of the CC for the subject with ACC was a statistical outlier (more than 2 SDs below the mean of the FAS/PFAS group), it would not be clinically valid to exclude this case from the study. All current published FASD diagnostic guidelines (Astley, 2004; Bertrand et al., 2004; Chudley et al., 2005; Hoyme et al., 2005) list ACC as an example of a CNS structural abnormality that meets the CNS diagnostic criteria for FASD. Thus, all analyses were conducted

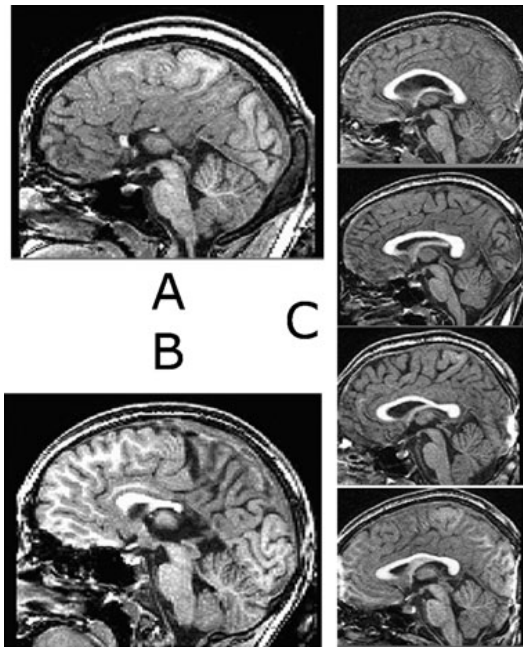

Fig. 2. Two subjects with (**A**) agenesis and (**B**) hypogenesis of the corpus callosum in the fetal alcohol syndrome (FAS)/partial FAS group. (**C**) Variability in corpus callosum shape among Controls with no prenatal alcohol exposure.

with inclusion of these 2 subjects. If their exclusion resulted in a statistical outcome that was discordant with the statistical outcome when the 2 subjects were included, both analyses are presented.

Power/Sample Size. This study had 80% power or greater to detect the following effect sizes at a two-tailed alpha level of 0.05: (i) a difference in 2 means equal to or greater than the SD of the mean difference; (ii) a correlation coefficient of 0.30 or greater; and (iii) a 35-point or greater difference in proportions between 2 groups.

RESULTS

Size of Brain Regions Across the 4 Groups (Primary Hypotheses 1–2)

Total Brain. The mean total brain volume decreased significantly progressing across the 4 study groups from Control to ND/AE to SE/AE to FAS/PFAS (Table 2). The linear trend remained significant with exclusion of the Control group, confirming that total brain size decreased incrementally across the 3 FASD groups. Indeed, all significant linear trends by brain region, reported in Table 2, remained significant with exclusion of the Control group. The mean total brain volume of the FAS/PFAS group was significantly smaller (11% smaller) than the mean of the Control group. The prevalence of microcephaly (occipital frontal circumference ≤−2 SD) was significantly higher in the FAS/PFAS group with the FAS facial phenotype than in the SE/AE group without the FAS facial phenotype (83.1% vs. 16.7%; $\chi^2 = 7.6$, two-tailed $p = 0.006$) (Astley et al., 2009b). This group difference was not influenced by the 4-Digit Code diagnostic criteria for CNS abnormality. The CNS criteria for FAS, PFAS, and SE/AE were identical (e.g., presence of structural and/or significant functional abnormality). Was brain size reduced simply because individuals with FASD were typically growth deficient? Although FAS is the only FASD subclassification in the 4-Digit Code that requires the presence of some level of growth deficiency (height and/or weight below the 10th percentile), all 3 FASD groups were significantly shorter in stature (but not lower in weight) than the Controls (Table 1). Despite the growth deficiency among the FASD, there was no significant correlation between height or weight percentile and total brain size across the 81 subjects.

Frontal Lobe. Absolute Volume: The mean absolute volume of the frontal lobe decreased incrementally and significantly, progressing across the 4 study groups from Controls to FAS/PFAS (Table 2). The mean absolute volume of the frontal lobe for the FAS/PFAS group was significantly smaller (11–18% smaller) than each of the other groups.

Relative Volume: The mean relative volume of the frontal lobe decreased significantly progressing across the 4 study groups from Control to FAS/PFAS (with and without inclusion of the 2 subjects with ACC/HCC). The mean volume of the frontal lobe for the FAS/PFAS group with the 2 subjects with ACC/HCC removed was 352.3 (62.1 SD). When the subjects with ACC/HCC were included in the FAS/PFAS group, no significant pair-wise group differences were observed. When the 2 subjects with ACC/HCC were excluded from the FAS/PFAS group, the mean relative volume of the frontal lobe for the FAS/PFAS group was significantly smaller (6–9% smaller) than each of the 3 other groups.

Gray/White Matter: The mean absolute volume of white and gray matter in the frontal lobe decreased significantly progressing across the 4 study groups from Control to ND/AE to SE/AE to FAS/PFAS. The mean absolute volume of the frontal gray matter for the FAS/PFAS group was also significantly smaller (19% smaller) than the mean of the SE/AE group. The mean percent white matter and percent gray matter in the frontal lobes were comparable across the 4 study groups.

Caudate. Absolute Volume: The mean absolute volume of the caudate decreased significantly progressing across the 4 study groups from Control to FAS/PFAS. The mean absolute volume of the caudate in both the FAS/PFAS and SE/AE groups were comparable with one another but significantly smaller (on average 23 and 19% smaller, respectively) than the mean of the Control group (Table 2).

Relative Volume: The mean relative volume of the caudate in both the FAS/PFAS and SE/AE groups were comparable with one another and significantly smaller (12 and 14%, respectively) than the mean of the Control group. No differences in absolute or relative size were observed between the right and left caudate.

CC, corpus callosum; CV, cerebellar vermis; L, left; R, right; T: *t* statistic from ANOVA a priori contrast; FAS, fetal alcohol syndrome; PFAS, partial FAS; SE, static encephalopathy; AE, alcohol exposed; ND, neurobehavioral disorder.

Duncan: multiple comparison range test; commas separate groups with homogeneous means at $p < 0.05$. LT: ANOVA unweighted linear trend across the four study groups. All significant linear trends remain significant with exclusion of the Control group.

[a]Only reported when overall ANOVA is statistically significant.

[b]Numerator degrees of freedom = 3; denominator df = total sample size minus 4.

[c]Numerator degrees of freedom = 1; denominator df = total sample size minus 4.

[d]Two subjects with agenesis and hypogenesis of the corpus callosum removed from FAS/PFAS group.

Putamen. Absolute Volume: The mean absolute volume of the putamen decreased significantly progressing across the 4 study groups from Control to FAS/PFAS (Table 2). This trend was no longer statistically significant ($F = 3.4$; df: 3,74; $p = 0.07$) after removal of the 2 subjects with ACC and HCC. The mean volume of the putamen for the FAS/PFAS group was significantly smaller (13% smaller) than the mean of the Control group. When the 2 subjects with ACC/HCC were excluded from the FAS/PFAS group, the mean volume of the putamen was 12% smaller than the mean of the Control group. This difference was no longer statistically significant ($t = 1.8$, $p = 0.08$).

Relative Volume: The mean relative volume of the putamen was comparable across all 4 study groups. No differences in absolute or relative size were observed between the right and left putamen.

Hippocampus. Absolute Volume: The mean absolute volume of the hippocampus decreased significantly progressing across the 4 study groups from Control to FAS/PFAS (Table 2). The mean absolute volumes of the hippocampus for each of the 3 FASD groups were significantly smaller (9–16% smaller) than the mean of the Control group.

Relative Volume: The mean relative volume of the hippocampus was comparable across the 4 study groups. No differences in absolute or relative size were observed between the right and left hippocampus.

Corpus Callosum. Absolute Area: The midsagittal area of the CC and each of the 5 subregions were 6–15% smaller in size (although not significantly) in each of the FASD groups relative to the Control group (Table 2). Exclusion of the 2 subjects with ACC/HCC did not alter these outcomes. When the 3 alcohol-exposed groups were combined, the mean midsagittal area of the genu (region 1) was significantly smaller (9%) (mean: 1.22 cm^2, 0.2 SD) relative to the Control group (mean: 1.34 cm^2, 0.2 SD) ($t = 2.0$; $p = 0.03$). This difference remained significant with exclusion of the 2 subjects with ACC/HCC. The mean absolute length of the corpus callosum decreased significantly progressing across the 4 study groups from Control to FAS/PFAS (with and without the ACC/HCC). The mean length of the corpus callosum for the FAS/PFAS group was significantly shorter (16%) than the mean of the Control group. The mean length of the corpus callosum for the FAS/PFAS group remained significantly shorter (9%) than the mean of the Control group after removal of the 2 subjects with ACC/HCC. Visual inspection of the CCs revealed substantial variability in the shape of the CC, even within the Control group (Fig. 2*C*).

Relative Area: The mean relative midsaggital area of the CC and its 5 subregions (after adjustment for total brain midsaggital area) were comparable across all 4 groups. When the 2 subjects with ACC/HCC were removed from the FAS/PFAS group, a significant increase in the relative size of Region 2 was observed, progressing across the 4 study groups from the Control group to the FAS/PFAS group.

Cerebellar Vermis. Absolute Area: The mean absolute midsagittal areas of the cerebellar vermis (CV) and lobules I–V were significantly smaller in the FAS/PFAS group (12 and 15%, respectively) than the mean of each area in the Control group (Table 2). Removal of the 2 subjects with ACC/HCC had no impact on these outcomes.

Relative Area: The mean relative midsagittal area of the CV and its 3 regions were comparable across all 4 groups.

Radiologist Review of MRI. Visual inspection of the study MRIs by the neuroradiologist on the investigative team identified the following prevalence of structural abnormalities: Control ($n = 0$, 0.0%), ND/AE ($n = 0$, 0.0%), SE/AE ($n = 3$, 12.5%), FAS/PFAS ($n = 3$, 15.0%). Three subjects in the FAS/PFAS presented with the following anomalies: 1 ACC, 1 HCC, and 1 with a 13 mm lesion in the left cerebellar hemisphere and slight deformity of the fourth ventricle. Three subjects in the SE/AE group presented with Chiari 1 malformations. Only the ACC and HCC were known to be present prior to the subjects' enrollment in the study. The neuroradiologist was masked to the subject's FASD diagnosis and study group assignment.

Size of Brain Regions Between FASD Subjects With and Without the FAS Facial Phenotype (Primary Hypothesis 2)

The mean absolute size of the frontal lobe, putamen, hippocampus, and CV were significantly smaller in the FAS/PFAS group than the SE/AE group (Table 2). The children with FAS/PFAS also had disproportionately smaller frontal lobes than the children with SE/AE (Table 2, Fig. 3). It is important to note that the only diagnostic feature that distinguishes the FAS/PFAS group from the SE/AE group in this study is the presence of the FAS facial phenotype in the former. Both groups had comparably severe CNS dysfunction (Astley et al., 2009b). The FAS Facial *D*-Score is a continuous measure of the magnitude of expression of the FAS facial features: the higher the *D*-Score, the more severe the expression of the FAS facial features (Astley and Clarren, 2001). The size of the following brain regions decreased significantly (Pearson Correlation Coefficients with two-tailed p values < 0.05) as the FAS Facial *D*-Score increased: frontal lobe volume (absolute size: −0.261, relative size: −0.215); midsagittal area of cerebellar vermis (absolute size: −0.299); and caudate volume (absolute size: −0.362, relative size: −0.262).

Structural Abnormality Correlations With FASD Group and CNS Function (Primary Hypothesis 3)

The number of subjects in each FASD study group, with 1 or more brain regions that were 2 or more SDs below the mean of the Control group, increased significantly as one advanced from the ND/AE to the SE/AE to the FAS/PFAS group (χ^2 for trend: 4.8, $p = 0.03$) (Fig. 4*A*).

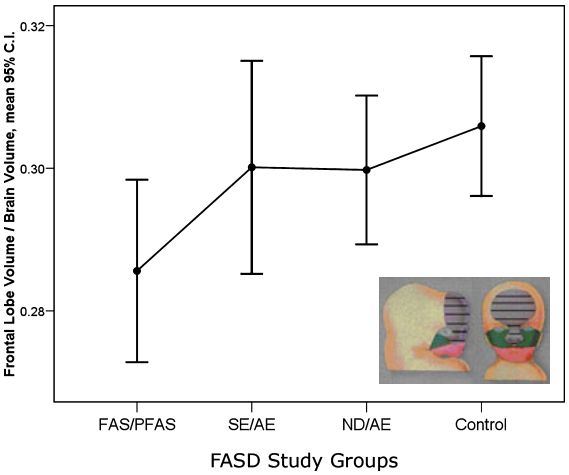

Fig. 3. The relative volume (cc) of the frontal lobe was significantly smaller in the fetal alcohol syndrome (FAS)/partial FAS (PFAS) group (after exclusion of the 2 subjects with agenesis of the corpus callosum/hypogenesis of the corpus callosum) compared with each of the other study groups. The FAS/PFAS group is the only group with the full FAS facial phenotype. Morphogenesis of the middle and upper face is heavily influenced by signals emanating from the forebrain to the frontonasal prominence (Marcucio et al., 2005). The frontonasal prominence is the striped region in the insert depicting a 5-week (left) and 10-week (right) fetus (Moore et al., 1994). C.I.: confidence interval; FASD, fetal alcohol spectrum disorders; SE, static encephalopathy; AE, alcohol exposed; ND, neurobehavioral disorder; FAS, fetal alcohol syndrome; PFAS, partial FAS.

Importantly, this demonstrated that even when the FAS facial phenotype was missing and the level of brain dysfunction was mild to moderate (4-Digit CNS Rank 2 in ND/AE group), there was a significant increased risk of underlying structural brain abnormality relative to the Control group (Fisher exact test, $p = 0.005$). Further evidence of structural brain abnormality along the full continuum of mild to severe brain dysfunction was observed by dividing the 81 subjects into 3 groups based on their 4-Digit CNS Rank: Rank 1 (no dysfunction), Rank 2 (mild to moderate dysfunction), and Rank 3 (severe dysfunction). The absolute size of all brain regions (with the exception of the CC, putamen, and CV) decreased significantly and incrementally progressing from CNS Rank 1 to 2 to 3. The only measures of the CC that decreased significantly with increasing CNS Rank were CC length and CC region 1 midsagittal area. Figure 4*B* serves to illustrate one of these findings, the significant decrease in the mean absolute volume of the caudate progressing from CNS Rank 1 to 2 to 3 (ANOVA overall $F = 13.5$; df: 2,77; $p < 0.001$: unweighted linear trend $F = 25.8$; df: 1,74; $p < 0.001$). The Duncan range test confirmed that all 3 mean caudate volumes were significantly distinct from one another.

Size of Brain Regions and Alcohol Exposure

Reported prenatal alcohol exposure patterns (frequency, quantity, and duration) across the 3 FASD study groups are

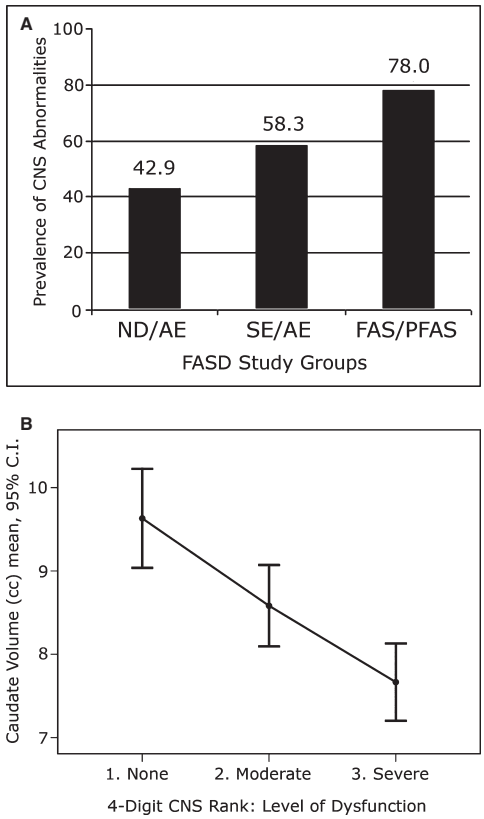

Fig. 4. (**A**) Prevalence of subjects in each FASD study group that had 1 or more brain regions, 2 or more SDs below the mean size observed in the Control group. (**B**) Mean absolute caudate volume decreased as a global measure of brain function (4-Digit Code CNS Rank) increased in impairment. C.I., confidence interval; FASD, fetal alcohol spectrum disorder; SE, static encephalopathy; AE, alcohol exposed; ND, neurobehavioral disorder; FAS, fetal alcohol syndrome; PFAS, partial FAS; CNS, central nervous system.

presented in detail in the neuropsychological/psychiatric report for this study (Astley et al., 2009b) and briefly in Table 1. Of the 65 subjects with FASD, 64 had confirmed prenatal alcohol exposure and one with full FAS had an unknown exposure. More detailed information on quantity, frequency, and/or trimester of alcohol use was available on 53 of the 65 alcohol-exposed subjects. The size of various brain regions decreased significantly and incrementally among the subjects with FASD with increasing frequency, quantity, and/or duration of reported alcohol exposure.

Days Per Week. Significant inverse correlations (Pearson Correlation Coefficients with p values < 0.05) were observed between the average number of days per week of drinking during pregnancy and the size of the following brain regions: midsagittal area of the brain (−0.306), absolute (−0.435) and relative (−0.306) volumes of the hippocampus, and CC length (−0.327).

Maximum Drinks Per Drinking Occasion. Significant inverse correlations were also observed between the maximum number of alcoholic drinks consumed per drinking occasion during pregnancy and the size of the following brain regions: relative volume of the frontal lobe (−0.430) (Fig. 5*A*), relative volume of the caudate (−0.373), and the absolute (−0.463) and relative (−0.538) volumes of the hippocampus.

Trimester of Exposure. A significant linear decrease in the mean relative volume of the frontal lobe was also observed when the FASD study sample was divided into groups based on their duration of exposure [exposure through first trimester only (n = 10, mean: 0.31, SD: 0.03); through the second trimester only (n = 9, mean: 0.29, SD: 0.02); and through all 3 trimesters (n = 32, mean: 0.28, SD: 0.02); ANOVA overall F = 3.1; df: 2,50; p = 0.05; unweighted linear trend, F = 6.1; df: 1,50; p = 0.017] (Fig. 5*B*). Post hoc comparison tests confirmed that the mean relative volume of the frontal lobe was significantly smaller among those with 3 trimesters of exposure relative to those with exposure through just the first trimester. Interestingly, the mean relative volume of the frontal lobe of the unexposed Control group (mean: 0.31, SD: 0.02, n = 16) was comparable with the 2 FASD groups with exposure through the first and second trimesters, but was significantly larger than the group with exposure through all 3 trimesters.

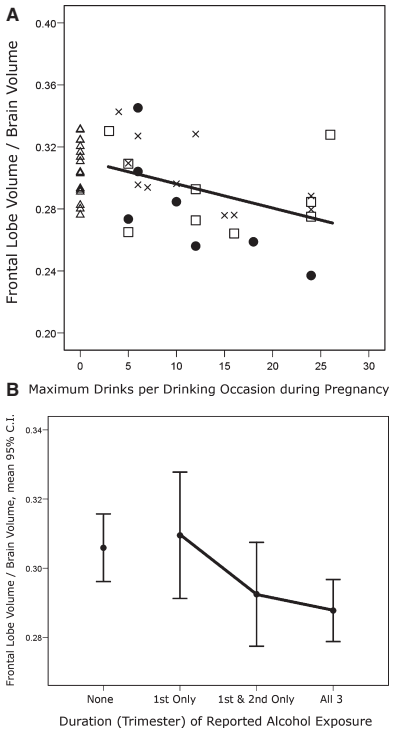

Fig. 5. (**A**) The relative volume of the frontal lobe decreased significantly with increasing maximum number of alcohol drinks per drinking occasion during pregnancy among subjects with FASD (Pearson Correlation Coefficient −0.430, $p < 0.02$). (**B**) A significant linear decrease in the mean relative volume of the frontal lobe was also observed when the FASD study sample was divided into groups based on their duration of exposure (exposure through first trimester only, n = 10, mean: 0.31, SD: 0.03; through the second trimester only, n = 9, mean: 0.29, SD: 0.02; and through all 3 trimesters, n = 32, mean, 0.28, SD: 0.02) (ANOVA overall F = 3.1; df: 2,50; p = 0.05; unweighted linear trend, F = 6.1; df: 1,50; p = 0.017). The unexposed Control group is plotted for visual comparison. C.I., confidence interval; FASD, fetal alcohol spectrum disorder. Circle = FAS/PFAS, square = SE/AE, X = ND/AE, triangle = control.

DISCUSSION

Overall, all 3 primary hypotheses were supported in this study. *Hypothesis 1:* progressing across the 4 study groups from Controls to ND/AE to SE/AE to FAS/PFAS, the mean absolute size of most brain regions decreased significantly in size. The frontal lobe and caudate were disproportionately reduced in size. *Hypothesis 2:* even though the FAS/PFAS and SE/AE groups had comparably severe levels of brain dysfunction (CNS Rank 3), those with the FAS facial phenotype had significantly smaller frontal lobes, frontal lobe gray matter volume, and CV. *Hypothesis 3:* the risk of underlying structural abnormalities increased linearly as one advanced from ND/AE to SE/AE to FAS/PFAS, relative to Controls. Most notably, 43% of subjects in the ND/AE group had 1 or more brain regions that were 2 or more SDs below the mean of the Control group, despite only mild to moderate brain dysfunction, no FAS facial phenotype, and the absence of microcephaly. MRI provided further validation that ND/AE, SE/AE, and FAS/PFAS, as defined by the FASD 4-Digit Code, are 3 clinically distinct and increasingly more affected diagnostic subclassifications under the umbrella of FASD. The significant inverse correlations between quantity, frequency, and timing of alcohol exposure and size of selected brain regions provided further evidence of a potential causal association between alcohol exposure and structural brain abnormality observed in this study population. It is important to note that the findings reported in this study are reflective of the 4-Digit Code definitions used to generate the FASD study groups. While all FASD diagnostic systems (Astley, 2004; Bertrand et al., 2004; Chudley et al., 2005; Hoyme et al., 2005) share some common clinical terminology (e.g., FAS and PFAS), the criteria used to define these diagnostic classifications are not the same.

FASD Diagnostic Classification Systems

When comparing outcomes across published FASD MRI studies, it is important to note that not all investigations use the same FASD diagnostic criteria to establish their FASD study groups. In many fields, readers of research data can draw their own conclusions about the comparability of diagnostic subgroups because the diagnostic criteria are widely established, or in newer fields of study, the diagnostic methods would be presented in sufficient detail. At present the FASD MRI literature lacks the diagnostic detail necessary

when a field has not yet settled on common diagnostic standards. Most FASD MRI studies to date have classified their subjects into 1 or more of the following groups: (i) an alcohol-exposed group with FAS facial features (FAS), (ii) an alcohol-exposed group without FAS facial features (e.g., ARND or FAE); or (iii) a group in which all FASD subgroups are combined into 1 group with PEA. Criteria used to define FAS groups are typically described qualitatively (e.g., known prenatal alcohol exposure, craniofacial anomalies consistent with FAS, prenatal or postnatal growth deficiency or both, and CNS dysfunction). Criteria used to define ARND groups are also described qualitatively (e.g., exposed to high levels of alcohol but display few or none of the facial features characteristic of FAS, and do not show growth retardation). But these qualitative descriptions do not adequately convey what goes into the classifications of FAS, ARND, or FAE. Missing are parameters such as what level of growth deficiency must be present, what level of CNS dysfunction must be present, which FAS facial features must be evident, and how severe the facial anomalies had to be. Without this information, it is not clear if clinically distinct study groups have been established or how they are clinically distinct. Nor can it be determined if the FAS/FASD group in 1 study is comparable with the FAS/FASD group in another study. As the field has matured, there is now clear consensus that more rigorous diagnostic methods should be used and several more rigorous methods have been published (Astley, 2004; Bertrand et al., 2004; Chudley et al., 2005). Two groups of investigators (Astley and Clarren, 2000; Hoyme et al., 2005) have demonstrated in 2 large clinical populations that the majority (50–87%) of FAS diagnoses rendered using gestalt diagnostic methods did not meet FAS criteria when more rigorous diagnostic criteria were applied.

To help bridge the gap between the different diagnostic terms used in the FASD literature, our ND/AE and SE/AE groups would be most comparable with mild and severe ARND, respectively. Our FAS/PFAS group will differ from other groups labeled FAS or PFAS if the diagnostic criteria used to establish the groups differ. Our FAS/PFAS, SE/AE, and NE/AE groups span the entire continuum of FASD. The effort here is to describe groups across the full fetal alcohol spectrum and to retain sufficient statistical power to detect clinically meaningful differences between diagnostic subgroups. Combining possible subtypes into 1 larger alcohol-exposed group may obscure actual differences between these subtypes. In the current study, most neuroimaging differences would not have been revealed if the 3 FASD study groups had been combined in any way and compared with the Controls. We suggest the following questions as standards for review and interpretation of current and future literature on neuroimaging and behavioral outcomes in FASD: (i) What diagnostic criteria are used to establish the study groups? (ii) Has the magnitude of growth deficiency, FAS facial features, CNS structural/functional abnormality, and alcohol exposure been reported to confirm that study groups are clinically distinct? (iii) When significant differences between groups are not observed, does the study have clinically distinct groups and sufficient sample size/power to support null findings? and (iv) When outcomes between FAS groups differ between studies, is this because outcomes differ or the definition of FAS differs?

MRI FASD Literature

In general, the FASD MRI literature documents significant reductions in the size of many but not all brain regions studied, when comparing full FAS to a healthy control group. The current study supports and extends these findings. The FASD MRI literature also documents marginal effects in PEA, FAE, or ARND groups relative to FAS or healthy controls, but these differences are rarely statistically significant. The current study provides definitive evidence that when these nondysmorphic FASD clinical subgroups are more rigorously defined and subdivided (e.g., SE/AE and ND/AE) (Astley, 2004), significant differences are observed not only when each of these FASD groups is compared with a healthy control group, but also when each is compared with the other. These findings provide compelling evidence that clinically meaningful and distinct subgroups do exist under the umbrella of FASD, and at least 2 distinct subgroups exist under the broad classification ARND (e.g., SE/AE and ND/AE). Key outcomes in the current study are discussed below and compared with the FASD MRI literature, with emphasis on findings specific to FASD clinical subgroups and how subgroups are clinically defined.

Total Brain. In the current study, total brain size became incrementally smaller progressing across the 4 study groups from Control to FAS/PFAS. This was influenced, in part, by the criteria used to construct the 4 groups. Microcephaly is a sufficient but not necessary CNS criterion for diagnosis of FAS, PFAS, and static encephalopathy/alcohol-exposed subjects. Of note, however, is the finding that the prevalence of microcephaly was fourfold greater in the FAS/PFAS group relative to the SE/AE group. Both groups were required to meet the same criteria for CNS damage/dysfunction (CNS Rank 3 and/or 4). The only difference between the criteria for the 2 groups was that the FAS/PFAS group had to have FAS facial features (Face Ranks 3 or 4) and SE/AE group had to have normal facial features (Face Ranks 1 and 2). Thus, the fact that microcephaly was far more prevalent in the group with the FAS facial features is a further evidence that 4-Digit Code definition of the FAS face is a marker for underlying structural abnormality. The impact of alcohol on reduction of overall brain size is well documented in the animal and human FASD literature (Archibald et al., 2001; Hoyme et al., 2005; Mattson and Riley, 1995; Sowell et al., 2001b; Stratton et al., 1996). The current study provided definitive evidence of the continuum of effects across the full spectrum, not just among those with FAS.

Frontal Lobe. The most notable and novel finding in the current study was a significant reduction in absolute and relative volume of the frontal lobe in the FAS/PFAS relative to all other groups including the SE/AE group. The significant difference observed between FAS/PFAS and SE/AE indicates individuals with FASD and the FAS facial features have smaller frontal lobes than those with FASD, but no facial features, despite the fact that both groups had comparably severe cognitive/behavioral impairment (4-Digit CNS Rank 3: 3 or more domains of function, 2 or more SDs below the mean) (Astley et al., 2009b). Archibald and colleagues (2001) using a study sample of 14 FAS and 12 PEA by gestalt diagnosis and 41 controls and Sowell and colleagues (2001b) using a subset of the Archibald study sample, 14 FAS and 7 PEA by gestalt diagnosis and 21 controls, were unable to detect significant differences in absolute or relative measures of frontal lobe volumes between FAS, PEA, and controls. Further analysis of the Sowell and colleagues (2001b) study population (Sowell et al., 2002a) using surface-based image analysis revealed a significant reduction in the absolute volume and a significant increase in the relative volume of the frontal lobe, when the 14 FAS and 7 PEA were combined and compared with 21 controls. Wass and colleagues (2001) reported significant reductions in the absolute size of the frontal cortex associated with prenatal alcohol exposure in an ultrasonographic study of 167 pregnant women. The percent of fetuses with a frontal cortex below the 10th percentile increased from 4% for nonexposed fetuses to 23% for heavily exposed fetuses.

Frontal Lobe Gray–White Matter. Although we observed significantly smaller absolute volumes of white matter and gray matter in the frontal lobes among subjects with FAS/PFAS relative to Controls, the proportion of the frontal lobe that contained white matter did not vary significantly across the 4 study groups. These findings are consistent with the literature. Archibald and colleagues (2001) identified a significant proportional reduction of white matter across the entire cerebrum among subjects with a gestalt diagnosis of FAS relative to Controls. When their analysis was repeated for each lobe (frontal, parietal, temporal, and occipital), a significant proportional reduction of white matter was only observed in the parietal lobe. When subsets of these children were further assessed by Sowell and colleagues (2001b, 2002a) proportional reductions in white matter were observed in the left hemisphere perisylvian cortices of the temporal and parietal lobes (not in the frontal lobes) among alcohol-exposed subjects relative to Controls.

Caudate. The caudate, lenticular nuclei, some subthalamic nuclei, and the substantia nigra are subcortical gray matter structures that form the basal ganglia (Cote and Crutcher, 1990). The caudate nucleus has extensive neural connections to the frontal lobes and is thought to mediate higher cognitive and executive function. Like the frontal lobe, the absolute and relative volume of the caudate was significantly reduced in the current study but unlike the frontal lobe this reduction in size was observed in both the FAS/PFAS and SE/AE groups relative to the Control group. Archibald and colleagues (2001) reported that the absolute and relative size of the caudate was significantly reduced in 14 children with a gestalt diagnosis of FAS relative to 41 controls. But no significant caudate reductions were observed among their group of 12 children with PEA. Cortese and colleagues (2006) assessed caudate size in an fMRI study with a very small sample of children (7 with FAS and 4 with FAE by gestalt diagnosis, and 4 controls). They reported significantly smaller absolute, but not relative, caudate volumes in the FAS group relative to controls, but the unconventional use of one-tailed p values increased the probability of achieving statistical significance. No caudate differences were detected between their FAE and control groups. It is noteworthy that no significant differences in intracranial volume were detected between their FAS, FAE, and control groups.

Putamen. The putamen (part of the lenticular nuclei) together with the caudate form the striatum. The putamen is innervated by neurons from the primary motor, premotor, supplementary motor, and somotosensory cortices, whereas the caudate receives input from frontal eye fields and association areas of the frontal and parietal lobes (Cote and Crutcher, 1990; Giedd et al., 1994). In the present study, the absolute but not relative volume of the putamen was significantly smaller in the FAS/PFAS group relative to the SE/AE, ND/AE, and Control groups. Mattson and colleagues (1996) in a study of 6 children with FAS (by gestalt diagnosis) reported that the absolute but not relative volume of the lenticular nuclei was significantly smaller relative to 7 controls. Archibald and colleagues (2001) reported no significant absolute or relative reduction in the size of the lenticular nucleus among 14 FAS or 12 PEA (by gestalt diagnosis) when compared with 41 controls.

Hippocampus. The hippocampus is a structure of the limbic system involved in learning, memory storage, and retrieval (Eichenbaum et al., 1992). In the present study, the mean absolute volume of the hippocampus decreased significantly, progressing across the 4 study groups from Control to FAS/PFAS. In contrast, Archibald and colleagues (2001) reported a disproportionate sparing of the hippocampus in an otherwise hypoplastic brain among 14 FAS participants (by gestalt diagnosis) relative to 41 controls.

Corpus callosum. The CC is a large bundle of nerve fibers connecting the 2 hemispheres of the brain. CC deficits have been linked to deficits including intellectual functioning, learning, memory, executive function, and attention. In this study, the absolute midsagittal area of the genu (Region 1) and the length of the CC were comparably small across the FASD groups and significantly smaller relative to the Control group. No significant differences were observed after adjustment for midsagittal brain area. Riley and colleagues

(1995) reported significant decreases in the absolute midsagittal area of the CC and regions 1, 3, 4, and 5 among 11 alcohol-exposed subjects (9 with FAS by gestalt diagnosis) relative to 12 controls. After adjustment for midsaggital brain area, regions 1 (genu), 4, and 5 (splenium) remained significantly smaller but overall midsagittal area did not. The more severe outcomes reported by Riley and his colleagues were not due to differences in diagnostic methodology, as our outcomes reflected our entire alcohol-exposed group. It does appear the alcohol-exposed group in the study by Riley and colleagues was more severely impaired than our alcohol-exposed group. They had a substantially lower FSIQ and were drawn from a sample with a higher estimated prevalence of ACC (3/44 or 6.8%). In a more recent study, Sowell and colleagues (2001a) observed the size, shape, and location of the CC among 20 alcohol-exposed subjects (13 with FAS by gestalt diagnosis) and 21 controls. Again, in contrast to our findings, they reported significant reductions in the absolute midsagittal area of the CC and all 5 subregions in their alcohol-exposed group relative to their control group. Their more severe findings could be explained by the much higher prevalence of microcephaly in their alcohol-exposed population (they report "most" were microcephalic). Only 18% of our alcohol-exposed group was microcephalic. After adjustment for brain volume, only the splenium in their alcohol-exposed group remained significantly smaller. Their key finding was a significant anterior-inferior displacement of the splenium in the alcohol-exposed relative to controls. Based on their published Figs. 2 and 3 illustrating this effect, this finding would appear to be commensurate to our finding of a shorter CC. Autti-Ramo (2000) reported that CC was significantly shorter (7.4%), the midsagittal area significantly smaller (13.8%), and the width of the splenium significantly smaller (12%) among 17 alcohol-exposed subjects (5 with FAS by gestalt diagnosis) relative to 17 controls. These differences were no longer significant after adjustment for midsagittal area of the brain. Forty-one percent of their alcohol-exposed population was microcephalic. Bookstein and colleagues (2002a,b) reported a variety of shape but not size differences in the CC of subjects with gestalt diagnoses of FASD versus controls. It is important to remember that brain regions are inherently highly variable in shape and size, even in typically developing individuals (Steen et al., 2007). This is clearly evident in our Control population. They present with extraordinary variability in CC shape (Fig. 2*C*) despite their high level of cognitive function and absence of alcohol exposure. One final comparison with the literature is warranted. Miller and colleagues (1999) reported that the absolute size of the CC was significantly larger in ethanol-exposed nonhuman primates relative to unexposed controls. The number of axons (not the axon size or myelin thickness) was significantly greater, especially in the rostral half of the CC (anterior to where the fornix joins the CC). It is important to note that total brain volume was comparable between the exposed and unexposed groups, no animal had microcephaly, and the alcohol-exposed animals had mild to moderate cognitive dysfunction with possibly only 1 animal having full FAS. Several human studies, including ours, have reported sparing of some anterior callosal regions in their alcohol-exposed group. We observed a significant relative sparing of CC Region 2. Riley and colleagues (1995) observed significant absolute and relative sparing of CC Region 2 and Sowell and colleagues (2001a) reported relative but not absolute sparing of anterior callosal regions.

What appears to be 1 recurring theme across several FASD studies is that the CC is reduced in length and the regions most impacted are the genu and splenium. These findings are consistent with the developmental spectrum of ACC. CC abnormalities are present in a multitude of syndromes and disease entities (Paul et al., 2007). ACC is not specific to prenatal alcohol exposure. ACC is present in 2 to 3 per 100 individuals with general developmental disability (Jeret et al., 1986). The CC is the major commissure forming a junction between the cerebral hemispheres. The formation of the CC starts with the development of the genu in week 11; the body, isthmus and splenium develop at a later stage through week 20 of gestation (Paul et al., 2007). If the normal developmental process is disturbed, the CC may be absent completely or partially ("hypogenetic"). As the developmental process starts from the anterior part and progresses from front to rear, when the CC is hypogenetic, it is usually the posterior portion that is affected the most (the posterior body and the splenium) (Fig. 2*B*).

Cerebellar vermis. The cerebellum is located at the base of the brain and is involved in motor, cognitive, and affective functions (Vidal et al., 2006). The absolute but not the relative midsagittal area of the CV and lobules I–V were significantly smaller in the FAS/PFAS group relative to the Controls and SE/AE in the current study. Sowell and colleagues (1996) reported a significant reduction in the absolute midsagittal area of lobules I–V in a group of alcohol-exposed subjects (6 FAS and 3 PEA by gestalt diagnosis) relative to 24 controls. They did not report if these findings remained significant when adjusted for overall brain size. More recently, O'Hare and colleagues (2005) reported significant reductions in the midsagittal area of lobules I–V and the VIII–X in a group of alcohol-exposed subjects (14 FAS and 7 PEA by gestalt diagnosis) relative to 21 controls. After correction for brain size, lobule I–V remained significantly reduced in size. Goodlett and colleagues (1990), using an animal model, demonstrated that the number of Purkinje cells was significantly reduced in earlier maturing regions of the CV (lobules I–V and VIII–X) after a single critical day of neonatal alcohol exposure. Notably, the Purkinje cells in the later maturing neocerebellar vermis (lobules VI and VII) were apparently spared.

Prevalence of CNS Structural Abnormalities Among FASD Clinical Subgroups

From a FASD diagnostic perspective, it is interesting to note how many subjects within all 3 FASD clinical subgroups

had 1 or more brain regions, 2 or more SDs below the mean of the Control group. Although we reported the prevalence of anomalies in our FASD study groups using our research control group as the reference, this would not be an appropriate practice in a clinical setting. Norms for the size of brain regions adjusted for gender and age must be established using large, representative, population-based samples, rather than small, convenient research control samples. The National Institutes of Health (NIH) MRI Study of Normal Brain Development (Waber et al., 2007) is a landmark study that is documenting structural brain development and behavior longitudinally from birth to young adulthood in a large population-based sample of healthy children targeted to the United States 2000 census distribution.

Validation of the FASD 4-Digit Diagnostic Code

This study further validated (Astley and Clarren, 1996, 2000, 2001; Astley et al., 2002) the measurement scales and procedures for diagnostic classification used in the FASD 4-Digit Diagnostic Code. Statistically significant differences in neuropsychological outcomes (Astley et al., 2009b) and measures of brain structure were observed between the FAS/PFAS, SE/AE, and ND/AE groups, confirming that these groups reflect 3 clinically distinct and increasingly more affected diagnostic subclassifications under the umbrella of FASD. The prevalence/severity of structural brain abnormality increased significantly as dysfunction increased from CNS Rank 1 (no dysfunction) to Rank 2 (mild to moderate dysfunction) to Rank 3 (severe dysfunction). Indeed, when these CNS Ranks were first defined 10 years ago (Astley and Clarren, 2000), the underlying principle was that as the magnitude and breadth of functional impairment increased, the probability of underlying structural abnormality would increase. It is for this reason that the 4-Digit CNS Ranks 1, 2, and 3 were labeled "unlikely," "possible," and "probable" underlying CNS abnormality, respectively (Fig. 1). The finding that the subjects in the FAS/PFAS group with the 4-Digit FAS facial phenotype had significantly smaller frontal lobes than the SE/AE group with no FAS facial phenotype provides the most compelling data yet that this facial phenotype truly is a marker for underlying brain abnormality (Fig. 3). Several animal and clinical studies have documented correlations between midline facial anomalies and underlying brain abnormality caused by prenatal alcohol exposure (Astley and Clarren, 1996, 2001; Johnston, 1975; Sulik, 2005; Sulik and Johnston, 1982; Sulik et al., 1981, 1984). Morphogenesis of the middle and upper face is heavily influenced by signals emanating from the forebrain. Marcucio and colleagues (2005) report that a role of Sonic hedgehog (Shh) in the forebrain is to regulate Shh expression in the face, and that together, these Shh domains mediate patterning within the frontonasal prominence (Fig. 3) and proximodistal outgrowth of the middle and upper face.

The primary limitation of this study is the presence of other prenatal and/or postnatal risk factors, in addition to alcohol, that are capable of adversely impacting brain development. Clinical records for this FASD study sample documented that up to 83% of the mothers reportedly smoked during pregnancy, up to 67% reportedly used illicit drugs during pregnancy, and over 75% of the children were in foster/adoptive care (Astley et al., 2009b). While the significant dose–response associations observed between alcohol exposure and neurostructural alterations in this study provided compelling evidence of alcohol's potential causal role, one cannot rule out the impact of the other risk factors.

In conclusion, the results of this study confirm that significant differences in the sizes of many brain regions exist between children with FASD and their healthy peers. More importantly, when the FASD 4-Digit Code is used to create clinically distinct diagnostic subgroups under the umbrella of FASD (FAS/PFAS, SE/AE, and ND/AE), statistically significant differences in neurostructure are identified between the FASD diagnostic subgroups. Structural abnormalities were prevalent across the full spectrum of FASD. MRI could importantly augment the diagnosis of FASD, once population-based norms for structural development of the human brain are established.

ACKNOWLEDGMENTS

This research was supported by NIAAA Grant R01-AA12915-01A1 to SJA. Support was also received from the Center on Human Development and Disability, University of Washington (National Institute of Child Health and Human Development Grant: P30 HD02274). We would like to acknowledge Katherine Field, Olivia Liang, Winslow Johnson, and Katherine Keller for their assistance in the measurement of MRI scans. Special thanks are extended to the children and their families who so kindly contributed time and effort to this study.

Abstract

Magnetic resonance (MR) technology offers noninvasive methods for in vivo assessment of neuroabnormalities. A comprehensive neuropsychological/behavioral, MR imaging (MRI), MR spectroscopy (MRS) and functional MRI (fMRI) assessment was administered to children with fetal alcohol spectrum disorders (FASD) to determine whether global and/or focal abnormalities could be identified and to distinguish diagnostic subclassifications across the spectrum. The four study groups included (1) FAS/partial FAS; (2) static encephalopathy/alcohol exposed (SE/AE); (3) neurobehavioral disorder/alcohol exposed (ND/AE) as diagnosed with the FASD 4-Digit Code; and (4) healthy peers with no prenatal alcohol exposure. Results are presented in four separate reports: MRS (reported here) and neuropsychological/behavioral, MRI and fMRI outcomes (reported separately). MRS was used to compare neurometabolite concentrations [choline (Cho), *n*-acetyl-aspartate (NAA) and creatine (Cre)] in a white matter region and a hippocampal region between the four study groups. Choline concentration in the frontal/parietal white matter region, lateral to the midsection of the corpus callosum, was significantly lower in FAS/PFAS relative to all other study groups. Choline decreased significantly with decreasing frontal white matter volume and corpus callosum length. These outcomes suggest low choline concentrations may reflect white matter deficits among FAS/PFAS. Choline also decreased significantly with increasing severity of the 4-Digit FAS facial phenotype, increasing impairment in psychological performance and increasing alcohol exposure. NAA and Cre concentrations did not vary significantly. This study provides further evidence of the vulnerability of the cholinergic system in FASD.

Keywords: Fetal alcohol spectrum disorder (FASD); Magnetic resonance spectroscopy (MRS); FASD 4-Digit Diagnostic Code; Choline; *n*-Acetyl-aspartate; Creatine

1. Introduction

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal alcohol consumption during pregnancy. FAS is defined by growth deficiency, a unique cluster of minor facial anomalies and central nervous system (CNS) dysfunction and/or structural brain

abnormalities [1]. The cognitive/behavioral problems in this condition stem from prenatal brain damage. Not all individuals with prenatal alcohol exposure present with measurable CNS dysfunction or structural brain abnormalities, and not all who present with measurable CNS dysfunction or structural brain abnormalities have FAS. Recently, the term *fetal alcohol spectrum disorders* (FASD) was coined to depict the spectrum of outcomes observed among individuals with prenatal alcohol exposure. FASD is not a medical diagnosis. Rather, medical diagnoses/conditions like FAS, Partial FAS, Static Encephalopathy/Alcohol Exposed and Neurobehavioral Disorder/Alcohol Exposed fall under the umbrella of FASD. The degree of brain damage among individuals with prenatal alcohol exposure may vary from microcellular and neurochemical aberrations to gross structural anomalies. Similarly, cognitive/behavioral dysfunction varies along the full continuum from mild developmental delay or learning disabilities to global developmental disability. The specificity of the FAS facial phenotype to prenatal alcohol exposure lends credence to the clinical judgment that the cognitive and behavioral dysfunction observed in individuals with FAS is due, at least in part, to brain damage caused by a teratogen [2-4]. Unfortunately, without the unique facial phenotype of FAS or at least a severe or clinically obvious expression of brain damage, the neurodevelopmental disabilities of an individual affected by prenatal alcohol exposure often go unrecognized and inappropriately served [5].

Many individuals with prenatal alcohol exposure exhibit cognitive difficulties and significant maladaptation that prevent them from leading productive, independent lives [6,7]. Across the population, the profile of cognitive dysfunction among individuals with prenatal alcohol exposure is highly variable, though there are some commonalities in functional compromise among subgroups, and conceptual models of overarching deficits have been proposed [8]. However, no single behavioral phenotype specific to alcohol teratogenicity has been described, and a single behavioral phenotype is unlikely. Without a behavioral phenotype specific to the teratogen alcohol, attributing an alcohol-exposed child's dysfunction to brain damage is often questionable at a clinical level [4]. If indisputable evidence of brain damage (e.g., alterations in neurostructure, neurometabolites and/or neuroactivation) could be found in these individuals, and linked to behavioral deficit, diagnostic efforts could be improved. The "disability" of these alcohol-exposed children would be clearly established and help facilitate eligibility for needed services. Furthermore, if specific alterations in neurostructure, neurometabolites and/or neuroactivation could be linked to clinically meaningful, discrete neuropsychological deficits, development of appropriate intervention programs could be accelerated.

The overall goal of this research study was to determine whether magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS) and/or functional MRI (fMRI) could serve as noninvasive methods for definitively identifying global and/or focal brain abnormality across the full continuum of FASD and distinguish diagnostic subclassifications within the spectrum. The results of this comprehensive study are presented in four separate reports: MRS (presented here), and the neuropsychological/behavioral [9], MRI (submitted for publication) and fMRI [10] outcomes reported separately.

MRS measures concentrations of neurometabolites, including choline-containing compounds (Cho), markers of cell membrane stability and myelination; *N*-acetyl aspartate (NAA), a neuronal or axonal marker; and creatine (Cre), a marker of metabolic activity [11-14]. Decreased concentrations of Cho and/or NAA have been correlated with organic brain damage in many different disease states and disorders, and with varying levels of cognitive/behavioral dysfunction among both humans and animals [15-20]. Only three FASD MRS studies have been conducted to date, with varied outcomes [16,21,22]. The first FASD MRS study was conducted in a nonhuman primate model of FASD, back in the early 1990s [16]. Cho/Cre was measured in a 34×34×34-mm^3 region of interest that included the thalamus, parts of the internal capsule and basal ganglia, and adjacent white matter (Fig. 1A). Cho/Cre increased significantly with increasing duration of prenatal alcohol exposure and increasing impairment in neuropsychological function among animals with the human equivalent of alcohol-related neurodevelopmental disorder (ARND) (cognitive/behavioral impairment, but no physical stigmata of FAS). Interestingly, the only animal to deviate from this pattern was the animal with the most profound cognitive/behavioral impairment and the only live-born animal with FAS-like facial dysmorphia. Rather than having the highest Cho/Cre level, as would have been expected, this animal had the lowest Cho/Cre level (more than two standard deviations below the mean of all other study groups). It was speculated and reported at the time that this animal may have sustained a level of damage that was beyond that of the other animals, perhaps severe enough to result in depletion of cholinergic nuclei. Research in mice had previously confirmed that in utero ethanol exposure could cause severe depletion of cholinergic nuclei, with the most severe effects observed among those with FAS-like craniofacial anomalies [23]. NAA/Cre was also evaluated in the nonhuman primate study. Levels did not vary significantly with exposure or neuropsychological function. More recently, two FASD MRS studies have been conducted in humans, one focusing on the caudate nucleus [22], the other targeting several regions (parietal and frontal cortices, frontal white matter, corpus callosum, thalamus and cerebellar dentate nucleus) [21]. No significant Cho or Cho/Cre differences were observed between the FASD and control groups in either study. Cortese et al. [22] reported that NAA/Cre was significantly higher in their FASD group relative to their control group, whereas Fagerlund et al. [21] reported that NAA/Cre levels

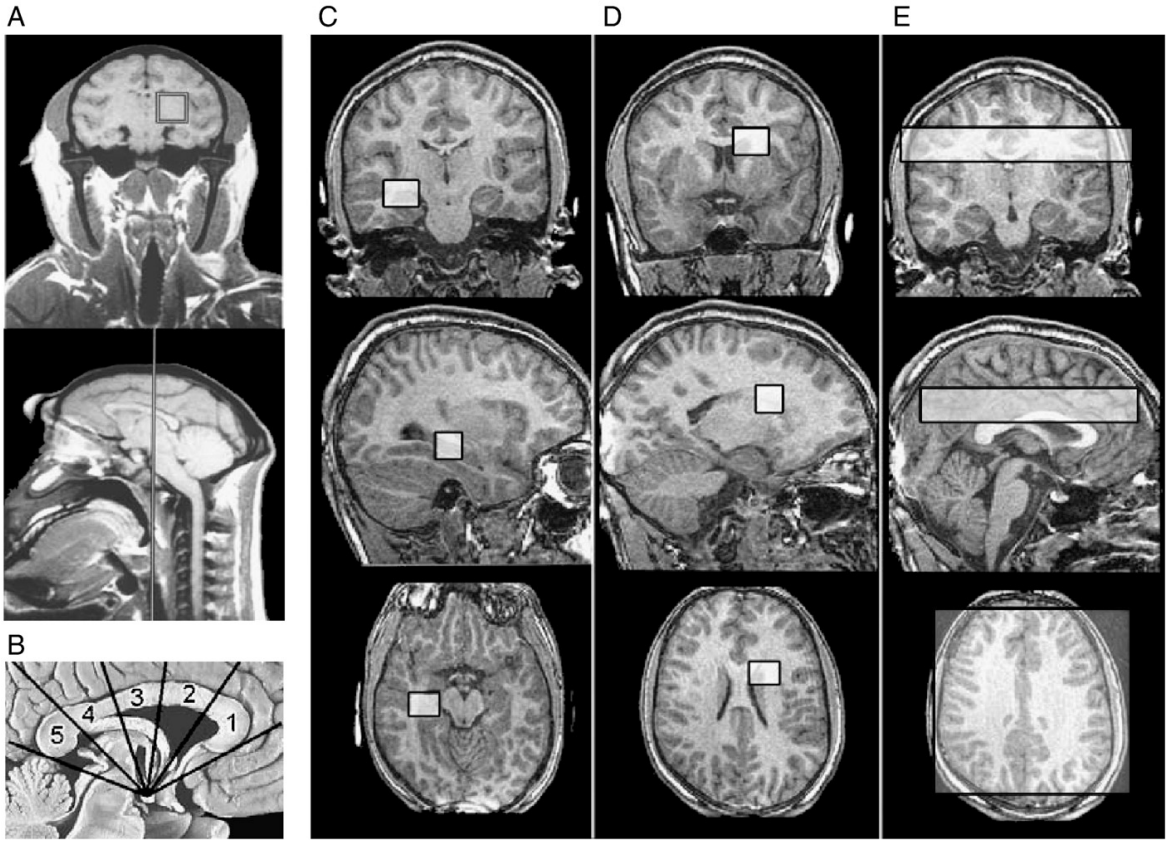

Fig. 1. Nonhuman primate FASD MRS study [16]. (A) The 34×34×34-mm^3 voxel included the thalamus, parts of the internal capsule and basal ganglia, and adjacent white matter. Current MRS Study. (B) Five equiangular subregions of the corpus callosum [(1) genu, (2) anterior body, (3) posterior body, (4) isthmus, (5) splenium] were constructed using the mammilary body as a point of reference. Coronal, sagittal and horizontal views of (C) 15×15×15-mm^3 hippocampus/basal nuclear voxel in the left hemisphere, (D) 15×15×15-mm^3 white matter voxel in the right frontal/parietal region (to replicate the voxel position in the previous nonhuman primate study) and (E) 20-mm-thick axial multivoxel slice (data to be presented in a separate report).

were significantly lower in their FASD group relative to their control group in parietal and frontal cortices, frontal white matter, corpus callosum, thalamus and cerebellar dentate nucleus.

The present study was conducted to assess absolute concentrations of Cho, NAA and Cre in two 15×15×15-mm^3 regions of interest: (1) a frontal/parietal white matter region, to replicate the region targeted in the nonhuman primate study [16]; and (2) a hippocampal/basal nuclear region, to extend the brain regions assessed in the human FASD MRS literature and overlap with a region assessed in the MRI component of this study.

2. Methods and materials

2.1. Subjects and study groups

The protocol was approved by the University of Washington Human Subjects Review Board. The three FASD groups were selected from among 1200 patients previously diagnosed by an interdisciplinary team in the WA State FAS Diagnostic & Prevention Network (FAS DPN) of clinics using the FASD 4-Digit Code [24,25]. Briefly, the four digits of the FASD 4-Digit Code reflect the magnitude of expression of the four key diagnostic features of FASD, in the following order: (1) growth deficiency, (2) characteristic FAS facial phenotype, (3) CNS structural/functional abnormalities and (4) prenatal alcohol exposure (Fig. 2). The magnitude of expression of each feature is ranked independently on a four-point Likert scale, with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong "classic" presence of the FASD feature. Each Likert rank is specifically case defined. There are 256 possible four-digit diagnostic codes, ranging from 1111 to 4444. Each four-digit diagnostic code falls into one of 22 unique clinical diagnostic categories (labeled A through V). Seven of the 22 diagnostic categories (4-Digit Categories A–C and E–H) fall under the umbrella of FASD [(A) FAS/

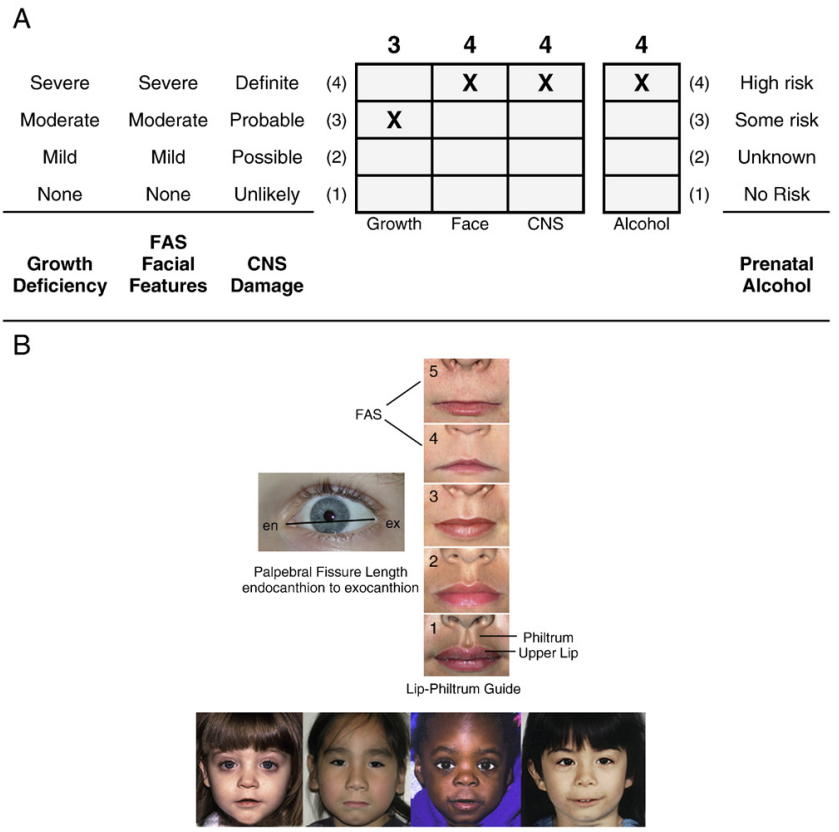

Fig. 2. (A) FASD 4-Digit Diagnostic Code. FASD is defined by growth deficiency, specific FAS facial features, evidence of CNS damage, and prenatal alcohol exposure. The 4-Digit Code ranks each of these areas on 4-point, case-defined, Likert scales. The 4-Digit Code (3444) inserted in the grid is 1 of 12 codes that meet the diagnostic criteria for FAS [25]. (B) The Rank 4 FAS facial phenotype, as defined by the FASD 4-Digit Diagnostic Code, requires the presence of all 3 of the following anomalies: (1) palpebral fissure length 2 or more standard deviations below the mean (2) smooth philtrum (Rank 4 or 5 on the Lip-Philtrum Guide); (3) thin upper lip (Rank 4 or 5 on the Lip-Philtrum Guide). Examples of the full Rank 4 FAS facial phenotype for Caucasian, Native American, African American, and Asian American children are shown (copyright Susan Astley Ph.D., University of Washington).

alcohol exposed, (B) FAS/alcohol exposure unknown, (C) partial FAS/alcohol exposed, (E–F) static encephalopathy/alcohol exposed and (G–H) neurobehavioral disorder/alcohol exposed]. The three FASD study groups in the current study represent these FASD diagnostic categories. This diagnostic system is currently being used by a wide variety of diagnostic teams in the USA and other countries. The control population was selected primarily from a large cohort of children enrolled at birth in a University of Washington study of typical development conducted through the Department of Speech and Hearing Sciences. With the enrollment of each child in the FAS/PFAS group, a child matched on age (within 6 months), gender and race was randomly identified and invited to enroll from the eligible SE/AE, ND/AE and control populations. The enrollment goal was 80 subjects (20 per group).

The study enrollment procedure produced a sample of 81 children of diverse ethnicity (Table 1). The age range (8 to 15.9 years) included the broadest age range of children that could be administered a comparable psychometric assessment battery and be reasonably capable of participating in the MR scanning. The 61 children with FASD were highly representative of the entire clinic sample of 1200 from which they were drawn. Each of the four study groups had 16–24 subjects successfully balanced on age, gender and race. The diagnostic features specific to each group were as follows:

1. Children in Group 1 had a four-digit diagnosis of *FAS or partial FAS (FAS/PFAS)* (e.g., 4-Digit Diagnostic Categories A–C: with Growth Ranks 1–4, Face Ranks 3–4, CNS Ranks 3 and/or 4, and Alcohol Ranks 2–4). Alcohol Rank 2 (unknown exposure) could only be present if the child had a diagnosis of full FAS because the Rank 4 FAS facial features are so specific to prenatal alcohol exposure [3,26]. Since the only clinical difference between FAS and PFAS in this study was the presence of growth deficiency in the former, FAS and PFAS were combined. In summary,

[a] Six of the 20 subjects in Group 1 had full FAS using the 4-Digit Code. Ten of the 14 PFAS had Rank 4 Faces, but received a diagnosis of PFAS because of their absence of growth deficiency (Growth Rank 1).
[b] Two subjects had agenesis (PFAS) or hypogenesis (FAS) of the corpus callosum.
[c] Definition of Rank 4 FAS Face: palpebral fissure lengths 2 or more SDs below the norm, and lip and philtrum are Rank 4 or 5 on the Lip-Philtrum Guide [24].
[d] All three children with moderate functional impairment had structural evidence of brain abnormality (microcephaly).
[e] The one child with unknown prenatal alcohol exposure had full FAS.

children in Group 1 had severe cognitive/behavioral dysfunction and the FAS facial phenotype.

2. Children in Group 2 had a four-digit diagnosis of *static encephalopathy/alcohol exposed (SE/AE)* (e.g., 4-Digit Diagnostic Categories E and F: with Growth Ranks 1–4, Face Ranks 1–2, CNS Ranks 3 and/or 4, and Alcohol Ranks 3–4). In summary, children in Group 2 had severe cognitive/behavioral dysfunction, comparable to Group 1, but did not have the FAS facial phenotype.
3. Children in Group 3 had a four-digit diagnosis of *neurobehavioral disorder/alcohol exposed (ND/AE)* (e.g., 4-Digit Diagnostic Categories G and H: with Growth Ranks 1–4, Face Ranks 1–2, CNS Rank 2, and Alcohol Ranks 3–4). In summary, children in Group 3 had prenatal alcohol exposure comparable to Groups 1 and 2, but had only mild to moderate cognitive/behavioral dysfunction and did not have the FAS facial phenotype.
4. Children in Group 4 (*healthy controls/no alcohol exposure*) were selected based on parental report that the child was healthy, had no academic concerns and no prenatal alcohol exposure [e.g., 4-Digit Diagnostic Category V: with Growth Ranks 1–2, FAS Face Ranks (no restrictions), CNS Rank 1, Alcohol Rank 1]. In summary, these were nonexposed, healthy, average to high-functioning controls.

With the use of the FASD terminology introduced by the Stratton et al. [6], the SE/AE group most closely reflects 'severe ARND' and the ND/AE group reflects 'mild ARND'. A comprehensive analysis of the between-group differences of these diagnostic features is presented in the neuropsychological/behavioral report for this study [9].

2.2. Study participation

Participation in the study involved five visits over a 4- to 6-week study period. The neuropsychological and sociodemographic data were collected during Visits 1 and 2. The MR data were collected during Visits 3 and 4. Outcomes of the neuropsychological assessments were shared with the caregivers on Visit 5 and submitted to the child's medical record with caregiver consent.

2.3. Sociodemographic and clinical assessment

A comprehensive sociodemographic and health/medication history of each child was obtained by parent interview and record review. Information included birth data, growth,

and all prenatal and lifetime exposures and adverse events. For subjects with FASD, most information was obtained at the time of their FASD diagnostic evaluation. All controls had a reported absence of prenatal alcohol exposure. All children had a standardized digital facial photograph taken at the time of enrollment. The facial photographs were analyzed using the FAS Facial Analysis Software [27] to document the magnitude of expression of the FAS facial phenotype [26]. A more detailed methodology and analysis of the socio-demographic and FASD diagnostic outcomes, including prenatal alcohol exposure histories, are presented in the neuropsychological/behavioral report from this study [9].

2.4. Neuropsychological and psychiatric assessments

A detailed description of the assessment battery and a comprehensive analysis of the between-group differences in neuropsychological outcome are presented in the neuropsychological/behavioral report for this study [9]. Briefly, a comprehensive, standardized assessment battery was administered to each child/caregiver by a psychologist masked to group assignment. The assessment battery was designed to capture the domains of potential neuropsychological impairment seen as the result of the typically diffuse brain damage arising from alcohol teratogenesis (e.g., deficits in executive functioning, visual–spatial skills, learning, memory, academic achievement, speech/language and attention) [8,28-32]. The neuropsychological/behavioral outcomes served to profile the study groups and confirm the groups were clinically and statistically distinct from one another; fundamental to the interpretation of the MR outcomes.

2.5. MR Scanner

All scans (MRI, MRS and fMRI) were acquired using a General Electric 1.5-T scanner in the Diagnostic Imaging Sciences Center at the University of Washington.

2.6. MRI and fMRI

The MRI and fMRI [12] components of this study are reported separately. Briefly, MRI was used to measure the size of the following brain regions: total brain, frontal lobe, caudate, putamen, hippocampus, corpus callosum and cerebellar vermis. fMRI was used to assess neuroactivation in selected brain regions during performance of N-back working memory tasks.

2.7. MR Spectroscopy

The MRS protocol included both single-voxel and multivoxel proton echo planar spectroscopic imaging (Fig. 1C–E). Both of these techniques were included because there are parts of the brain (axial slice at the level of the thalamus) which allow for multivoxel spectroscopy and there are parts of the brain (hippocampus) that best scan with single-voxel techniques due to magnetic field susceptibility problems near the base of the brain. Metabolite concentrations including Cho, NAA and Cre were obtained in absolute concentrations from the single-voxel spectroscopy and relative concentrations (Cho/Cre and NAA/Cre) from the multivoxel spectroscopy. Due to the vast amount of data acquired in the MRS component of this study, this report will focus on the single-voxel spectroscopic imaging. The multivoxel methodology and outcomes will be summarized in a separate, future publication.

2.7.1. Single voxel

Single-voxel MR spectroscopy targeted two 15×15×15-mm^3 regions of interest: a right frontal/parietal white matter region and a left hippocampus/basal nuclear region (Fig. 1C and D). The *hippocampus voxel* targeted the left hippocampus, but due to the size of the voxel, a portion of the left basal nuclear region was also included. The *white matter voxel* was predominated by white matter superior to the caudate and lateral to Regions 2 and 3 of the corpus callosum. Due to the size of the voxel, the superior tip of the caudate was included. The exact position of the MRS single voxel in three dimensions was overlayed on top of the 3D anatomical image for coregistration purposes to define the extent of tissue overlap as shown in Fig. 1C and D. Point-resolved-spectroscopy pulse sequence and the proton brain exam technique developed by General Electric [33] were used. This technique allows the MR technician to choose the location and size of the volume of interest and then fully automates the adjustment of (1) RF transmit power; (2) center frequency; (3) magnetic field homogeneity; (4) water suppression pulses parameters; and (5) phasing and display of the proton spectra. The 15×15×15-mm^3 voxels were positioned over the left hippocampal region and the right frontal/parietal white matter region. Data was then acquired using the following parameters: FID size 2048 complex points; spectral width 2000 Hz; spectral frequency of 63.8 MHz; TR/TE 2000/30 ms. The MRS signal was averaged 128 times so the total acquisition time was 4 min and 16 s. A water spectrum of the same region was also acquired (without water suppression) for quantification used in the LC model software. To optimize the LCModel parameters, phantoms with known concentrations of brain metabolites were prepared and scanned at various acquisition settings. From these spectra, libraries of phantom data, or basis sets, were created as detailed in the LCModel manual [34]. The MR signal strength from the metabolites scanned in the phantoms were used to calculate brain tissue concentrations. The absolute concentrations (millimoles) of Cho, NAA and Cre were computed as detailed in the LCModel manual [34,35] consistent with other techniques employing water referencing [36,37]. Following line fitting, both metabolites and water amplitudes were adjusted for acquisition parameters (receiver settings and transmitter gain) and voxel size compared to the phantom data. Water amplitudes were then adjusted using estimates of water molarity and attenuation [36] and multiplied by the tissue fraction within the voxel. Dividing adjusted metabolite peak amplitudes by this

corrected water term yielded metabolite concentrations. Tissue fraction was calculated by summing the CSF voxels within the larger MRS voxel which were segmented out using the high-resolution 3D anatomical image and then dividing the brain volume (total volume−CSF volume) by the total MRS voxel volume. In other words, this software does a correction for the MRS signal attenuation caused by CSF volume based on each individual high-resolution anatomical scan. Quantification of Cho, Cre and NAA required an additional step to correct metabolite data for the differential T2 of the phantom data compared to typical in vivo estimates [34]; this step served to scale concentration output similar to our previous work [37,38]. The ratios Cho/Cre and NAA/Cre were also assessed for comparison to a previous nonhuman primate FASD MRS study [16]. Throughout this report, these metabolites will be preceded by the letter 'h' or 'w' to reflect whether they were derived from the hippocampus or white matter voxels.

2.8. MRS Hypotheses

In this report, the analyses focus on neurometabolite differences between the four study groups. The hypotheses were derived from the previous nonhuman primate FASD MRS study [16], the human FASD MRS literature [21] and confirmation from the neuropsychological/behavioral [9] and MRI components of this study that the four study groups present along a continuum of increasing impairment.

2.8.1. Primary hypotheses

1. The mean Cho concentration (and/or Cho/Cre) in the white matter and/or hippocampus voxels will be lower in the FAS/PFAS group than in the control, ND/AE and SE/AE groups [16].
2. The mean Cho concentration and/or Cho/Cre in the white matter and/or hippocampus voxels will be higher in the functionally impaired but nondysmorphic alcohol-exposed groups (SE/AE and ND/AE) relative to the control group [16].
3. The mean NAA concentrations and/or NAA/Cre in the white matter and/or hippocampus voxels will decrease as one advances across the four study groups from controls to ND/AE to SE/AE to FAS/PFAS [21].

2.8.2. Secondary exploratory hypotheses

1. Cho and/or NAA concentrations in the hippocampal and/or white matter voxels will correlate with alterations in size of brain regions measured in the MRI component of this study.
2. Cho and/or NAA concentrations will correlate with prenatal alcohol exposure (quantity, frequency, timing) [16].

2.9. Statistical analysis

The statistical analyses used to confirm the four study groups were effectively balanced on age, gender and race as described in Part I of this study [9].

2.9.1. Primary hypotheses

Multivariate ANOVA was used to determine whether differences in mean metabolite concentrations existed among the study groups. If significant differences existed, the Duncan post hoc range test was used to identify which group means differed. The Duncan test makes pairwise comparisons using a stepwise procedure. Means were ordered from highest to lowest, and extreme differences were tested first. The Duncan test sets a protection level for the error rate for the collection of tests and identifies homogeneous subsets of means that are not different from one another at the P=.05 level. Age, gender and race were assessed as potential covariates. An a priori test for linear trend was included in the ANOVA to determine whether the mean concentration of Cho, Cho/Cre, NAA and/or NAA/Cre increased or decreased as one advanced across the study groups as specified in the hypotheses. Two-tailed P values of .05 were used throughout the analyses.

2.9.2. Secondary hypotheses

The objective of the secondary analyses was to test additional a priori hypotheses that further supported and extended the primary hypotheses. Due to the increased risk of type I errors resulting from multiple comparisons, all secondary analyses should be considered exploratory and P values interpreted accordingly. These secondary analyses take advantage of a rich dataset and generate hypotheses for future studies. Pearson correlation coefficients were used to assess the strength and direction of an association between two variables measured on continuous scales. ANOVA was used to compare means between groups. Chi-square tests were used to compare proportions between two or more groups.

2.9.3. Power/sample size

This study had 80% power or greater to detect the following effect sizes at a two-tailed alpha level of 0.05: (1) a difference in means equal to or greater than the standard deviation of the mean difference; (2) a correlation coefficient of 0.30 or greater; and (3) a 35-point or greater difference in proportions between two groups. Brooks et al. [37] demonstrated that changes in metabolite concentrations (NAA, Cre, Cho) as small as 12% could be confidently discerned when rigorous positioning guidelines and automated spectral fitting for measuring the cerebral metabolites were used.

3. Results

3.1. Metabolite concentrations across the four study groups: (primary hypotheses)

Metabolite concentrations did not vary by age, race, or gender in this study population.

3.1.1. Choline: white matter voxel

The mean absolute wCho concentration in the frontal/parietal white matter voxel, situated in the right hemisphere, was significantly lower (7% to 12% lower) in the FAS/PFAS

group relative to each of the other study groups (Table 2, Fig. 3A). No significant linear trends were observed across the study groups.

3.1.2. Choline: hippocampus voxel

The mean absolute hCho concentration in the hippocampus voxel was on average 7% to 8% lower in the FAS/PFAS group relative to each of the other study groups (Table 2). These differences were not statistically significant. The mean, absolute hCho concentration was 8% lower in the FAS/PFAS group relative to all other groups combined (mean 1.41, S.D. 0.21) (Table 2, Fig. 3B). This difference was near significant (t=−1.8, P=.07). No significant linear trends were observed across the study groups.

3.1.3. NAA: White matter and hippocampus voxels

The mean absolute NAA concentrations in the white matter and hippocampus voxels were on average 2% to 6% lower in the FAS/PFAS group relative to the control group, but no significant differences or linear trends were observed across the study groups (Table 2).

3.1.4. Cre: White matter and hippocampus voxels

No significant group differences or linear trends across the groups were observed in the mean absolute Cre concentrations in the white matter or hippocampus voxels (Table 2).

3.1.5. Cho/Cre: White matter and hippocampus voxels

The Cho/Cre ratios followed the same pattern as the absolute measures of Cho, but the magnitudes of the differences were slightly smaller and the variability of the differences slightly greater (Table 2). The mean Cho/Cre ratios in the white matter and hippocampus voxels were lower in the FAS/PFAS group relative to each of the other groups, but the overall ANOVAs were not statistically significant. Although it is customary not to conduct post hoc pairwise contrasts when the overall ANOVA is not significant, it is important to report from an exploratory standpoint that the mean Cho/Cre level was 9% lower in the FAS/PFAS group relative to the control group in both the white matter (t=2.0, P=.058) and hippocampus (t=1.9, P=.061) voxels. In addition, the mean hCho/Cre in the hippocampus voxel was significantly lower in the FAS/PFAS group than in the other three groups combined (mean 0.26, S.D. 0.03) (t=2.1, P=.041). The lower hCho/Cre ratios in the FAS/PFAS group appeared to be driven by low hCho, not by high hCre. No significant linear trends were observed across the groups.

3.1.6. NAA/Cre: White matter and hippocampus voxels

No significant group differences or linear trends across the groups were observed in mean NAA/Cre in the white matter or hippocampus voxels (Table 2).

Table 2

Duncan: The Duncan multiple comparison range test is reported if the overall ANOVA is statistically significant; commas separate groups with homogeneous means at P<.05. F: F-statistic. Linear trend: ANOVA unweighted linear trend across the four study groups. N/A: Not applicable.

[a] Linear trends involving Cho and Cho/Cre were assessed across three groups (control, ND/AE, SE/AE). All other linear trends were assessed across all four groups.

[b] Numerator degrees of freedom (df)=3; denominator df=total sample size minus 4.

[c] Numerator df=1; denominator df=total sample size minus number of groups.

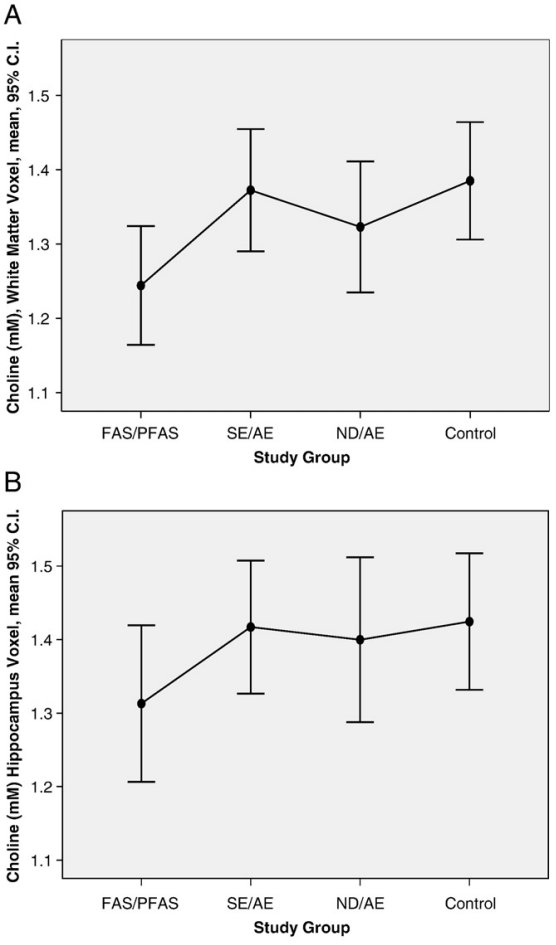

Fig. 3. Choline concentration (millimolar) across all the four study groups in the (A) frontal/parietal white matter and (B) hippocampus voxels.

3.2. Correlation between brain structure and metabolite concentrations (Secondary Hypothesis 1)

Significant differences in the sizes of brain regions between the four study groups were observed in the MRI component of this study. Correlations between metabolite concentrations and the size of brain regions assessed by MRI are presented in Table 3.

3.2.1. White matter voxel

The 15×15×15-mm^3 voxel in the right hemisphere included the superior tip of the caudate, but was predominated by white matter in the frontal/parietal region, lateral to Regions 2 and 3 of the corpus callosum (Fig. 1B). The wCho concentration decreased significantly with decreasing volume of the frontal lobe white matter and the midsagittal area of cerebellar vermis lobules 1–5. wCho also decreased significantly with decreasing midsagittal area of the corpus callosum as a whole and of each of its five subsections (most strongly with Region 3). wCho concentration was not significantly correlated with total brain volume. The wNAA concentration in the white matter voxel, situated lateral to Regions 2 and 3 of the corpus callosum, decreased significantly with decreasing midsagittal area of Region 3 of the corpus callosum.

3.2.2. Hippocampus voxel

The hCho concentration in the voxel that included the hippocampus and basal nuclear region in the left hemisphere decreased significantly with decreasing size of the left hippocampus, frontal lobe, corpus callosum, cerebellar vermis lobules 6–7, putamen and total brain (Table 3). hNAA, hCre, hNAA/Cre and hCho/Cre levels in the hippocampus voxel did not correlate significantly with the size of any brain region.

3.2.2.1. Partial voluming. It is important to note that a fixed-size voxel will capture more surrounding tissue in a smaller brain than in a larger brain. This is referred to as partial voluming. This could influence the mean metabolite concentration within a voxel, since metabolite concentrations vary normally by region and tissue type. The mean total volume of the brain for the FAS/PFAS group was 11% smaller than that for the control group. Thus, the fixed-size voxel in the hippocampal region would capture, on average, 11% more surrounding tissue in the FAS/PFAS group than in the control group. The mean hCho concentration in the FAS/PFAS group was 1.31 mM compared to 1.42 mM in the control group. If the lower hCho level in the FAS/PFAS group was solely an artifact of inclusion of 11% more tissue from adjoining regions, those adjoining regions would have to have exceptionally low hCho levels (0.32 mM or lower, if one assumes the remaining 89% of the voxel had a mean hCho level of 1.42 like the controls) to reduce the mean hCho level in the FAS/PFAS hippocampus voxel to 1.31. This magnitude of variation in Cho concentration between adjacent tissues far exceeds the normal regional variation reported in the literature [39,40]. Due to the size of the voxel placed in the hippocampus region, hippocampal and basal nuclear regions were captured in all subjects, including those in the control group (Fig. 1C). It would appear from visual inspection of the hippocampus voxel that inclusion of adjacent tissue would likely increase the white matter content of the voxel. Cho levels are typically higher in white matter than in gray matter [39-41]. If the FAS/PFAS voxel had a higher proportion of white matter, one would expect the hCho level in the hippocampus voxel in the FAS/PFAS group to be higher than that in the control group, not lower. The FAS/PFAS group was not the only group with microcephaly. Two subjects in the SE/AE group had microcephaly. The mean hCho concentrations in the two subjects with microcephaly were identical to the mean hCho level in the remaining subjects with normocephaly in

Table 3
MRS-MRI: Pearson correlation coefficients between the size of brain regions and absolute Cho and NAA concentrations in the left hippocampus and right white matter voxels

* $P<.05$.
** $P<.01$.

the SE/AE group. Thus, inclusion of adjacent tissue in the hippocampus voxel of these two subjects did not result in a lower hCho level. These results suggest, but do not confirm, that the lower hCho among the FAS/PFAS group is not solely an artifact of partial voluming.

3.3. Alcohol and metabolite concentrations (Secondary Hypothesis 2)

Differences in prenatal alcohol exposure histories between the four study groups are presented in Part I [9]. Although all three FASD groups had comparably high levels of exposure, the proportion of subjects with exposure in all three trimesters increased significantly as one advanced across the four groups from controls to FAS/PFAS. Several measures of prenatal alcohol exposure (quantity, frequency, timing) correlated with metabolite concentrations. For example, the wCho decreased significantly with increasing number of days per week of drinking reported just prior to pregnancy (Pearson correlation coefficient −.300, P=.031, n=52). Of the 53 alcohol-exposed subjects with documented exposure by trimester, 11 were reportedly exposed only in the first trimester, 9 only through the second trimester and 33 through all three trimesters. The mean wCho concentration was identical between the 16 controls (mean 1.39, S.D. 0.14) and the nine subjects with first trimester-only exposure (mean 1.39, S.D. 0.18) (Fig. 4). The mean wCho concentration was significantly lower among the 42 subjects with exposure through the second or third trimesters (mean 1.29, S.D. 0.18) than the 26 subjects with no exposure or exposure only through the first trimester (mean 1.39, S.D. 0.15) (t=2.1, P=.48). A near-significant correlation was observed between hCho and alcohol exposure when average number of days of drinking was multiplied by average number of drinks per occasion just prior to pregnancy (Pearson correlation coefficient −.281, P=.07, n=41). No significant correlations were observed between alcohol exposure and NAA or Cre concentrations in either the hippocampus or white matter voxels.

4. Discussion and conclusions

4.1. Primary MRS findings

The primary findings of this study include the following.

4.1.1. Frontal/parietal white matter voxel

A significant decrease (7–12%) was observed in the wCho concentration in the FAS/PFAS group relative to each of the other study groups. wCho in the frontal/parietal white matter voxel also decreased significantly with decreasing

Fig. 4. The mean Cho concentration (millimolar) in the frontal/parietal white matter voxel was significantly lower among the 46 subjects with alcohol exposure through the second and third trimesters than the 26 subjects with no exposure or exposure only through the first trimester.

corpus callosum size, frontal lobe white matter volume and increasing level of alcohol exposure. The wNAA concentration also decreased with decreasing size of corpus callosum region 3. The white matter voxel was aligned lateral to corpus callosum regions 2 and 3.

4.1.2. Hippocampus voxel

A near significant 8% decrease was also observed in the hCho concentration in the FAS/PFAS group relative to all other groups combined. The hCho concentration in the left hippocampus voxel decreased significantly with decreasing size of several brain regions, most notably the left hippocampus and the frontal lobe. The frontal lobe is innervated by cholinergic projections from the nucleus basilis of Meynert (basal nucleus) [42]. Both the basal nucleus and hippocampus were captured in the hippocampus voxel.

4.2. What do the Cho, NAA and Cre metabolite levels reflect?

4.2.1. NAA (A neuronal or axonal marker)

NAA is an amino acid found only in neurons and is synthesized in the brain. The –CH3 group of NAA is visible as a large narrow peak at 2.02 ppm in ^{1}H spectra obtained from human brain [14] (Fig. 5). The quantity of NAA varies regionally; some studies demonstrate it increases rostrally [41]. NAA is an indicator of neuronal development/degradation [43]. Reduced cranial NAA has been associated with axonal loss, active degradation of NAA, injured neurons, gliosis and/or dysfunctional or inhibited mitochondria.

4.2.2. Cre (A marker of metabolic activity)

The creatine signal, constituted of both creatine and phosphocreatine, reflects energy phosphate metabolism [13]. The Cre peak was thought to be relatively constant between individuals and in most brain areas [36]; therefore, it was often used as an internal reference. However, the accuracy of Cre as an internal standard is controversial, because Cre can vary under pathological conditions [44]. Cre is found in greater concentrations in gray matter than in white matter [45].

4.2.3. Cho (A marker of cell membrane integrity, myelination)

Cho is a precursor of two important molecules: phophatidylcholine (PtdCho) and acetylcholine (ACho). Cho is present in membranes of all cells, where it constitutes the polar subunit of PtdCho (i.e., lecithin), sphingomyelin and plasmalogens. Within cholinergic neurons, Cho is also the precursor for the synthesis of the neurotransmitter ACho [46]. The rate of ACho synthesis is regulated by the concentration of substrate Cho in cholinergic neurons. ACho is a neurotransmitter that is critical for many aspects of memory, cognition and mood [47]. The Cho peak at 3.22 ppm includes phosphorylcholine, glycerophosphocholine and a relatively negligible amount of free choline [14]. Phosphorylcholine and glycerophosphocholine constitute the precursors and degradation products of PtdCho. Thus, the Cho signal reflects the precursors and degradation products of PtdCho, not PtdCho itself. PtdCho is the membrane-bound form of Cho. An increase in the Cho peak is associated with an increase in membrane breakdown or turnover, myelination or inflammation, and has been observed in demyelinating diseases [48] and in brain tumors [49,50]. The major phospholipids in brain membranes are PtdCho, phosphatidylserine (PtdS) and phosphatidylethanolamine (PtdE). The phosphatides account for 85% of total brain phospholipids. Moreover, the choline in PtdCho represents about 80% of the total membrane-bound choline in the brain. PtdCho is a cellular phospholipid reservoir that

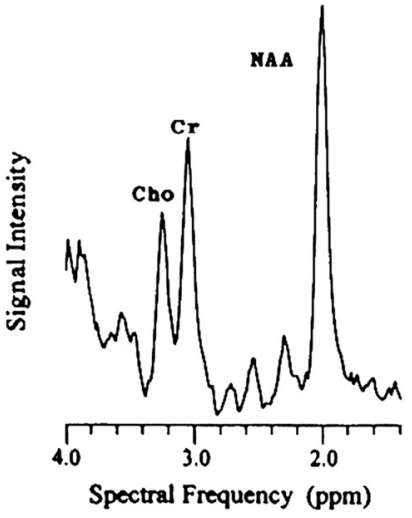

Fig. 5. Spectral frequency showing key metabolites: Cho, Cre and NAA.

provides free choline for ACho synthesis. When free extracellular Cho is absent, stimulated cells experience a decrease in PtdCho, PtdE and PtdS in the membranes. Addition of extracellular Cho protects the membranes from declines in PtdCho, PtdE and PtdS. The protective effect of exogenous Cho on the stimulus-induced depletion of membrane phosphatides depends on its concentration [51].

4.3. Regional variation of Cho, NAA and Cre in healthy individuals

Metabolite concentrations vary between white and gray matter tissue and between different regions of the brain in healthy individuals [39-41]. Wiederman et al. [41] reported that NAA in frontal gray matter is 15% lower than in frontal white matter and 14% lower than in parietal gray matter. Cho in frontal gray matter is 41% lower than in frontal white matter and 25% greater than in parietal gray matter. Cho in parietal gray matter is 53% lower than in parietal white matter. Cre in parietal gray matter is 13% higher than in parietal white matter. Deganonkar et al. [52] and Soher et al. [53] both found that Cho concentrations were higher in the genu than in the splenium of the corpus callosum of normal subjects. The cause of these regional variations is unclear, but it presumably reflects the cellular composition of the different brain regions, with glial cells believed to have higher Cho levels than neuronal cell types [54,55]. Their results were consistent with those of Pouwels and Frahm [40] who demonstrated an anterior–posterior concentration gradient in Cho along the midline, with the highest value in the frontal region among normal subjects.

4.4. Comparison to the nonhuman primate FASD MRS study

Consistent with the nonhuman primate FASD-MRS study [16], only the group with FAS/PFAS had significantly low wCho. In contrast to the nonhuman primate FASD MRS study, significant increases in Cho/Cre with increasing duration of alcohol exposure or functional impairment were not observed across the nondysmorphic control, ND/AE and SE/AE groups. It is important to note that advancements in design and technology afforded greater precision and accuracy in the current study. Although the scans from both studies were obtained in the same scanner and the white matter voxels were placed in the same region, advanced technology allowed the current voxel to be one-third the size of the voxel used in the primate study, and the absolute concentration of Cho (rather than the concentration relative to Cre) could now be accurately obtained. Most importantly, the human study included more severely affected individuals (20 with FAS/PFAS). The primate study had only one animal with facial dysmorphia and cognitive impairments consistent with the human equivalent of FAS. The remaining alcohol-exposed primates had outcomes commensurate with the SE/AE and ND/AE groups. No animal had microcephaly. In the primate study, it was speculated that the increased Cho/Cre signal in the primates may have been associated with membrane breakdown, based on the mechanism of cholinergic membrane vulnerability postulated by Wurtman et al. [56]. Wurtman et al. [56] hypothesized that Cho-deprived cholinergic neurons catabolize their own membranes to free up Cho for acetylcholine synthesis. They suggested that this dual use of Cho for membrane and neurotransmitter synthesis could make acetylcholine-producing cells particularly vulnerable to alterations in Cho levels. If acetylcholine was deficient, as has been reported in several animal models of in utero alcohol exposure [57], breakdown of cholinergic neuron membranes could serve as a compensatory measure to free up Cho for acetylcholine synthesis. If cholinergic membranes were breaking down, one would expect to observe elevated Cho/Cre signals. The only animal that deviated from the pattern of increased Cho/Cre with increasing cognitive/behavioral impairment was the one animal with FAS. That animal had the lowest Cho/Cre. It was speculated at the time that that animal may have sustained a level of damage that was beyond that of the other animals, perhaps severe enough to result in depletion of cholinergic nuclei. In such case, compensatory measures such as membrane breakdown would be less successful in achieving adequate acetylcholine levels and would result in a lower Cho/Cre signal. Schambra et al. [23] confirmed that in utero ethanol exposure can cause severe depletion of cholinergic nuclei. In the mildly affected brains of fetal mice, fewer cells were immunoreactive for CAT in the medial septal nucleus and diagonal band of Broca. In the severely affected brains, cells immunoreactive to CAT were totally absent. The severely affected mice had craniofacial anomalies consistent with those in humans with FAS and the single primate with 'FAS'. Schambra et al. [23] reported that without the projection of the cholinergic neurons of the medal septal nucleus and diagonal band of Broca to the hippocampus, hypoplasia of the hippocampus occurs and memory deficits as well as difficulty inhibiting unwanted behaviors could be expected, as is typically reported in FASD. As presented below, this is consistent with what was observed in the current study.

4.5. wCho concentration, frontal white matter volume and corpus callosum length

The volume of white matter in the frontal lobe and the length of the corpus callosum were significantly smaller in the FAS/PFAS group relative to all other groups (Fig. 6B and C). wCho in the voxel located in the right frontal/parietal white matter, lateral to Regions 2 and 3 of the corpus callosum, was also significantly lower in the FAS/PFAS group relative to all other groups (Fig. 6A). wCho levels decreased significantly with decreasing corpus callosum length and frontal white matter volume across all four study groups (Fig. 6D–F). And wNAA (a purported measure of neuronal or axon density) decreased with decreasing size of corpus callosum region 3. These findings suggest the decreased wCho levels among FAS/

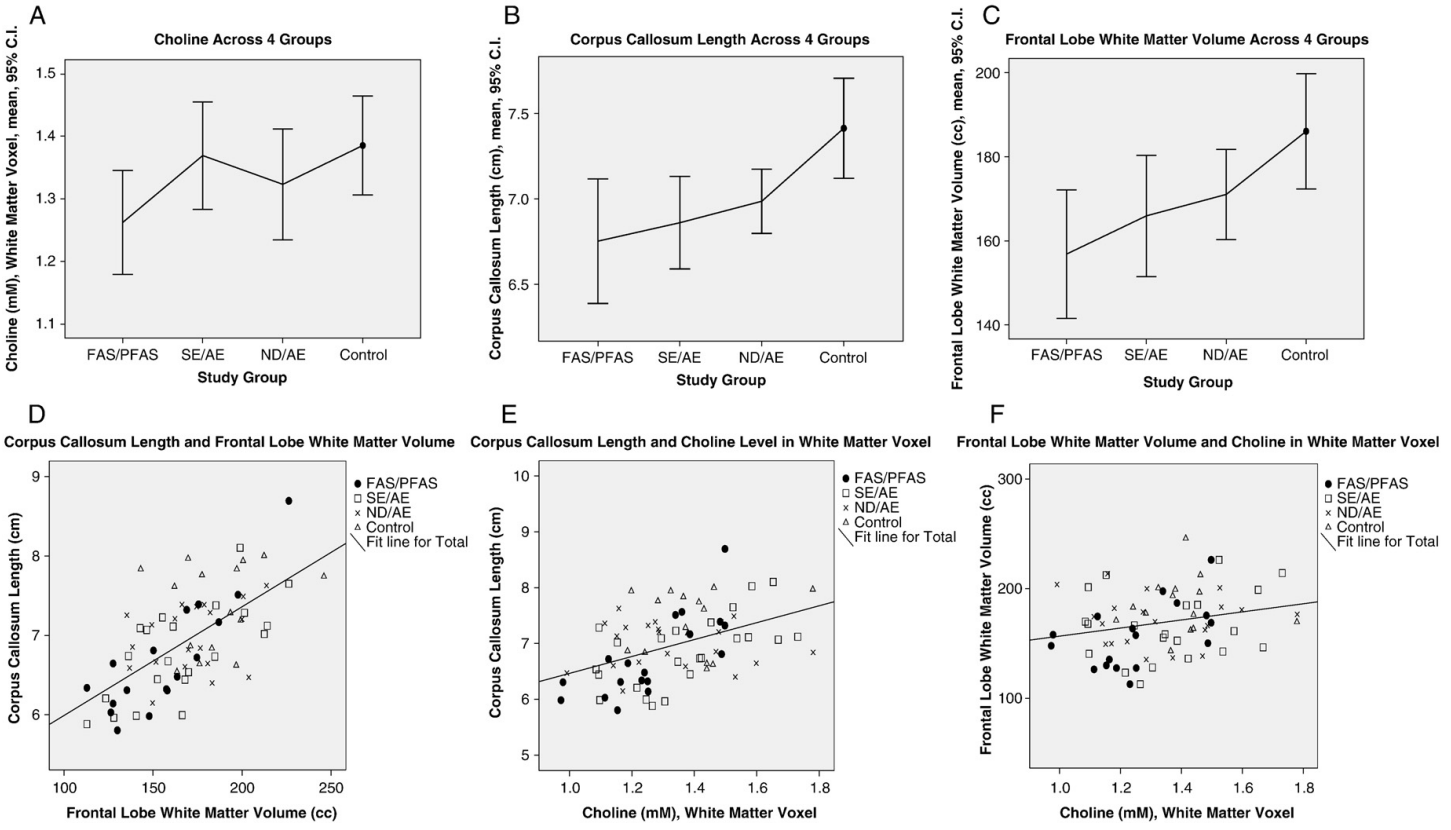

Fig. 6. The FAS/PFAS group had (A) significantly lower wCho concentration in the white matter voxel, (B) shorter corpus callosum lengths and (C) smaller frontal lobe volumes than controls. (D) The smaller the frontal lobe, the shorter the corpus callosum (Pearson correlation coefficient 0.64; $P<.001$). (E) The shorter the corpus callosum, the lower the wCho concentration (Pearson correlation coefficient 0.45; $P<.001$). (F) The smaller the frontal lobe, the lower the wCho concentration (Pearson correlation coefficient 0.24; $P=.04$). Four study groups: FAS/Partial FAS, SE/AE; ND/AE; healthy control with no alcohol exposure.

PFAS in this study may be reflective of white matter deficits among FAS/PFAS. Studies of the regional distribution of Cho in the normal brain show that Cho concentrations are higher in white matter than in gray matter due to the multiple phospholipid layers of myelin [40]. The main metabolites that contribute to the proton-detected Cho resonance in vivo are phosphocholine and glycerophosphocholine. These compounds are involved in the metabolism of the membrane lipids phosphatidylcholine (i.e., lecithin) and certain amidephosphocholines (i.e., sphingomyelin). Due to its high myelin content, white matter contains more lipids than gray matter (15.6% vs. 5.9% of total wet weight) and also shows a different lipid composition. Under normal physiologic conditions, both lecithin and sphingomyelin are subject to continuous breakdown and resynthesis. Cho concentrations in older children (5–18 years) are about 15% below the levels in infants and young children (0–5 years) [58]. This difference has been attributed to the fact that myelination during early childhood causes a pronounced turnover of membrane precursor molecules. Although there is also a continuous turnover of myelin in adults, the initial process of myelination requires a considerably larger amount of phosphocholine, which is both a key substrate for the glycerophospholipids in myelin and a major contributor to the proton MRS-detected Cho resonance.

Volumetric neuroimaging studies in FASD have also shown that white matter structures have suffered larger losses than gray matter structures [20,59,60]. High-resolution 3D MRI and whole-brain surface-based image analysis procedures [60] have shown increased gray matter density and decreased white matter density bilaterally in posterior temporal and inferior parietal regions in alcohol-exposed subjects, suggestive of abnormal myelination. Myelin is made of the membranous processes from glial cells that wrap themselves around axons [61]. Animal studies have shown that astroglial cells, which are integral in the development of myelin, are particularly affected by alcohol exposure [62,63].

4.6. hCho and frontal lobe volume

The hippocampus voxel included the hippocampus and basal nuclear region (nucleus basilis of Meynert). During brain development, cholinergic neurons project from the nucleus basilis of Meynert to the frontal lobe [42]. Lauder and Schambra [64] reported that prenatal ethanol exposure in the mouse led to severely affected development of the forebrain CNS cholinergic system with deleterious effects on the synaptic targets of these cholinergic neurons, including reduced thickness of the cerebral cortex. The frontal lobe was significantly smaller (relative and absolute) in FAS/PFAS relative to all other groups (Fig. 7A). The hCho concentration in the voxel placed in the left hippocampus was near significantly lower in the FAS/PFAS (1.31±.23) group relative to all other groups combined (1.41±.21) (t=−1.7, P=.07) (Fig. 7B). hCho in the hippocampus/basal nuclear

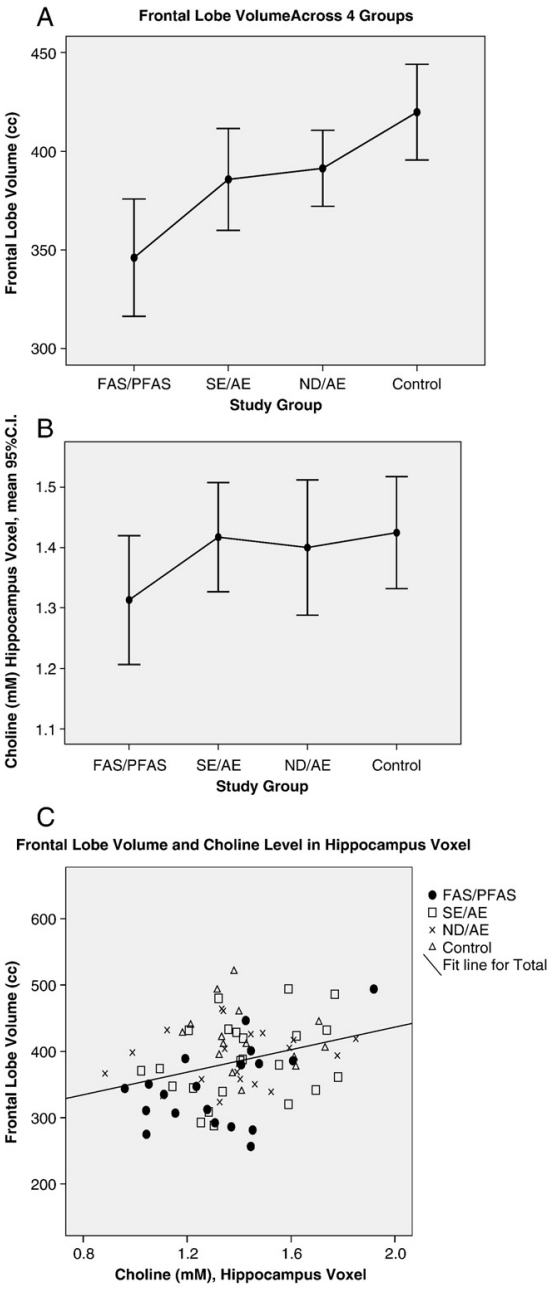

Fig. 7. Correlation between frontal lobe volume (cubic centimeter) and choline concentration (millimolar) in the hippocampus voxel containing the nucleus basilis of Meynert. The frontal lobe is innervated by cholinergic projections from the nucleus basilis of Meynert. (A) Frontal lobe volume was significantly smaller in FAS/PFAS relative to all other groups. (B) hCho in the hippocampus voxel was significantly lower in the FAS/PFAS group relative to all other groups. (C) Frontal lobe volume decreased significantly with decreasing hCho concentration in the hippocampus voxel.

voxel decreased significantly with decreasing size of the frontal lobe (Fig. 7C).

4.6.1. hCho and hippocampus size

The hippocampal system plays a critical role in learning and memory. The absolute size of the left hippocampus became significantly smaller as one advanced across the four study groups from the control group to the FAS/PFAS group (Fig. 8A). hCho in the voxel placed in the left hippocampus was near significantly lower in the FAS/PFAS (mean±S.D. 1.31±.23) group relative to all other groups combined (mean±S.D. 1.41±.21) (t=−1.7, P=.07) (Fig. 8B). hCho decreased significantly with decreasing absolute volume of the left hippocampus (Pearson correlation coefficient .22, P=.049) (Fig. 8C). The volume of the left hippocampus decreased significantly with increasing impairment on measures of visual memory using the Rey Complex Figure Test [65], verbal memory using the California Verbal Learning Test [66] and working memory on an N-back task [67]. Memory performance can be correlated with cholinergic activity in the hippocampus, measured by high affinity Cho uptake or choline acetyltransferase activity. Moreover, mechanical disruption of the septal projections to the hippocampus or lesions of the medial septal nuclei disturb memory retention [68]. Gibson et al. [69] reported that chronic prenatal ethanol exposure

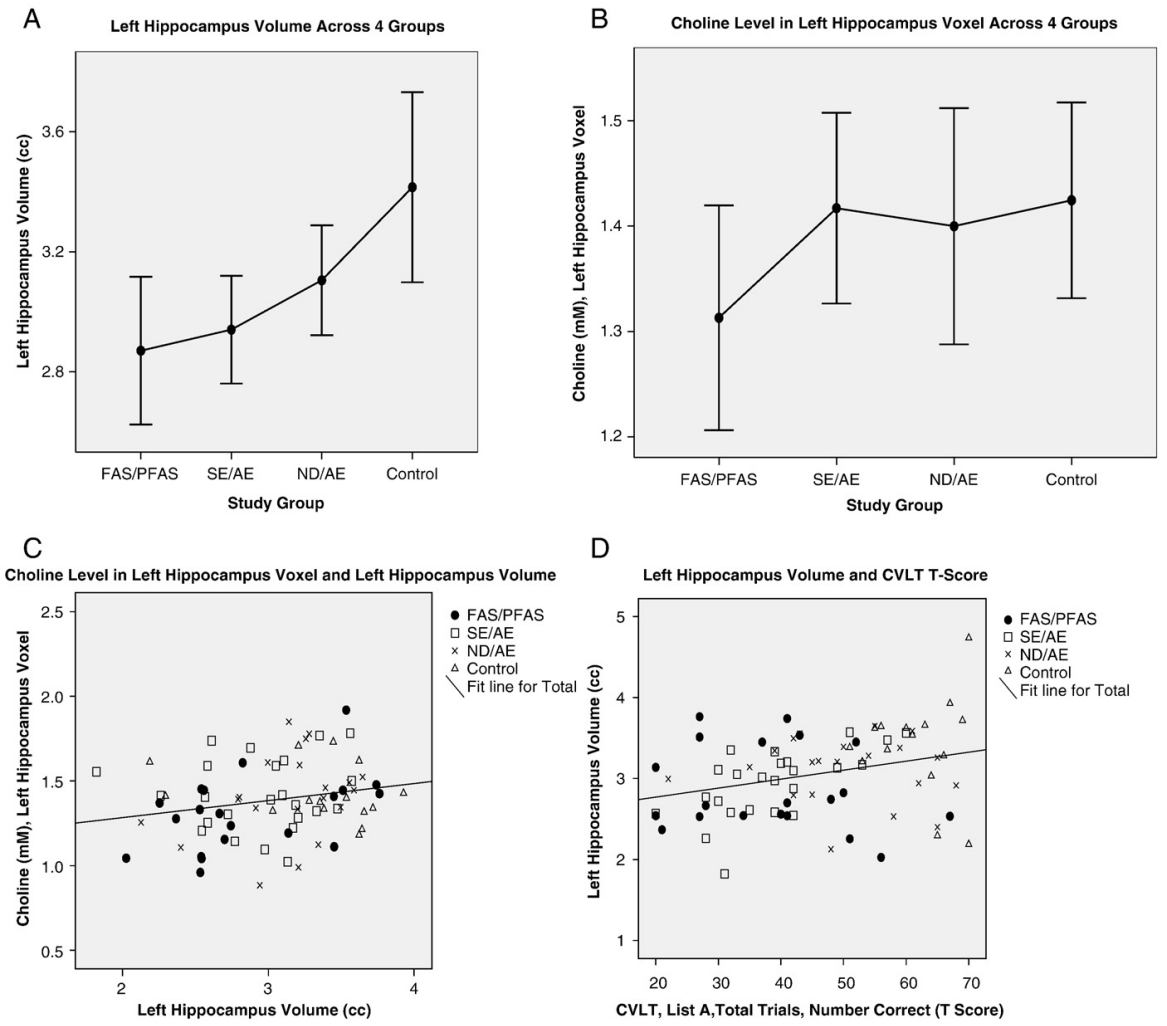

Fig. 8. Intercorrelations between hCho, hippocampus volume and cognition. (A) Hippocampus volume increased significantly as one advances across the four study groups from FAS/PFAS to controls. (B) hCho in the hippocampus voxel was lower in the FAS/PFAS group. (C) hCho decreased significantly with decreasing size of the hippocampus (Pearson correlation coefficient 0.22, P=.049.). (D) Performance on the California Verbal Learning Test decreased significantly with decreasing hippocampus volume (Pearson correlation coefficient 0.30, P=.007).

produced hyperactivity, decreased the brain and hippocampal weights with no change in body weight and decreased the number of hippocampal CA1 pyramidal cells by 25–30% in the guinea pig.

4.6.2. Morphogenetic roles of acetylcholine

Early work by Sulik and Johnston [70,71], Sulik [72], Schambra et al. [23] and Lauder and Schambra [64] illustrated the teratogenic impact of alcohol on the developing cholinergic system. As reported by Lauder and Schambra [64], in the adult nervous system, neurotransmitters mediate cellular communication within neuronal circuits. In developing tissues, neurotransmitters subserve growth regulatory and morphogenetic functions. Accumulated evidence suggests that ACho, released from growing axons, regulates growth, differentiation and plasticity of developing CNS neurons. In addition to intrinsic cholinergic neurons, the cerebral cortex and hippocampus receive extensive innervation from cholinergic neurons in the basal forebrain. Acute exposure to ethanol in early gestation (which prevents formation of basal forebrain cholinergic neurons) significantly compromises cortical development and produces persistent impairment of cognitive functions. The results of this study provide further evidence of the vulnerability of the cholinergic system in FASD and are particularly compelling considering recent promising intervention outcomes using neonatal and perinatal choline supplementation in FASD [73,74].

4.7. FASD MRS human literature

Very few MRS studies have been conducted to date in the field of FASD. Cortese et al. [22] conducted an MRI/MRS investigation of the caudate region in a very small population of children (seven FAS and two FAE by gestalt diagnosis, and four controls). The investigators reported that FAS and FAE were defined on prenatal alcohol exposure and facial dysmorphia, but did not report what facial dysmorphia distinguished their FAS and FAE groups. When the seven children with FAS were compared to the four controls, the FAS group (1) did not have significantly smaller total brain volumes; (2) did have significantly smaller absolute, but not relative caudate volumes; and (3) had significantly higher NAA/Cre and NAA levels in the caudate. No significant Cho or Cho/Cre differences were reported. The investigators used one-tailed *P* values for all tests of significance. In contrast to the FASD literature [75,76], FAS groups typically have significantly smaller brain volumes, by clinical definition. And in contrast to the general MRS literature [43], including the current FASD MRS study and the FASD MRS study conducted by Fagerlund et al. [21], neuronal dysfunction is typically associated with a decrease in absolute concentration of NAA, not an increase. Although Cortese et al. [22] reported comparisons between the two children with FAE and four controls, these samples were too small to provide clinically or statistically meaningful results.

Fagerlund et al. [21] conducted an MRS study on 10 adolescents/adults with FASD (three FAS, three PFAS and four ARND, using the Hoyme FASD diagnostic guidelines [77]) and 10 healthy controls. All subjects with FAS and PFAS had microcephaly. The controls were matched to the FASD group on head circumference. The FASD group had lower NAA/Cre and NAA/Cho ratios than the control group in several brain regions, but not in the regions that were the focus of this report (hippocampus and caudate). The authors noted, however, that the decreased NAA/Cre and NAA/Cho metabolite ratios appeared to be driven by higher Cho or Cre in the denominators, not by lower NAA in the numerators. Although their absolute metabolite intensities were subject to error, they noted that, on average, NAA was 7% higher and Cre and Cho were 14% higher in their FASD group relative to their control group. Separating numerator from denominator effects is problematic in studies reporting metabolite ratios. Prior to advancements in technology that now allow absolute metabolite levels to be computed, early studies, including the nonhuman primate study [16], had to assess Cho and NAA relative to Cre. The Cre was used as an internal standard with the hope that Cre reflected a stable metabolite across regions and individuals. But numerous studies [14,41,44,52,78] have since demonstrated that Cre varies by region and clinical status. The mean Cre concentration in the current study varied by as much as 9% between regions and study groups. The variability of these Cre concentrations had a marked impact on some of the metabolite ratios observed in the current study. For example, the mean absolute concentrations of wNAA and wCre were both 9% lower in the FAS/PFAS group than in the controls. But when these metabolites were presented as a ratio (wNAA/Cre), the mean wNAA/Cre level for the two groups was identical. Fagerlund et al. [21] did not observe significantly lower Cho/Cre in their FASD group relative to their control group. The current study would not have observed significantly lower wCho either if the three FASD groups (FAS/PFAS, SE/AE and ND/AE) had been combined and the Cho had been assessed as a ratio with Cre. The significantly low absolute concentration of wCho was unique to the FAS/PFAS group in the current study. Many factors differ between the two studies which likely contributed to the different outcomes. The Fagerlund et al. [21] study had a smaller sample size, used different FASD diagnostic criteria, matched their FASD and controls on a key diagnostic feature of FAS (microcephaly), combined their FASD groups and assessed metabolite ratios rather than absolute concentrations of the metabolites.

4.8. Limitations

A limitation of the current study is the use of a fixed-size voxel in brains that vary in size. A fixed-size voxel will include more surrounding tissue in a smaller brain than a larger brain. This, in turn, could influence the mean

metabolite concentration within the voxel, since metabolite concentrations vary normally by region and tissue type. wCho levels did not vary significantly with total brain size. hCho levels were positively correlated with total brain size. While secondary analyses suggest the lower mean hCho among the FAS/PFAS group was unlikely to be due entirely to partial voluming, the impact of partial voluming needs to be addressed in future studies. One might consider matching controls to cases on total brain size to eliminate the partial voluming problem, but in so doing, the definition of a healthy, typically developing comparison group is compromised if the subjects in the comparison group have microcephaly.

4.9. Conclusion

This study demonstrated that the FAS/PFAS group has significantly low Cho levels that may reflect white matter deficits in this group. NAA and Cre were comparable between the FASD groups and the controls. This study provides further evidence of the vulnerability of the cholinergic system in FASD and is particularly compelling what with the growing FASD literature on positive outcomes associated with choline supplementation.

Acknowledgments

We would like to acknowledge Katherine Field, Olivia Liang, Winslow Johnson and Katherine Keller for their assistance in the measurement of MRI scans. A special thanks is extended to the children and their families who so kindly contributed time and effort to this study.

Abstract A comprehensive neuropsychological/psychiatric, MR imaging, (MRI), MR spectroscopy (MRS), and functional MRI (fMRI) assessment was administered to children with fetal alcohol spectrum disorders (FASD) to determine if global and/or focal abnormalities could be identified, and distinguish diagnostic subclassifications across the spectrum. The four study groups included: 1. FAS/Partial FAS; 2. Static Encephalopathy/Alcohol Exposed (SE/AE); 3. Neurobehavioral Disorder/Alcohol Exposed (ND/AE); and 4. healthy peers with no prenatal alcohol exposure. fMRI outcomes are reported here. The neuropsychological/psychiatric, MRI, and MRS outcomes are reported separately. fMRI was used to assess activation in seven brain regions during performance of *N*-back working memory tasks. Children across the full spectrum of FASD exhibited significant working memory deficits and altered activation patterns in brain regions that are known to be involved in working memory. These results demonstrate the potential research and diagnostic value of this non-invasive MR tool in the field of FASD.

Introduction

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal alcohol consumption during pregnancy. FAS is defined by growth deficiency, a unique cluster of minor facial anomalies, and central nervous system (CNS) dysfunction and/or structural brain abnormalities [1]. The cognitive/behavioral problems in this condition stem from prenatal brain damage. Not all individuals with prenatal alcohol exposure present with measurable CNS dysfunction or structural brain abnormalities,

and not all who present with measurable CNS dysfunction or structural brain abnormalities have FAS. Recently, the term Fetal Alcohol Spectrum Disorders (FASD) was coined to depict the spectrum of outcomes observed among individuals with prenatal alcohol exposure. FASD is not a medical diagnosis. Rather, diagnoses like FAS, Partial FAS, Static Encephalopathy/Alcohol Exposed, and Neurobehavioral Disorder/Alcohol Exposed fall under the umbrella of FASD. The degree of brain damage among individuals with prenatal alcohol exposure may vary from microcellular and neurochemical aberrations to gross structural anomalies. Similarly, cognitive/behavioral dysfunction varies along the full continuum from mild developmental delay or learning disabilities to global developmental disability. The specificity of the FAS facial phenotype to prenatal alcohol exposure lends credence to the clinical judgment that the cognitive and behavioral dysfunction observed in individuals with FAS is due, at least in part, to brain damage caused by a teratogen [2–4]. Unfortunately, without the unique facial phenotype of FAS or at least a severe or clinically obvious expression of brain damage, the neurodevelopmental disabilities of an individual affected by prenatal alcohol exposure often go unrecognized and inappropriately served [5].

Many individuals with prenatal alcohol exposure exhibit cognitive difficulties and significant maladaptation that prevent them from leading productive, independent lives [6, 7]. Across the population, the profile of cognitive dysfunction among individuals with prenatal alcohol exposure is highly variable, though there are some commonalities in functional compromise among subgroups, and conceptual models of overarching deficits have been proposed [8]. However, no single behavioral phenotype specific to alcohol teratogenicity has been described. Without a behavioral phenotype specific to the teratogen alcohol, attributing an alcohol-exposed child's dysfunction to brain damage is often questionable at a clinical level [4]. If indisputable evidence of brain damage (e.g., alterations in neurostructure, neurometabolites and/or neuroactivation) could be found in these individuals, and linked to behavioral deficit, diagnostic efforts could be improved. The "disability" of these alcohol-exposed children would be clearly established, and help facilitate eligibility for needed services. Further, if specific alterations in neurostructure, neurometabolites, and/or neuroactivation could be linked to clinically meaningful, discrete neuropsychological deficits, development of appropriate intervention programs could be accelerated.

The overall goal of this research study was to determine if magnetic resonance imaging, (MRI), magnetic resonance spectroscopy (MRS), and/or functional MRI (fMRI) could serve as non-invasive methods for definitively identifying global and/or focal brain abnormality across the full continuum of FASD, and distinguish diagnostic subclassifications within the spectrum. The results of this comprehensive study are presented in four separate reports: fMRI (presented here), and the neuropsychological/behavioral [9], MRI (submitted for publication), and MRS [10] outcomes reported separately.

fMRI is a potentially powerful tool that can assess regional brain activation in response to performance on specific cognitive, perceptual, or motor tasks. Many studies, spanning a broad array of disease states and disorders, have used this tool to document activation that is different in intensity and/or spatial extent in subjects with brain damage and/or impairment on the specific tasks being assessed [11–13]. Only three FASD fMRI studies have been published to date. Significant differences in brain activation patterns were observed between FASD and Control groups during verbal learning [14], response inhibition [15], and spacial working memory [16] tasks. All of these tasks require higher-order cognitive abilities that are often deficient in individuals with FASD [17–21]. All three studies clearly demonstrated the value of fMRI in this clinical population. The present study extends this line of inquiry to nonspatial working memory, using an fMRI *N*-back paradigm. Working memory is the ability to hold and manipulate information online in the brain [22, 23]. The constituent processes involved in working memory are encoding, rehearsal, storage, and executive processes on the contents of stored memory [13]. Working memory is subserved by a neurocognitive network comprising regions involved in attention (anterior cingulate), executive function (dorsolateral prefrontal cortex), and short-term mnemonic strategies (parietal cortex and precuneous) [24–26].

Materials and methods

Subjects and study groups

The protocol was approved by the University of Washington Human Subjects Review Board. The three FASD groups were selected from among 1,200 patients previously diagnosed by an interdisciplinary team in the WA State FAS Diagnostic & Prevention Network (FAS DPN) of clinics using the FASD 4-Digit Code [27, 28]. Briefly, the four digits of the FASD 4-Digit Code reflect the magnitude of expression of the four key diagnostic features of FASD, in the following order: (1) growth deficiency, (2) characteristic FAS facial phenotype, (3) CNS structural/functional abnormalities, and (4) prenatal alcohol exposure (Fig. 1). The magnitude of expression of each feature is ranked independently on a four-point Likert scale, with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong "classic" presence of the FASD feature. Each Likert

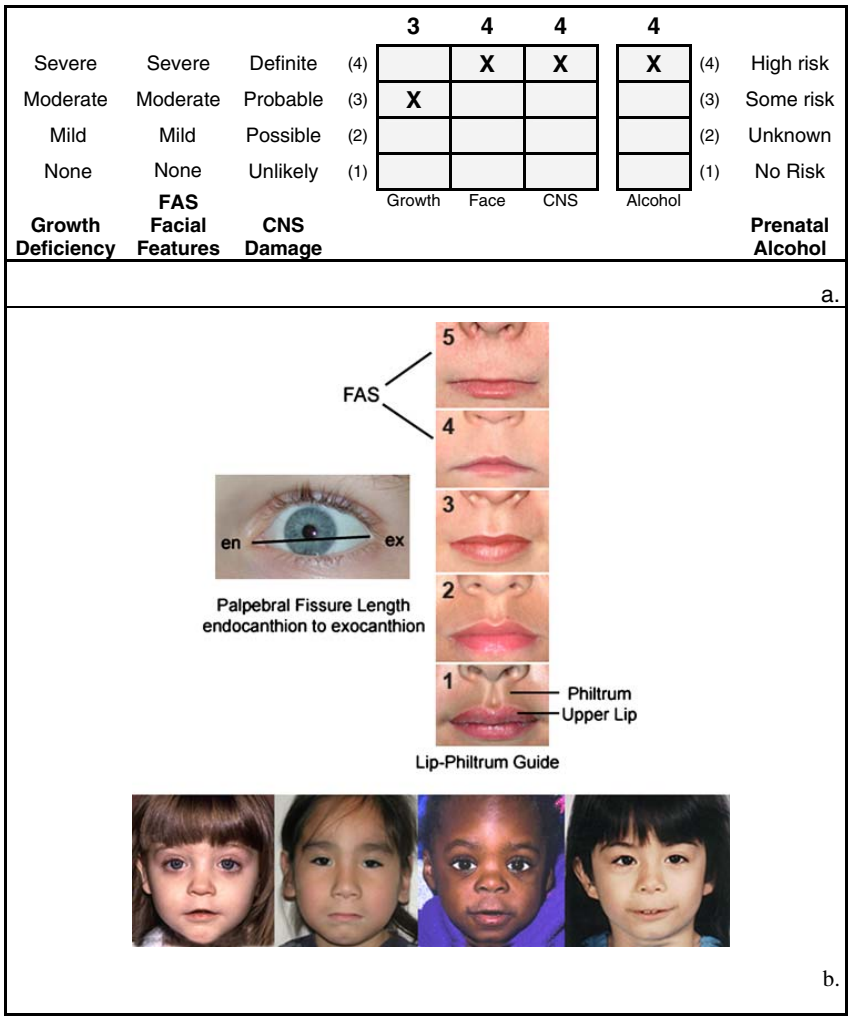

Fig. 1 **a** FASD 4-Digit Diagnostic Code grid. FASD is defined by growth deficiency, specific FAS facial features, evidence of CNS damage and prenatal alcohol exposure. The 4-Digit Code ranks each of these areas on four-point, case-defined, Likert scales. The 4-Digit Code (*3444*) inserted in the grid is one of 12 codes that meet the diagnostic criteria for FAS. **b** FASD 4-Digit Code FAS facial phenotype. The rank 4 FAS facial phenotype as defined by the 4-Digit Diagnostic Code requires the presence of all three of the following anomalies: (1) palpebral fissure lengths 2 or more standard deviations below the norm mean; (2) a smooth philtrum (rank 4 or 5 on the Lip–Philtrum Guide), and (3) a thin upper lip (rank 4 or 5 on the Lip–Philtrum Guide). Examples of the rank 4 FAS facial phenotype for Caucasian, Native American, African American, and Asian American children are shown. © 2009 University of Washington. Reproduced with permission from Susan Astley, Ph.D.

rank is specifically case defined. There are 256 possible 4-Digit Diagnostic Codes, ranging from 1,111 to 4,444. Each 4-Digit Diagnostic Code falls into one of 22 unique clinical diagnostic categories (labeled A through V). Seven of the 22 diagnostic categories (4-Digit Categories A–C and E–H) fall under the umbrella of FASD (A. FAS/Alcohol Exposed, B. FAS/Alcohol Exposure Unknown, C. Partial FAS/Alcohol Exposed, E–F. Static Encephalopathy/Alcohol Exposed, and G–H. Neurobehavioral Disorder/Alcohol Exposed). The three FASD study groups in the current study represent these FASD diagnostic categories. The control population was selected primarily from a large cohort of children enrolled at birth in a University of Washington study of typical development conducted through the Department of Speech and Hearing Sciences. With the enrollment of each child in the FAS/PFAS group, a child matched on age (within 6 months), gender, and race was randomly identified and invited to enroll from the eligible SE/AE, ND/AE and Control populations. A stratified–randomized block design was used to select children with FAS/PFAS from the eligible clinic population to achieve an equal distribution of gender, the full eligible age range (8–15.9 years), and a racial distribution that matched the clinic population.

The study enrollment procedure produced a sample of 81 children in the overall MR study [9]. A representative subset of 71 children contributed data to the fMRI component of this study (Table 1). Each of the four fMRI study groups had 13–22 subjects successfully balanced on age, gender, and race. Each study group spanned the full

	Other	1 (6.3)	9 (40.9)	3 (15.0)	1 (7.7)
Growth rank from 4-Digit Code: *n* (%)	1. none	9 (56.3)	13 (59.1)	12 (60.0)	12 (92.3)
	2. mild	1 (6.3)	2 (9.1)	6 (30.0)	1 (7.7)
	3. moderate	4 (25.0)	3 (13.6)	1 (5.0)	0 (0.0)
	4. severe	2 (12.5)	4 (18.2)	1 (5.0)	0 (0.0)
Face rank from 4-Digit Code: *n* (%)	1. none	0 (0.0)	3 (13.6)	6 (30.0)	9 (69.2)
	2. mild	0 (0.0)	19 (86.4)	14 (70.0)	4 (30.8)
	3. moderate	3 (18.8)	0 (0.0)	0 (0.0)	0 (0.0)
	4. severe[d]	13 (81.3)	0 (0.0)	0 (0.0)	0 (0.0)
CNS ranks 1–3 from 4-Digit Code					
Level of functional impairment: *n* (%)	1. none	0 (0.0)	0 (0.0)	0 (0.0)	13 (100.0)
	2. moderate	0 (0.0)	3 (13.6)[g]	20 (100.0)	0 (0.0)
	3. severe	16 (100.0)	19 (86.4)	0 (0.0)	0 (0.0)
CNS rank 4 from 4-Digit Code	Structural/neurological abnormality present: *n* (%)	9 (56.3)	6 (27.3)	0 (0.0)	0 (0.0)
Alcohol rank from 4-Digit Code: n (%)	1. No exposure	0 (0.0)	0 (0.0)	0 (0.0)	13 (100.0)
	2. Unknown exposure[e]	1 (6.3)	0 (0.0)	0 (0.0)	0 (0.0)
	3. Confirmed exposure. Level moderate or unknown	5 (31.3)	11 (50.0)	11 (55.0)	0 (0.0)
	4. Confirmed exposure: Level high	10 (62.5)	11 (50.0)	9 (45.0)	0 (0.0)

A comprehensive profile of the entire study sample is presented in Astley et al. [9]

[a] Percent female: chi-square=0.8 (*df* 3), p=0.84

[b] Mean age: ANOVA $F(3, 67)$ 3.2, p=0.56

[c] Percent Caucasian: chi-square=4.0 (*df* 3), p=0.26

[d] Definition of rank 4 FAS face: palpebral fissure lengths 2 or more SDs below the mean norm, and lip and philtrum are Rank 4 or 5 on the Lip–Philtrum Guide [27]

[e] The one child with unknown prenatal alcohol exposure had full FAS

[f] Four of the 16 subjects in group 1 had full FAS using the FASD 4-Digit Code. Nine of the 12 PFAS had rank 4 faces, but received a diagnosis of PFAS because of their absence of growth deficiency (growth rank 1)

[g] All three children with moderate functional impairment had structural evidence of brain abnormality (microcephaly)

age range of 8.0 to 15.9 years at the time of enrollment. The diagnostic features specific to each group were as follows:

1. Children in Group 1 had a 4-Digit diagnosis of FAS or Partial FAS (*FAS/PFAS*) (e.g., 4-Digit Diagnostic Categories A, B, C: with Growth Ranks 1–4, Face Ranks 3–4, CNS Ranks 3 and/or 4, and Alcohol Ranks 2–4) (Fig. 1). Alcohol Rank 2 (unknown exposure) could only be present if the child had a diagnosis of full FAS because the Rank 4 FAS facial features are so specific to prenatal alcohol exposure [3, 29]. Since the only clinical difference between FAS and PFAS in this study was the presence of growth deficiency in the former, FAS and PFAS were combined. Children in Group 1 had severe cognitive/behavioral dysfunction and the FAS facial phenotype.
2. Children in Group 2 had a 4-Digit diagnosis of Static Encephalopathy/Alcohol Exposed (*SE/AE*) (e.g., 4-Digit Diagnostic Categories E and F: with Growth Ranks 1–4, Face Ranks 1–2, CNS Ranks 3 and/or 4, and Alcohol Ranks 3–4). Children in Group 2 had severe cognitive/behavioral dysfunction, comparable to Group 1, but did not have the FAS facial phenotype.
3. Children in Group 3 had a 4-Digit diagnosis of Neurobehavioral Disorder/Alcohol Exposed (*ND/AE*) (e.g. 4-Digit Diagnostic Categories G and H: with Growth Ranks 1–4, Face Ranks 1–2, CNS Rank 2, and Alcohol Ranks 3–4). Children in Group 3 had prenatal alcohol exposure comparable to Groups 1 and 2, but had only mild to moderate cognitive/behavioral dysfunction, and did not have the FAS facial phenotype.

4. Children in Group 4 (Healthy *Controls*/No Alcohol Exposure) were selected based on parental report that the child was healthy, had no academic concerns, and no prenatal alcohol exposure (e.g., 4-Digit Diagnostic Category V: with Growth Ranks 1–2, FAS Face Ranks (no restrictions), CNS Rank 1, Alcohol Rank 1).

Using the FASD terminology introduced by the Stratton et al. [6], the SE/AE group most closely reflects 'severe ARND' and the ND/AE group reflects 'mild ARND'. A comprehensive analysis of the between-group differences of these diagnostic features is presented in the neuropsychological/behavioral report for this study [9].

Study participation

Participation in the study involved five visits over a 4 to 6 week study period. The neuropsycological and sociodemographic data were collected during visits 1 and 2. The MR data were collected during visits 3 and 4. Outcomes of the neuropsycological assessments were shared with the caregivers on visit 5, and submitted to the child's medical record with caregiver consent.

Sociodemographic and clinical assessment

A comprehensive sociodemographic and health/medication history of each child was obtained by parent interview and record review. Information included birth data, growth, and all prenatal and lifetime exposures and adverse events. For subjects with FASD, most information was obtained at the time of their FASD diagnostic evaluation. All controls had a reported absence of prenatal alcohol exposure. All children had a standardized digital facial photograph taken at the time of enrollment. The facial photographs were analyzed using the FAS Facial Analysis Software [30] to document the magnitude of expression of the FAS facial phenotype [29]. A more detailed methodology and analysis of the sociodemographic and FASD diagnostic outcomes, including prenatal alcohol exposure histories, are presented in the neuropsychological/behavioral report from this study [9].

Neuropsychological and psychiatric assessments

A detailed description of the assessment battery and a comprehensive analysis of the between-group differences in neuropsychological outcome are presented in the neuropsychological/behavioral report for this study [9]. Briefly, a comprehensive, standardized assessment battery was administered to each child/caregiver by a psychologist masked to group assignment. The assessment battery was designed to capture the domains of potential neuropsychological impairment seen as the result of the typically diffuse brain damage arising from alcohol teratogenesis [8, 20, 31–34]. The neuropsychological/behavioral outcomes served to profile the study groups and confirm the groups were clinically and statistically distinct from one another; fundamental to the interpretation of the MR outcomes.

MR scanner

All scans (MRI, MRS, and fMRI) were acquired using a General Electric 1.5 Tesla scanner in the Diagnostic Imaging Sciences Center (DISC) at the University of Washington.

MRI and MRS

The MRI and MRS [10] components of this study are reported separately. Briefly, MRI was used to measure the size of the following brain regions: total brain, frontal lobe, caudate, putamen, hippocampus, corpus callosum, and cerebellar vermis. MRS was used to measure the concentrations of three neurometabolites: (1) choline, a marker of cell membrane stability and myelination, (2) N-acetyl aspartate, a neuronal or axonal marker, and (3) creatine, a marker of metabolic activity in selected brain regions.

fMRI: *N*-back working memory task

An existing fMRI paradigm [35] was modified for this clinical population to assess activation in specific brain regions during working memory. In agreement with other fMRI studies of working memory [24–26], testing with normal controls using this paradigm demonstrated consistent activation of the dorsolateral prefrontal cortex (DLPFC). The *N*-back task [36] involved viewing a series of images (e.g., faces), one at a time, and deciding whether the present image matched the image presented *n* images back, where *n* is 1 or 2. The images were four male and four female faces. *N*-back paradigms often use numbers for stimuli. Because research indicates alcohol-affected children often have math deficits and difficulty with numbers, faces were selected as the stimuli. Two tasks were developed, one using a 0-back and 1-back condition, and one using a 0-back and 2-back condition. The 0-back (control) condition required the subject to press the button whenever a man's face was presented. The 1-back (activation) condition required the subject to press the button whenever the face they were currently viewing was the same as the one immediately preceding it. The 2-back (activation) condition required the subject to press the button whenever the face they were currently viewing was the same as the one presented two images back. The subjects were presented with a series of

80 images (one at a time) for each of the 1-back and 2-back tasks. The 80 images for the 1-back task were presented in the following order: the first 20 images represented the 0-back condition with seven man's faces presented in random order. The next 20 images represented the 1-back condition with six randomly placed images meeting the 1-back criteria. The next 20 images returned to the 0-back condition with seven man's faces presented in random order. The final 20 images presented the 1-back condition with six randomly placed images meeting the 1-back criteria. The 2-back task followed the same pattern alternating the 0-back and 2-back conditions. Of the 80 images, 26 were positive (the subject should press the button because the image met the *N*-back condition) and 54 were negative (the subject should not press the button because the image did not meet the *N*-back condition). The *N*-back tasks were scored based on the number of true-positive, true-negative, false-positive, and false-negative responses recorded across the 80 images. Subject's reaction times (ms) also were measured.

To collect meaningful activation data during an *N*-back task, it is essential for subjects to be actively engaged in the task while lying perfectly still in the scanner. To prepare the child for the fMRI session in the scanner, the child was acclimated to the scanner environment in the mock scanner. A single practice session of the *N*-back task was administered to the child while in the mock scanner, to confirm the child understood the task well enough to perform it in the real scanner. Children performing with >65% accuracy on the practice version of the 1-back task were scanned using the 1-back condition. Children performing with >65% on the practice version of the 2-back task were scanned using the 2-back condition. Children performing at <65% accuracy on the *N*-back tasks were unlikely to perform the tasks in the scanner so as to yield meaningful activation data. Once in the scanner, only data from *N*-back tasks where the number of true-positive and true-negative responses were >65% correct were used to assess activation.

fMRI acquisition and analysis

Scans were acquired on a 1.5 T GE Signa MR scanner, using a 21 slice blood oxygenation level-dependent (BOLD) EPI pulse sequence with the following parameters: gradient echo pulse, TR=3,000 ms, TE=50 ms, flip angle=90, matrix=64 X 64, FOV=24, slice thickness=6.0 mm, 0 gap. Two scans were acquired; one during the 1-back task and one during the 2-back task. Each scan lasted 5 min and 18 s. The 1-back task included two repetitions of the following: 18 s of fixation, followed by 6 s of instruction, 60 s of 0-back (control) condition, 6 s of instruction, and 60 s of 1-back (activation) condition. The scan ended with another 18 s of fixation. The 2-back task followed the same pattern, using the 2-back condition for the activation condition.

Data from the fMRI scans were transferred from the scanner to the UNIX workstation, globally normalized, and archived on CD-ROMs. fMRI scans were analyzed using the software package MEDx 3.2, a multimodal radiological image processing program (Sensor Systems, Sterling, VA), run on a workstation with Linux operating system software. Motion detection was performed using a center-of-intensity plot. Scans with greater than five volumes with motion that exceed 0.3 mm from the center of intensity in any plane were considered unusable.

For scans with motion not exceeding this threshold, motion correction was performed, using the AIR algorithm [37, 38] (version 3.08, including the alignlinear and alignwarp programs). This algorithm minimizes the variance of the ratio of the intensities of two images. A gradient descent search was performed to arrive at a global minimum. All images were registered to the same reference image normalized to Tailarach space. A linear rigid body (six parameter) model, with trilinear interpolation was used. Pixel-by-pixel linear detrending was applied to correct for gradual drift in pixel intensity during the time course of the series. Paradigms were then applied, assigning individual volumes to either the control (0-back) or activation (1- or 2-back) conditions. Based on examination of the hemodynamic lag, 3 s of data were omitted from the beginning of the series. A statistic summarizing the activation difference between control and activation conditions was computed for each voxel. The statistic was computed as that of a two-sample *t*-test, and was subsequently transformed to a *Z*-score via the Fisher transformation [11]. Active voxels were then identified as those with *Z*-scores exceeding a fixed threshold (a *z*-score>3). Previous experience with normal subjects indicated that threshold values in the range of 2.4–6.0 (corresponding to 1-tailed *P*-value of <0.0082) provide informative, reliable binary activation maps.

Group maps were first produced for each of the four study groups, and areas of primary activation (for any group) were identified. Consistent with previous literature, these regions included left and right anterior cingulate, parietal lobe, particularly the anterior parietal region, dorsolateral prefrontal, inferior frontal, middle frontal and precentral regions of the frontal lobe (Fig. 2). Using the ROIs identified on the template brain, two measures of activation were computed for each subject for each of these brain regions: (1) the number of voxels whose *z* value exceeded the threshold (*z*=3.0; cluster corrected), and (2) the average z score within the region. For each subject and each region, number of activated voxels (i.e., those whose z value exceeded the threshold) was divided by the number of voxels in the region, yielding a measure reflecting the percent of activated voxels within the region. Comparison

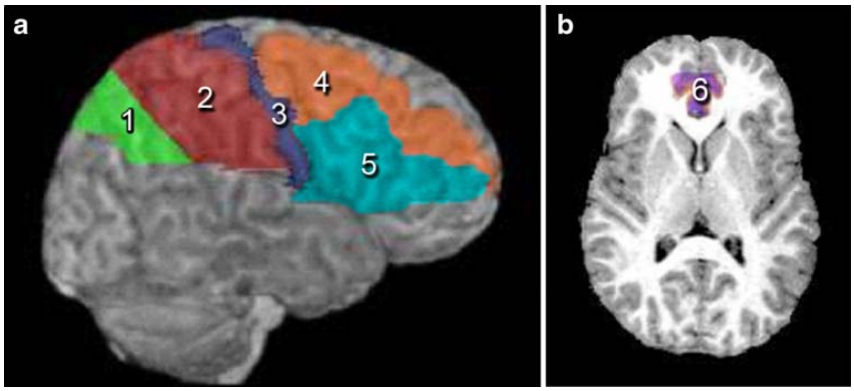

Fig. 2 Regions of interest: *1* posterior parietal lobe, *2* anterior parietal lobe, *3* precentral gyrus, *4* middle frontal gyrus, *5* inferior frontal gyrus, and *6* anterior cingulate gyrus

of groups was performed using traditional statistical techniques on these measures.

For clarity, the following nomenclature will be used throughout the remainder of this report. The term 'activation' refers to the difference in activation between the control condition (0-back) and the activation condition (1- or 2-back). The term 'task' (as in 1-back task) refers to the 0-back and 1-back conditions that together make up the 1-back task. The term 'condition' (as in 1-back condition) refers to the 1-back condition within the 1-back task.

fMRI hypotheses

In this report, the neural substrates of working memory in children with FASD were investigated. Given that subjects with FASD have significant deficits in working memory [16] and executive function [17–21] it was hypothesized they would show significant deficits in performance on the *N*-back tasks. It was also hypothesized that they would show significant alterations in activation in brain regions known to be involved in working memory, since prior FASD fMRI studies have shown activation alterations during memory and response inhibition tasks [14–16]. Trends across the four study groups were hypothesized because the neuropsychological/psychiatric report for this study [9] confirmed the four study groups were clinically distinct and increasingly more affected as one advanced across the four groups from the Controls to the FAS/PFAS.

1. Performance on the 1-back and 2-back conditions of the *N*-back tasks will decline as one advances across the four study groups from Controls to ND/AE to SE/AE to FAS/PFAS. Measures of performance include number of true-positive, true-negative, false-positive, and false-negative responses, and subjects' reaction times (seconds) for positive responses.
2. Activation (across the selected brain regions; primarily the DLPFC) will increase or decrease as one advances across the four study groups from Controls to ND/AE to SE/AE to FAS/PFAS. Two measures of activation (summarizing the difference in activation between control and activation conditions) were assessed: (1) the mean activation *z*-score across all voxels in a brain region, and (2) the percent of voxels with an activation *z*-score >3 in a brain region.

It was not specified, a priori, whether activation levels among the FASD groups would be higher or lower than the Control group, because this is the first FASD fMRI study of visual working memory, and impairment in brain function can manifest as higher or lower activation relative to a healthy Control group.

Statistical analyses

Chi-square and oneway ANOVA were used to confirm race, gender and mean age were effectively balanced across the four study groups. ANOVA, including multivariate and repeated measures, were used to test hypotheses 1 and 2. Full factorial designs, which included all main effects and all interactions for within-subjects factors were used. Factors included group (FAS/PFAS, SE/AE, ND/AE, Control), Task (1-back, 2-back), Condition (control, activation), Region (middle frontal gyrus, DLPFC, posterior parietal lobe, anterior parietal lobe, inferior frontal gyrus, precentral gyrus, anterior cingulate gyrus), and hemisphere (right, left). A priori contrasts were used to test for differences among the levels of a factor. For example, a polynomial contrast was included in the ANOVA to determine if mean outcomes changed incrementally as one advanced across the four study groups from Control to FAS/PFAS. Significant linear trends across these four study groups were observed in the magnitude of neuropsychological impairment [9] and reduction in size of brain regions. If significant differences existed among group means, the Duncan post hoc range test was used to identify which groups differed. The Duncan test makes pairwise comparisons using a stepwise procedure. Means are ordered

from highest to lowest, and extreme differences are tested first. The Duncan test sets a protection level for the error rate for the collection of tests and identifies homogeneous subsets of means that are not different from one another at the $p=0.05$ level. Two-tailed p-values of 0.05 were used throughout the analyses.

Results

Proportion of subjects who were able to participate successfully in *N*-back-fMRI tasks

Seventy-one of the 81 children enrolled in the larger MR study were able to participate successfully in the *N*-back tasks and fMRI evaluation (Table 2). To obtain valid activation data, the subject had to: (1) provide adequate performance/effort during the *N*-back tasks (the child had to be engaged throughout the task, even if they failed to get the correct answers), and (2) lay sufficiently still throughout the scan. Because of the cognitive/behavioral impairment of our FASD study groups, there was concern that many would not be able to successfully participate in the fMRI portion of the study. Only one subject in each study group failed to demonstrate adequate performance/effort during the 1-back task (Table 2). Adequate performance/effort was defined as >65% correct true-positive and true-negative responses with active response throughout the task. One to four subjects per group failed to demonstrate adequate performance/effort during the more difficult 2-back task. Subjects in the alcohol-exposed groups were more likely to perform below criteria on the 2-back task than Controls, but the group contrasts were not significantly different. The subjects in the FAS/PFAS were more likely to have difficulty in adapting adequately to the scanner (entering the scanner or lying still within the scanner) in order to produce valid fMRI data, than the remaining groups, but this contrast was also not statistically significant (Table 2). Overall, the subset of 71 children (16/20 FAS/PFAS, 22/24 SE/AE, 20/21 ND/AE and 13/16 Controls) who were able to participate successfully in this fMRI study were highly representative (clinically and sociodemographically) of the full set of 81 children enrolled in the larger MR study.

As described in the neuropsycological/behavioral report from this study [9], two subjects in the FAS/PFAS group had agenesis (ACC) and hypogenesis (HCC) of the corpus callosum. These anomalies were known prior to enrollment into the study. The subject with ACC was able to provide adequate performance on both *N*-back tasks, but valid activation data could not be obtained. The subject with HCC was not able to provide adequate performance on either *N*-back task, thus activation data were not assessed. As a consequence, data on these two individuals are not included in this report.

N-back performance across the four study groups (hypothesis 1)

N-back performance did not vary by age, race, or gender in this study population. *1-back Task.* Performance and reaction times for the control condition (0-back) were comparable between the four groups (Table 3). The FAS/PFAS group had significantly poorer performance and longer reaction times than the Control group on the 1-back condition. Performance on the 1-back condition decreased and reaction times increased linearly as one advanced across the four groups from Control to FAS/PFAS. *2-back Task.* Performance and reaction times for the control condition (0-back) were again comparable between the four groups (Table 4). The FAS/PFAS group had significantly

Table 2 Number of subjects able to participate successfully in the *N*-back tasks and the fMRI scan across the four study groups

fMRI—*N*-back task participation	1. FAS/PFAS *N*=20 *N* (%)	2. SE/AE *N*=24 *N* (%)	3. ND/AE *N*=21 *N* (%)	4. Control *N*=16 *N* (%)

2-back task				
Unable to enter or lie still in the scanner	5 (25.0)	2 (8.3)	2 (9.5)	2 (12.5)
Entered scanner				
But did not provide adequate performance/effort[a]	2 (10.0)	4 (16.7)	3 (14.3)	1 (6.3)
And provided adequate performance/effort[a]	13 (65.0)	18 (75.0)	16 (76.2)	13 (81.3)

[a] Adequate performance on *N*-back was defined as ≥65% correct true-positive and true-negative responses

poorer performance and longer reaction times than the Control group on the 2-back condition. Performance on the 2-back condition decreased and reaction times increased linearly as one advanced across the four groups from Control to FAS/PFAS. *1-back Condition versus 2-back Condition*. In general, children in the FASD study groups performed more poorly with longer reaction times during the more difficult 2-back condition relative to the 1-back condition (Table 5). The Control group performed comparably across 1-back and 2-back conditions, but had significantly longer reaction times during the more difficult 2-back condition.

Activation by brain region across the four study groups during *N*-back tasks (hypothesis 2)

Pattern of activation across brain regions Activation patterns did not vary by age, race or gender in this study population. The level of brain activation during the *N*-back conditions, relative to the control condition, increased across the brain regions in the following order: precentral gyrus, anterior cingulate gyrus, anterior parietal lobe, inferior frontal gyrus, posterior parietal lobe, DLPFC, and middle frontal gyrus (Figs. 3a, b, Tables 6 and 7). This regional pattern of activation was observed bilaterally for both the 1-back and 2-back tasks across each study group. In general, among the Controls, the mean level of activation was significantly greater bilaterally in the anterior parietal lobe, inferior frontal lobe, posterior parietal lobe, DLPFC, and middle frontal gyrus relative to the region with the lowest level of activation (precentral gyrus) (Table 7). Comparable results were obtained regardless of which activation outcome variable was used (mean percent of voxels with a *z*-score>3 in each brain region, or mean *z*-score across all voxels in a brain region) (Table 7). Activation patterns did not vary significantly by age, race, or gender in this study population.

1-back task Activation Across Groups. The level of activation (mean percent of voxels with *z*-scores>3) during the 1-back condition, relative to the control condition, was comparable across all study groups (Table 6, Fig. 3a). The level of activation (when measured as the mean activity *z*-score across all voxels within each brain region) during the 1-back task was also comparable across all study groups (data not shown). *Right versus Left Hemisphere Activation*. No significant contrasts were observed between mean activation levels in the right versus left hemispheres of each brain region within each group during the 1-back task. *Activation and 1-back Task Performance.* The level of activation in each region was not significantly correlated with any measure of performance on the 1-back task. All Pearson Correlation Coefficients had two-tailed *p*-values> 0.05 (data not presented).

2-back task Activation across Groups. Activation levels (mean percent of voxels in each brain region with activity *z*-scores>3) during the 2-back condition, relative to the control condition, were significantly lower in the FAS/PFAS group than the Control group in the right posterior parietal lobe, right DLPFC, and right middle frontal regions (Fig. 3b, Table 7). Activation levels (when measured as mean activity *z*-score across all voxels in each brain region) during the 2-back task were significantly lower in the FAS/PFAS group than the Control group in the right inferior frontal gyrus, right posterior parietal lobe, right DLPFC, and right middle frontal regions (Table 7). Activation levels increased significantly in these regions as one advanced across the four groups from FAS/PFAS to Control. *Right versus Left Hemisphere Activation*. When significant contrasts were observed between the FAS/PFAS and Control groups, it always involved structures on the right side of the brain. In general, activation was consistently higher (although not statistically significantly) in the right versus left sides of the posterior parietal lobe, DLPFC, and middle frontal gyrus among the Controls during the 2-back task (Table 7). A similar, but weaker pattern was observed among the ND/AE and SE/AE groups. The pattern reversed (left comparable to or higher than right) among the FAS/PFAS group. *Activation and 2-back Task Performance.* Performance on the 2-back task was significantly correlated with activation level in several brain regions. More specifically, the higher the activation (mean percent of voxels with *z*-scores>3) in the R. and L. DLPFC, and R. and L. middle frontal gyrus, the lower the number of error responses (false-positives and false-negatives combined) on the 2-back task. Statistically significant Pearson correlation coefficients ranged from −0.25 to −0.28.

1-back task versus 2-back task Among Controls, activation (mean % of voxels with *z*-scores>3) was significantly higher (2 to five-fold higher) in the 2-back task (2-back condition relative to control condition) than in the 1-back task (1-back condition relative to the control condition). This was observed in all areas except the anterior cingulate and precentral regions (Table 8, Figs. 3a–c). Among the FAS/PFAS subjects, activation (mean % of voxels with *z*-scores>3) was not significantly higher (less than two-fold higher) in 2-back task relative to 1-back task across all brain regions (Table 8, Figs. 3a–c). As one advanced across the four study groups, the number of brain regions that showed a significant increase in activation in 2-back task relative to 1-back task increased (Table 8). The most marked contrasts in activation between 1-back and 2-back tasks occurred in the middle frontal, DLPFC, and posterior parietal lobe regions (Fig. 3c). Important associations were observed between *N*-back performance and neuroactivation levels. Controls were able to perform equally well on both

the 1-back and 2-back conditions (e.g., the mean number of correct responses were comparable on 1-back and 2-back conditions) (Table 5, Fig. 4a), but a significantly higher level of activation (five-fold higher) was observed during the more difficult 2-back activation to 'achieve' this outcome (Table 8, Fig. 4b). In contrast, the subjects in the FAS/PFAS group performed significantly worse on the 2-back condition relative to the 1-back condition (e.g., the mean number of correct responses was significantly lower on the 2-back than the 1-back condition). And, although the level of activation among the FAS/PFAS was higher during the more difficult 2-back task than the 1-back task, it was considerably lower than the 2-back task activation level observed in the Controls and only two-fold higher than the activation level in the FAS/PFAS during the 1-back task.

[a] Mean and SD of the difference in response or reaction time in the 2-back activation condition minus the response or reaction time in the 1-back activation condition (e.g., subjects in the FAS/PFAS group had on average 2.7 fewer true-positive responses during the activation condition for the more difficult 2-back task, than during the activation task for the less difficult 1-back task)

Discussion

Primary fMRI findings

In summary, 74% of the 81 subjects were able to provide valid fMRI data on both *N*-back tasks, demonstrating that fMRI studies of children with FASD are feasible, albeit challenging. As expected, performance on the 1-back and 2-back conditions decreased significantly as one advanced across the four groups from the Controls to FAS/PFAS. Activation levels decreased significantly on the 2-back task, but not the 1-back task, as one advanced across the four groups from Controls to FAS/PFAS. Decreased BOLD responses during task conditions are thought to reflect decreases in neuronal activation [39]. Controls performed well on both 1-back and 2-back conditions, but showed significantly higher activation during the more difficult 2-back task. The FAS/PFAS group performed significantly more poorly on the 2-back condition relative to the 1-back condition, despite a higher (albeit not statistically significant) activation during 2-back task. The increase in activation from the 1-back task to 2-back task in the FAS/PFAS group, however, was significantly less than the increase observed in the Control group. Of the regions assessed, those with the greatest activity during the *N*-back tasks were the right inferior frontal gyrus, right posterior parietal lobe, right DLPFC, and right middle frontal gyrus. The level of activation during 2-back task in these regions was significantly lower in the FAS/PFAS relative to the Controls, with the SE/AE and ND/AE groups showing levels of activation intermediate to the FAS/PFAS and Controls. When significant contrasts in activation were observed between FAS/PFAS and Controls, the contrasts always involved regions in the right hemisphere. Within each group, reaction times slowed with increasing difficulty

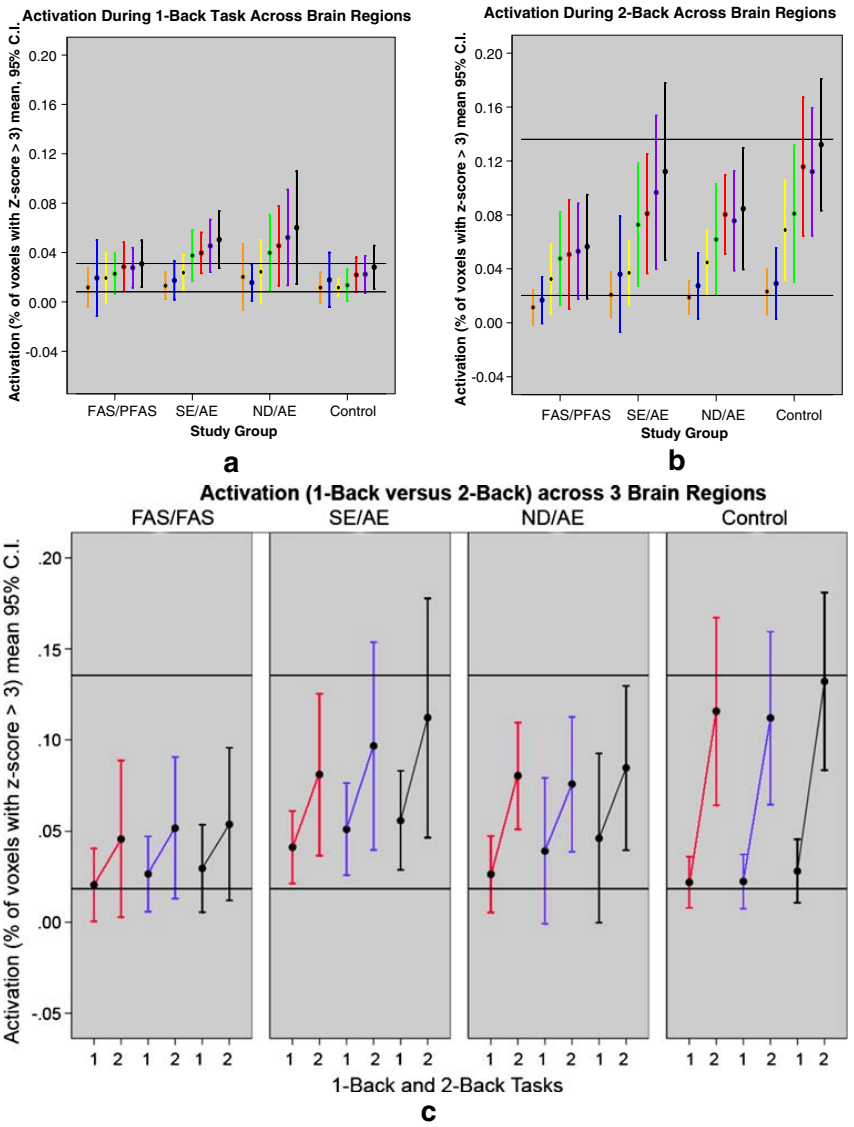

Fig. 3 Activation (mean percent of voxels with *z*-scores>3) in right brain regions **a** 1-back task. **b** 2-back task. **c** 1-back task versus 2-back task for three regions with greatest levels of activation: right middle frontal gyrus, DLPFC, and posterior parietal lobe. of the task. Across the groups, reaction times were slower in the FASD groups than in the Control group.

All groups in the present study showed comparable activation in the anterior cingulate region, which is involved in affective behaviors, nociception, and executive functions [40]. As summarized by Malisza et al. [16], the activity of this region, which is modulated by task demands and response selection, has been shown to increase during working memory tasks in both children and adults [41–43]. These increases, however, may be more closely linked to the attention demands of working memory tasks, than to the memory demands themselves (which have been associated with DLPFC and parietal activations) [43]. In one of the few FASD-fMRI studies conducted to date (and presented more fully below), Malisza et al. [16] 4 also reported consistent activation in the cingulate region across all subjects in their FASD and Control groups. They speculated that the consistent activity may reflect the fact that participants were paying comparable attention to the task; a conclusion strengthened by the fact that their FASD and Control groups performed comparably on a continuous performance task. The consistent anterior cingulate activity observed across the four study groups in the current study may also reflect that participants in all four groups were

paying comparable attention to the task. Perhaps this is an indication that the method used to identify subjects truly engaged in the tasks (>65% correct true-positive and true-negative responses on the *n*-back tasks) was successful. It is also worth noting that event-related fMRI studies [44, 45] have shown activation in the anterior cingulate associated with error commission and detection. More specifically, Kiehl et al. [45] used event-related fMRI techniques to examine the neural responses to appropriate (correct rejects and correct hits) and inappropriate (errors of commission) behavioral responses during a go/no-go task. Analyses of the inappropriate responses revealed extensive activation in the rostral anterior cingulate cortex and in the left lateral frontal cortex. These areas were not activated for correctly classified trials (correct rejects and correct hits). Although significantly more *N*-back commission errors were observed among the FAS/PFAS group relative to the Controls in the current study, anterior cingulate activation was not higher in the FAS/PFAS group relative to the Controls. Perhaps this reflected an absence of error detection among the FAS/PFAS, which could explain, in part, their poorer performance on *N*-back. When typically developing subjects make an error, their reaction times are typically slower on the subsequent trial [44, 46]. This phenomenon is considered evidence for central error monitoring. When reaction times during correct responses and commission errors were compared between the FAS/PFAS and Control groups in the current study, the children with FAS/PFAS exhibited significantly less slowing of reaction time after commission errors. For Control subjects, the mean reaction time was significantly slower (mean 207, SD 1.2 ms) during commission errors than during correct responses (mean 115, SD 58 m) (paired $t=31.9$, $p=0.03$) in the 2-back condition. In contrast, the FAS/PFAS group had comparable reaction times during commission errors and correct responses (mean 212, SD 64 and mean 183, SD 55 respectively) (paired $t=0.3$, $p=0.80$). This observation further supports that the FAS/PFAS group may not have been detecting their errors.

fMRI and working memory in healthy populations

Research on healthy populations suggest regional activation patterns during working memory tasks that closely mirror the findings in our Control group. The DLPFC, posterior parietal cortex, middle frontal gyrus, and Broca's area are essential in successful working memory performance [41, 47–55]. The middle frontal gyrus is known to be important for ongoing storage and maintenance of information [50, 56, 57], while posterior parietal lobe is seen activated in most working memory tasks with some spatial processing component, and DLPFC is highly activated the greater the

demands of the task [41, 47, 50, 52, 56, 58, 59] Studies have also observed contrasts in right versus left hemisphere activation that appear to be influenced by age and type of task. Positron emission tomography (PET) involving working memory tasks have shown predominantly right hemisphere activation in the frontal cortex [51, 60], posterior parietal cortex, and anterior cingulate [43] of healthy children and young adults, but bilateral activation in older adults [60]. While spatial working memory tasks activate bilaterally, there are key regions (DLPFC and posterior parietal cortex) that have shown activation predominantly in the right-hemisphere [55]. Smith [23] showed object memory activates right DLPFC.

fMRI and working memory in fragile X syndrome

In an fMRI study of visuospatial working memory among children with fragile X syndrome, Kwon et al. [13] observed similar outcomes to the present FASD study. Relative to their comparison group, subjects with fragile X syndrome performed significantly worse on the 2-back task, but not on the 1-back task. In a region-of-interest analysis

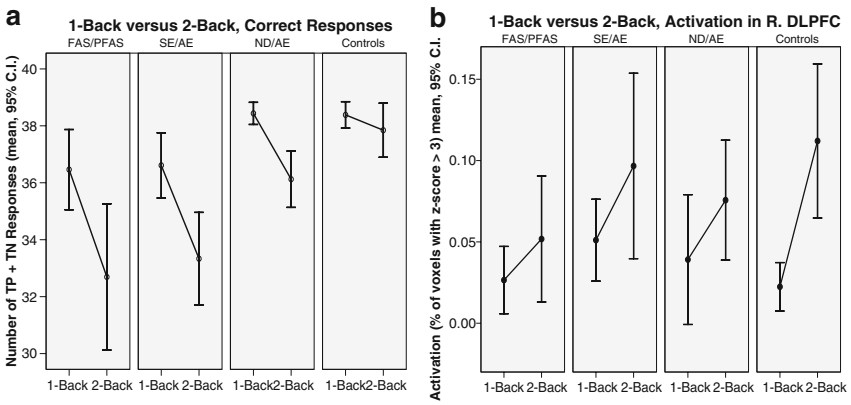

Fig. 4 **a** Mean number of correct (true-positive and true-negative) responses during 1-back versus 2-back conditions across the four groups. **b** Increase in activation (mean percent of voxels with *z*-score>3) during 1-back task versus 2-back task across the four groups in the right dorsolateral prefrontal cortex (*DLPFC*)

focused on the inferior frontal gyrus, middle frontal gyrus, superior parietal lobule, and supramarginal gyrus, comparison subjects showed significantly increased brain activation between the 1-back and 2-back tasks, but subjects with fragile X syndrome showed no change in activation between the two tasks. The investigators concluded that subjects with fragile X syndrome were unable to modulate activation in the prefrontal and parietal cortex in response to an increasing working memory load. They speculated these findings may be explained by a ceiling effect. The subjects with fragile X syndrome may have recruited all of their neuronal resources needed for working memory in the 1-back task. In the 2-back task, the fragile X syndrome group experienced significant deterioration in performance with a lack of coherent recruitment in areas subserving working memory.

It is interesting to note in the current study that during the 1-back task, the FAS/PFAS group exhibited activation levels that were comparable (if not slightly higher) than the Controls, but demonstrated significantly poorer 1-back performance. During the more difficult 2-back task, both activation and performance were significantly lower in the FAS/PFAS group than the Control group. One might speculate that the 1-back outcome reflected 'neural inefficiency' [12, 61], while the 2-back outcome reflected a 'ceiling effect' [13]. What is 'neuronal inefficiency'? Casey [12] postulated in an fMRI study of nonspatial working memory in healthy children, that incomplete myelination may result in poorer conduction efficiency and thus greater energy expenditure. And, in an fMRI study of working memory in girls with and without ADHD, significantly higher activation in the DLPFC was observed among the girls with ADHD, despite comparable working memory performance [61]. The investigators interpreted these findings as evidence of neural inefficiency. In the present FASD study, evidence of significant white matter/myelin deficiencies, and poorer performance despite comparable activation levels were observed in the FAS/PFAS group relative to the Controls. One could postulate that if the requisite neuronal resources for the 1-back task were deficient and/or inefficient in our FAS/PFAS group, comparable activation could have produced inferior performance. When the more difficult 2-back task is encountered, a ceiling effect [13] may have occurred. The Control group demonstrated that a significantly higher level of activation was required to achieve accurate performance on the more difficult 2-back task. The FAS/PFAS group may have been activating all of the neuronal resources they had, but the resources were too deficient, not just inefficient, to achieve comparable activation or performance.

FASD fMRI studies

To our knowledge, only three fMRI-FASD studies have been published to date [14–16]. Marlisza et al. [16] examined fMRI activation patterns corresponding to *N*-back spatial working memory tasks in adults and children with FASD, and in age- and sex-matched Controls. It is important to note their subjects with FASD performed too poorly on the 2-back task to include these findings, so it was dropped from all analyses. To be included in their analyses, all participants had to achieve a minimum of 50% correct responses on the Simple task, and on at least one of the remaining *N*-back tasks (Blank or 1-back). Complete data were available for 23 children (nine FASD, 14 Controls) and 19 adults (ten FASD and nine Controls). Subjects with FASD were diagnosed with FAS, partial FAS, or ARND in accordance with the Canadian FASD diagnostic guidelines [32]. The Canadian diagnostic criteria are near identical to the FASD 4-Digit Diagnostic Code used in the present study. Children with FASD displayed greater inferior-middle frontal lobe activity, while greater superior frontal and parietal lobe activity was observed in Controls. Children in the Control group also showed an overall increase in frontal lobe activity with increasing task difficulty, while children with FASD showed decreased

activity. Adults with FASD demonstrated less functional brain activity overall, but greater inferior middle frontal lobe activity during the simpler tasks, relative to Controls. Adults in the Control group demonstrated greater inferior frontal activity with increasing task difficulty, while this pattern was not consistently observed in adults with FASD. All four groups showed increasing activity with increases in task difficulty in the parietal and frontal regions at more superior slice levels. They concluded their results suggested impairment in spatial working memory in those with FASD that does not improve with age.

Sowel et al. [14] examined fMRI activation patterns corresponding to verbal paired associate learning in a group of 11 children with FASD (two FAS, four PFAS, five Neurobehavioral disorder/alcohol exposed diagnosed with the 2004 FASD 4-Digit Code [27]. Controls included 16 typically developing children with little or no prenatal alcohol exposure (they were excluded if they were prenatally exposed to one drink or more per week, or more than two drinks on any one occasion). Among the children with typical development, prominent activation was observed in the left medial temporal lobe, left dorsal frontal lobe, and bilateral posterior temporal cortices during learning and recall. Analyses revealed significantly less activation in left medial and posterior temporal regions and significantly more activation in right dorsal frontal cortex in the alcohol-exposed children relative to Controls, even when group differences in memory test performance were statistically controlled. The investigators concluded their results may indicate an increased reliance on frontal memory systems, when in the children with heavy prenatal alcohol exposure, perhaps compensating for dysfunctional medial temporal memory systems, when presented with a difficult verbal memory task.

Fryer et al. [15] examined fMRI activation patterns corresponding to a Go/No-Go task in a group of 13 adolescents (8–18 years old) with prenatal alcohol exposure (six FAS and seven without FAS) and nine Controls with no prenatal alcohol exposure. The alcohol-exposed group was evaluated by a dysmorphologist. No FASD diagnostic criteria were cited. The Go/No-Go task is quite different from an *N*-back working memory task, as it requires response inhibition and perhaps involves a lighter working memory load. Mean total brain volume was not significantly different between the alcohol-exposed and Control groups. Interestingly, performance on the go/no-go task was also not significantly different between the alcohol-exposed group and the Control group. During portions of the task that required response inhibition, alcohol-exposed subjects showed greater blood oxygen level-dependent (BOLD) response across prefrontal cortical regions (including the left medial and right middle frontal gyri), while they showed less right caudate nucleus activation, compared to Control subjects. The investigators concluded their results suggest that the frontal–striatal circuitry thought to mediate inhibitory control may be sensitive to alcohol teratogenesis.

Overall, the three FASD fMRI studies report significant differences in brain activation patterns were observed between FASD and Control groups during verbal learning [14], response inhibition [15], and spacial working memory [16] tasks. Significant differences in brain activation patterns were also detected between FASD and Control groups in our study of nonspatial working memory. All of these tasks require higher-order cognitive abilities that are often deficient in individuals with FASD [17–21].

In conclusion, the results of this study demonstrate it is possible (albeit challenging) to use fMRI to study brain activation in children with FASD. This study also shows that children across the full spectrum of FASD exhibit significant working memory deficits. These deficits are correlated with abnormalities in activation in brain areas that are known to be involved in working memory. Alterations in brain activation provide compelling evidence that cognitive and behavioral deficits among individuals with FASD are, to an important extent, "brain-based." An important component of a FASD diagnostic evaluation is confirmation of CNS abnormality. Our ability to detect CNS abnormalities is dependent on the sensitivity of today's measurement tools. These results demonstrate the potential research and diagnostic value of this non-invasive MR tool.

Acknowledgments This research was supported by NIAAA grant R01-AA12915-01 A1 to SJA. Support was also received from the Center on Human Development and Disability, University of Washington (National Institute of Child Health and Human Development grant P30 HD02274). Special thanks are extended to the children and their families who so kindly contributed time and effort to this study.

ABSTRACT

It is well established that prenatal exposure to alcohol causes damage to the developing fetus, resulting in a spectrum of disorders known as fetal alcohol spectrum disorders (FASDs). Although our understanding of the deficits and disturbances associated with FASDs is far from complete, there are consistent findings indicating these are serious, lifelong disabilities—especially when these disabilities result from central nervous system damage. Until recently, information and strategies for interventions specific to individuals with FASDs have been gleaned from interventions used with people with other disabilities and from the practical wisdom gained by parents and clinicians through trial and error or shared through informal networks. Although informative to a limited degree, such interventions have been implemented without being evaluated systematically or scientifically. The purpose of this article is to provide a brief overview of a general intervention framework developed for individuals with FASDs and the methods and general findings of five specific intervention research studies conducted

☆ The findings and conclusions in this report are those of the author(s) and do not necessarily represent the official position of the Centers for Disease Control and Prevention. The authors would like to thank the participating children and families for their tremendous contribution to each of these studies.

within this framework. The studies evaluated five different interventions in five diverse locations in the United States, with different segments of the FASD population. Nonetheless, all participants showed improvement in the target behaviors or skills, with four studies achieving statistical significance in treatment outcomes. Important lessons emerged from these five interventions that may explain success: including parent education or training, teaching children specific skills they would usually learn by observation or abstraction, and integration into existing systems of treatment. A major implication of these research studies for families dealing with FASDs is that there are now interventions available that can address their children's needs and that can be presented as scientifically validated and efficacious to intervention agents such as schools, social services, and mental health providers. In the field of FASD research and clinical service, a common theme reported by families has been that clinicians and professionals have been reluctant to diagnose their children because there were no known effective treatments. Results of these five studies dispel that concern by demonstrating several interventions that have been shown to improve the lives of individuals with FASDs and their families.

Published by Elsevier Ltd.

It is well established that prenatal exposure to alcohol can damage a developing fetus, resulting in a spectrum of disorders known as fetal alcohol spectrum disorders (FASDs; Jones, Smith, Ulleland, & Streissguth, 1973; Warren et al., 2004). Affected individuals can experience a wide range of negative life long effects, including structural malformations, learning disabilities (including mental retardation), or complex and persistent psychosocial problems. The full spectrum includes diagnoses of fetal alcohol syndrome (FAS), partial FAS (pFAS), alcohol-related neurodevelopmental disorder (ARND), and alcohol-related birth defects (ARBD) (Bertrand et al., 2004; Stratton, Howe, & Battaglia, 1996).

Despite ongoing efforts to prevent alcohol-exposed pregnancies, infants continue to be born with FASDs (Hymbaugh et al., 2002; May & Gossage, 2001; May et al., 2006). FASDs are not as rare as generally thought and studies of particularly vulnerable populations have yielded prevalence estimates that exceed those of other, more widely recognized developmental disabilities. Studies in the United States have reported prevalence rates for the full FAS case definition, ranging from 0.2 to 1.5 cases per 1000 births across various populations (Astley, Stachowiak, Clarren, & Clausen, 2002; Bertrand et al., 2004; May & Gossage, 2001). Prevalence estimates for the entire spectrum range from 3 to 10 times the prevalence of full FAS (Stratton et al., 1996) resulting in thousands of children born affected by prenatal alcohol exposure each year.

As is true for all children with developmental disabilities, access to interventions, especially early interventions, is a protective factor that improves the long-term developmental outlook for those with an FASD (Streissguth, Barr, Kogan, & Bookstein, 1996). Thus, interventions for individuals affected by prenatal alcohol exposure are an important educational and public health need. Despite the troubling number of children with FASDs, information and strategies for interventions specific to this population have been gleaned from interventions used with other disabilities without adaptation and from the practical wisdom gained by parents and clinicians through trial and error or informal networks. In 2001, in response to the Healthy Children Act of 2000, the Centers for Disease Control and Prevention (CDC) provided federal funding to develop systematic, specific, and scientifically evaluated interventions appropriate for children with FASDs and their families. Awards were made to five grantees to develop interventions. All five interventions specifically addressed the neurodevelopmental needs of children with FASDs. The purpose of this article is to provide a brief overview of the

RIDD-730; No of Pages 21 ARTICLE IN PRESS

general framework and procedures for these intervention projects and their central findings. More in-depth descriptions of the methodology and results for each intervention study are addressed in publications elsewhere (Chasnoff et al., submitted for publication; Kable, Coles, & Taddeo, 2007; O'Connor et al., 2006; Olson et al., in preparation).

1. Intervention framework

All of the interventions were designed to improve the developmental outcomes of individuals with FASDs, reduce secondary conditions, and improve the lives of families affected by FASDs. Although our understanding of the deficits and disturbances associated with FASDs is far from complete, individuals exposed to alcohol during fetal development can show evidence of central nervous system (CNS) dysfunction resulting from structural brain damage (Ma et al., 2005; Spadoni, McGee, Fryer, & Riley, 2007). These CNS disabilities can range from subtle to serious, with affected individuals presenting variable combinations of deficits in memory, information processing, academic skills, social skills (including pragmatic language and social communication skills), attention, motor skills, and executive functioning, as well as significant behavioral and mental health issues (Bertrand et al., 2004; Kable & Coles, 2004; O'Connor et al., 2002; Streissguth et al., 1996). Learning and life skills affected by prenatal exposure vary greatly among individuals, depending on the amount of alcohol exposure, the timing and pattern of exposure, and the affected individual's current environmental history (Streissguth, 1997). As a result, the intervention appropriate for an individual with an FASD and his or her family vary according these factors.

Grantees were requested to incorporate three common components in their intervention trials: (a) interventions targeting a specific area of deficit or risk among the study population (rather than entering into a single, collaborative intervention to be implemented by all sites), (b) provide children in both treatment and control groups with multidisciplinary assessments that guided referrals for standard care as indicated (e.g., speech therapy), and (c) incorporate specific instruction and training for parents and caregivers regarding basic information about FASDs, advocacy skills, and caregiver support. Across sites, specific interventions focused on math skills, behavioral regulation, peer relations and social communication, executive functioning, compliance, learning readiness, and challenging behaviors of clinical concern.

2. Human subjects approval

All studies were approved by the CDC Institutional Review Board (IRB) and by the individual IRBs from each research site. For children under state guardianship, the IRB of the applicable state Department of Children and Family Services reviewed and approved the research. Informed consent was obtained from the parent(s) or legal guardian(s), and assent was obtained from children at appropriate ages for each intervention.

3. Diagnosis of participants across intervention sites

Participants for all interventions were recruited from established FASDs and genetics clinics. Every child received a multidisciplinary evaluation by trained clinicians to assess for the presence of the diagnostic features of an FASD. Children with any of the diagnoses within the spectrum were eligible. Two of the study sites (University of California at Los Angeles and University of Washington) used the *Diagnostic Guide for Fetal Alcohol Spectrum Disorders: The 4-Digit Diagnostic Code* (Astley, 2004). This system uses a 4-digit diagnostic code reflecting the magnitude of expression of four key diagnostic features of fetal alcohol syndrome (1) growth deficiency; (2) the FAS facial phenotype, including short palpebral fissures, flat philtrum, and thin upper lip; (3) CNS dysfunction; and (4) gestational alcohol exposure.

Two sites (Children's Research Triangle and University of Oklahoma Health Sciences Center) used a modified system adapted from the IOM (Stratton et al., 1996) and incorporated aspects of the 4-digit diagnostic code to assess severity of features. One site (Marcus Institute) used Pedscore, a weighted pediatric dysmorphia checklist (Fernhoff, Smith, & Falek, 1980) that has been demonstrated to

Child composite IQ on K-Bit (M, SD)	97.24 (14.83)	81.08 (13.4)	89.79 (16.11)	87.90 (11.20)	94.3 (12.50)
Primary caregiver education (years)	16.28 (0.26)	12.84 (1.4)	14.41 (2.51)	13.90 (2.73)	14.47 (2.26)
Living with biological mother (%)	21.0	1.7	NA	1.1	13.4
Fetal alcohol syndrome (%)[a]	12.0	6.6	14.1	4.6	7.7

[a] FAS diagnosis based on criteria from *Fetal Alcohol Syndrome: Guidelines for Referral and Diagnosis*, 2004

accurately reflect common features associated with the diagnosis of an FASD. The Pedscore is the sum of the 30 weighted items on a standard pediatric dysmorphia checklist used to identify alcohol-related dysmorphic features. This checklist is a modification of the usual "genetics" checklist, upon which characteristics associated with the disorder are listed and weighted based on their saliency for the diagnosis (e.g., hypoplastic philtrum is a "3" on a 0–3 scale). The total dysmorphia score obtained is the sum of the 30 weighted items. Pedscores greater than 10 are assumed to indicate a clinically significant degree of alcohol-related dysmorphology. This score is then used with other criteria to diagnose children according to the IOM system (Stratton et al., 1996).

To provide consistency for comparison across sites, all sites re-categorized their participants according to the 2004 guidelines published by the National Taskforce on Fetal Alcohol Syndrome and Fetal Alcohol Effects (NTFASFAE), presented in Table 1. These guidelines address only the full FAS diagnosis. A diagnosis of FAS is applied if: (a) a child demonstrates all three cardinal facial dysmorphic features (small palpebral fissures, smooth philtrum, and thin vermillion border); (b) has prenatal or postnatal growth below the 10th percentile for height or weight; and (c) demonstrates structural, neurological or functional CNS deficits (Bertrand et al., 2004). A confirmed history of prenatal alcohol exposure is a qualifier of the diagnosis, but not a prerequisite according these guidelines.

4. Study 1. Project bruin buddies: a social skills training program to improve peer friendships for children with fetal alcohol spectrum disorders (University of California at Los Angeles)

This study was designed to examine the effect of parent-assisted children's friendship training (CFT) (Frankel & Myatt, 2003) compared with the effect of delayed treatment control (DTC) on the social skills of children with a history of prenatal alcohol exposure, and to examine the maintenance of social skills gained over a 3-month period.

Research suggests that children with FASDs exhibit considerable social impairment. Problems understanding social cues, indiscriminant social behavior, and difficulty communicating in social contexts have been reported among this population (Streissguth, 1997). Both caregivers and teachers have rated children with prenatal exposure to alcohol as having poorer social skills than unexposed children, even after controlling for differences in cognitive functioning (Roebuck, Mattson, & Riley, 1999; Whaley, O'Connor, & Gunderson, 2001). Furthermore, studies of adolescents and adults with FASDs have indicated that social skills deficits continue into adulthood (Carmichael-Olson, Feldman, Streissguth, Sampson, & Bookstein, 1998). Given the high percentage of individuals with prenatal exposure to alcohol, who have significant social problems as they grow older, it is important to intervene early to promote adequate social problem solving and competence.

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

The procedure used in this study and all its social skills components were based on the developmental psychology literature pertaining to children's friendships, had been validated empirically, and had been successfully implemented for children 6–12 years of age in multiple clinical contexts and with children having a variety of developmental and psychiatric disorders (Frankel, 2005; Frankel & Myatt, 2003). The procedure included parents as facilitators of their children's social skill performance, which has proven to be a highly successful component of social skills training (Frankel, 2005; Ladd, Profilet, & Hart, 1992). The procedure was modified with specific treatment adaptations to account for the neurocognitive deficits common among children with FASDs. Modifications made primarily involved augmentation in how the treatment was delivered, rather than changes in the content or components of the intervention, thus, preserving the basic integrity of the treatment. Skills taught included: (a) social network formation with the aid of the, (b) informational interchange with peers leading to a common-ground activity, (c) entry into a group of children already in play, (d) in-home play dates, and (e) conflict avoidance and negotiation. Skills were taught didactically through instruction on simple rules of social behavior; modeling, rehearsal, and performance feedback during treatment sessions; rehearsal at home; homework assignments; and coaching by parents during play between children.

4.1. Method

4.1.1. Participants

A total of 183 children 6–12 years of age were assessed for eligibility in the study. Of that number, 83 were excluded for not meeting inclusion criteria ($N = 63$) or failing to keep evaluation appointment ($N = 20$). Of the remaining 100 children, 96 completed the study with 4 families failing to complete the study (2 during intervention and 2 during the delayed treatment waiting period). Sample participants had to have had measurable social skills deficits (≥ -1 standard deviation below the mean) on the socialization domain of the Vineland Adaptive Behavior Scales (VABS; Sparrow, Balla, & Cicchetti, 1984), and a verbal IQ of ≥ 70 on the Kaufman Brief Intelligence Test (K-BIT; Kaufman & Kaufman, 1990). Sample characteristics are presented in Table 1.

4.1.2. Measures and procedures

A two-group CFT or DTC longitudinal design was used. Each consecutive set of 14–16 eligible children formed a cohort. The children within a cohort were assigned, in alternating sequence, to one of the two study conditions (7–8 children in each condition), with an attempt to equate groups on sex and ethnicity. The CFT group received 12 sessions, 90 min in length, delivered over the course of 12 weeks. Parents attended separate concurrent sessions in which they received education on the issues related to FASDs and were instructed on key social skills being taught to their children. On completion of the 12-week intervention, participants in the CFT condition were administered a post-treatment assessment. Children in the DTC condition, for whom treatment had been delayed, then received the CFT. After completing treatment, the DTC participants were then assessed. At the same time, the CFT group completed a 3-month follow-up assessment.

Children and parents were assessed prior to CFT or DTC training, 12 weeks later, and then again at 3 month's follow-up. Children's understanding of the rules of social behavior was measured using the Test of Social Skills Knowledge (TSSK; Frankel, 1994), which is a 17-item forced–choice, criterion-based measure. This measure and similar measures have been used successfully in evaluating treatment gains in other studies of social skills training (Frankel & Myatt, 2003; Pfiffner & McBurnett, 1997). Scores range from 0 to 17, with a higher score reflecting higher social skills knowledge.

Social skill performance was evaluated with the Social Skills Rating System Parent Form (SSRS-P) (Gresham & Elliott, 1990). The SSRS-P is comprised of two scales: Social Skills and Problem Behaviors, presented as standard scores ($M = 100$; $SD = 15$). The Social Skills scale measures cooperation, assertion, responsibility, and self-control. Lower scores represent poorer social functioning. The Problem Behaviors scale measures internalizing, externalizing, and hyperactivity. Higher scores represent greater problem behaviors. The SSRS-P has high criterion-related validity, correlating significantly with other established measures of child social and problem behaviors.

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

The Test of Parent Knowledge of FASDs, a project-developed questionnaire in a true/false, forced-choice format, was used to assess parental knowledge about the neurodevelopmental effects associated with prenatal alcohol exposure and of parent advocacy opportunities.

Following treatment, parents were queried regarding their satisfaction with the intervention using the Parent Satisfaction Questionnaire, a project-developed measure consisting of questions rated on a Likert scale with values ranging from negative to neutral to positive.

4.2. Results

Chi-square and independent *t*-tests revealed no statistically significant differences at baseline between the CFT and DTC conditions on demographic variables. To examine the effect of social skills training on children with FASDs, a two-condition (CFT, DTC) ANCOVA design was used. Analyses were conducted on the scores derived from the TSSK completed by the children and on the scores on the SSRS-P completed by the parents. The post-treatment score was the dependent variable and the baseline score was used as a covariate to control for initial levels. After controlling for covariates, children in the CFT group showed statistically significant improvement in their knowledge of appropriate social behavior compared with children in the DTC group (prior to their receipt of the social skills training, $p < .0001$). According to parent report, similar results also were obtained in increasing actual social skills ($p < .03$) and in decreasing problem behaviors ($p < .05$). To examine the maintenance of social skills over a 3-month period following treatment, data from children in the CFT condition were analyzed using two-tailed pairwise *t*-tests. The DTC group received treatment during this time period so they could not be used as a comparison group. Change scores on the TSSK and the SSRS-P from baseline to 3 month's follow-up constituted the dependent variables. Results indicated that children's social skills knowledge, improvement in social skills, and decrease in problem behaviors were maintained over the 3-month follow-up period. Importantly, social skills improved significantly from post-treatment to 3 month's follow-up ($p < .002$), suggesting that children were continuing to benefit from the intervention targeting social skills performance. Similar gains were reported for the children in the DTC group following treatment with CFT.

Results from questionnaires on parent knowledge about prenatal alcohol exposure and parent satisfaction revealed that, following treatment, parents in both groups reported more knowledge about their children's conditions and a high level of satisfaction with the intervention. More than 85% of parents reported that the approach to treating their children's social skills problems was appropriate and 89.2% said they would recommend the training to a friend or relative. Regarding the information that they learned in the sessions, 92.5% of parents reported that the information was useful to them.

4.3. Discussion and conclusions

This study was the first systematic evaluation of a treatment for improving the social functioning of children with FASDs. As such, it represents a promising intervention for these children, who experience multiple failures in social interaction leading to poor peer choices and, for some, juvenile delinquency (Schonfels, Mattson, & Riley (2005)). However, the treatment was performed in a highly controlled university setting. Thus, the next step in determining its effectiveness would be to test the treatment among children enrolling in more typical community-based programs. Given the high rates of mental health problems among children with FASDs (Streissguth et al., 1996; Streissguth & O'Malley, 2000), these children are likely to be seen for treatment in such community settings. Providing increased access to interventions that have been demonstrated empirically to be efficacious with this population is a critical step toward reducing some of the devastating secondary disabilities faced by children with FASDs and in helping their families facilitate change.

5. Study 2. Georgia-sociocognitive habilitation using the math interactive learning experience (MILE) program (Marcus Institute)

This project was developed to evaluate the effect of a sociocognitive habilitation program designed to improve the behavioral and mathematical functioning of alcohol-affected children. Deficits in

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

mathematical functioning have been reported consistently among alcohol-affected individuals (Coles et al., 1991; Goldschmidt, Richardson, Stoffer, Geva, & Day, 1996; Howell, Lynch, Platzman, Smith, & Coles, 2006; Jacobson et al., 2003; Mattson, Riley, Gramling, Delis, & Jones, 1998; Streissguth et al., 1996) and have been demonstrated throughout the lifespan of these individuals (Kopera-Frye, Dehaene, & Streissguth, 1996). Poor myelinization, particularly in areas affecting the cross-hemispheric transfer of information (Ma et al., 2005; Wozniak et al., 2006) and altered development and functioning of parietal regions of the brain that are involved in the visual-spatial processing of information (Dehaene, 1997; Geary, 1993) have been posited as potential reasons for the relative deficit in mathematics skills seen among alcohol-affected children.

A psychoeducational program for alcohol-affected children that provided learning strategies to compensate for core alcohol-related neurodevelopmental deficits was developed to facilitate mathematics learning. The program included intensive, short-term individual instruction of each child, as well as training for the child's caregivers and teachers. The goal was to provide a consistent method of instruction of mathematical concepts across therapeutic, home, and school environments. Most clinically referred children have problematic medical and caregiving histories, as well as socioeconomic problems and behavior problems that must be taken into account in designing intervention studies (Kalberg & Buckley, 2007; Kable & Coles, 2004). Therefore, support – which included caregiver education, case management services, and psychiatric consultations, as needed – also was incorporated to allow the child to achieve *readiness to learn*.

Program developers hypothesized that the learning readiness components of the intervention program would increase parental knowledge, would be viewed as helpful, and would result in improved parental perception of behavior. It also was hypothesized that children randomly assigned to a targeted habilitative program to facilitate their mathematical development would demonstrate greater maturation in mathematics skills compared with children who received standard psychoeducational services.

5.1. Method

5.1.1. Participants

Children 3–10 years of age who had a clinical diagnosis of FAS or pFAS were recruited from the Atlanta metropolitan area. Participants were required to have been with their current caregiver for at least 6 months prior to enrollment and to be projected to remain with that same caregiver for the next 6 months. Participants were excluded if their cognitive functioning was in the moderately intellectually deficient range or below, or if they had other serious mental health problems that might have interfered with their ability to benefit from academic instruction. Children who had a dual diagnosis of an FASD and attention deficit disorder were not excluded from participation. A total of 87 participants consented and were enrolled in the study, but only 61 completed study requirements for randomization. Of these, 56 completed post-testing. The mathematics group had two participants drop out and the psychoeducational only group had three families who failed to return for post-testing. Sample characteristics are presented in Table 1.

5.1.2. Measures and procedures

5.1.2.1. Readiness to learn. To establish readiness to learn among participants, case management and psychiatric consultation were provided as needed. Caregivers of participants also were required to attend two training workshops. The first workshop educated parents about FAS and provided information about special education and methods for advocating for their children. The second provided training in how to build positive behavioral regulation skills among children. Parents were given informational manuals elaborating workshop content to use as a reference.

5.1.2.2. Mathematics intervention overview. After caregivers completed the workshops, participants were randomly assigned to either the mathematics intervention group or a standard psychoeducational treatment only contrast group. All participants received the standard psychoeducational treatment consisting of a comprehensive neurodevelopmental evaluation, assistance with educational placement,

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

and development of an individualized educational plan within the context of their home school. In addition to the standard psychoeducational services, those in the mathematics intervention group received 6 weeks of tutoring services. Caregivers in the mathematics intervention group also received instruction in supporting mathematics learning at home and weekly home assignments to complement the individualized tutoring sessions. The staff special educator also met with the participant child's teacher to discuss the alcohol-related neurodevelopmental problems the participant had and the individualized educational goals for the program.

The mathematics instructional component of this program was called the math interactive learning experience (MILE). The program incorporated an active learning approach to instruction that was adapted from the "plan-do-review" methodology developed by the High-Scope Perry Preschool Project and was found to have positive long-term consequences on academic achievement and educational attainment (Luster & McAdoo, 1996; Weikart & Schweinhart, 1992) among high-risk children and to be beneficial in cognitive rehabilitation programs for children with acquired brain damage (Ylvisaker et al., 2007).

Children and caregivers in the mathematics intervention group were evaluated prior to participating in the group workshops and within 4 weeks of completing the tutoring program. To control for time between assessments, a participant child from the standard psychoeducational only group was assessed in the same week as a participant child from the mathematics intervention group. Children were evaluated by a psychologist or psychology trainee who was blind to group status.

5.1.2.3. Satisfaction. Following the workshops, caregiver satisfaction for both groups was assessed using Likert scale responses to questions regarding their experiences with the specific treatment components and interactions with staff members.

5.1.2.4. Treatment and FAS knowledge. Caregiver knowledge was assessed for both groups also. Assessed areas included the neurodevelopmental compromises associated with prenatal exposure to alcohol, the specific challenges to learning presented by these difficulties, and behavioral regulation principles. Questionnaires used multiple choice formats.

5.1.2.5. Behavioral outcomes. To measure caregiver experience of children's behavior, the Child Behavior Checklist (CBCL: Achenbach & Rescorla, 2001a, 2001b) was administered at pre-test and post-test to caregivers in both groups.

5.1.2.6. Academic outcomes. All children were administered the *Test of Early Mathematical Ability*, 2nd edition (TEMA-2; Ginsburg & Baroody, 1990) and selected mathematics-related subtests from the *Bracken Early Concept Scales–Revised* (Bracken, 1998). For children 5 years of age or older, the *Key Math-R/NU* (Connolly, 2001) also was administered. For children younger than 5 years of age, developmental testing of premathematics concepts was done using items from the *Bayley Scales of Infant Development*, 2nd edition (Bayley, 1993). Finally, the quality of number writing was assessed by rating the child's number writing for order, orientation, neatness, consistency, and general recognizability using an instrument developed as part of this study (Coles, Kable, Dent, & Lee, 2004).

5.2. Results

Analyses were conducted of the 56 participants who completed post-testing using a two-condition ($N = 29$ mathematics intervention; $N = 27$ psychoeducation only) MANOVA design. Caregiver satisfaction with workshops was very high, with over 90% of caregivers in both study groups agreeing that trainers were knowledgeable and materials were easy to understand and helpful. Pre-test and post-test score differences revealed significant gains in knowledge of FASDs, advocacy topics ($p < .05$), and behavioral regulation ($p < .000$). At post-testing, caregivers also reported fewer problem behaviors on the CBCL ($p < .000$).

Because of the passage of time and the fact that students in both groups were receiving mathematics instruction in school, it was predicted that both groups of children would demonstrate gains in mathematics knowledge, but significantly higher gains would be observed for children in the

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

group receiving direct mathematics instruction. This prediction was confirmed: 58.6% of those in the mathematics treatment group demonstrated a gain of over one standard deviation on any of the four mathematics outcome measures used, while only 23.1% of those in the psychoeducation only group did so ($p < .008$).

5.3. Discussion and conclusions

Study results suggested that parent-training components of the program were well received and were associated with reports of improved behavior at post-testing. Although it was possible that these findings might have been temporary or the result of experimenter or participant expectation, they did suggest that educational interventions might be helpful for caregivers and might lead to positive behavioral changes for children. Additional research is needed to further assess the clinical efficacy of the parent training components of this intervention. This study used only a pre-test/post-test design and not a control group with random assignment to evaluate the effect of the workshop, as was done to evaluate the mathematics intervention component.

The results of the mathematics intervention component suggested that a targeted psychoeducational program that addresses the alcohol-related neurodevelopmental difficulties might help to remediate deficits associated with prenatal alcohol exposure. Although the program was relatively short in duration, participants in the mathematics treatment group were more likely to have made a clinically significant gain than were participants assigned to the standard psychoeducational intervention group, providing evidence that effective teaching methods can improve learning for alcohol-affected children.

6. Study 3. Neurocognitive habilitation for children with fetal alcohol spectrum disorders (Children's Research Triangle)

The specific aim of this study was to develop and evaluate a program of neurocognitive habilitation for children who had been in foster care or who had been adopted, and who had a diagnosis of FAS or ARND. In 1998, the U.S. General Accounting Office (1998) reported that 74% of children in foster care in Illinois had at least one parent who was required to undergo drug or alcohol treatment as part of the case plan for family reunification. In about half the cases, alcohol was used alone or in combination with illegal drugs such as cocaine or heroin, and almost all of the children had been prenatally exposed. The pervasiveness of alcohol involvement in these cases indicated that children in foster care were a group of children at very high risk of an FASD. Even children who eventually were adopted, still had foster care as part of their developmental history (Astley et al., 2002; Streissguth et al., 1996). Unfortunately, the very factors that protect children with FASDs from developing secondary disabilities are the ones that children in the child welfare system frequently lack, such as being raised in a stable, nurturing home; being diagnosed before 6 years of age; having no sexual or physical abuse history; not changing households every few years; not living in a poor quality home; and receiving early intervention services (Streissguth et al., 1996). Thus, children with FASDs and their families need interventions tailored to their foster care experiences, and which can provide skills that mitigate negative experiences as well as counteract any lack of protective factors.

The neurocognitive habilitation program was developed to be a systematic intervention strategy for children in the child welfare system that had a diagnosis of FAS or ARND. The program provided education and support to enhance the families' capabilities to care for the children, and focuses on improving the children's executive functioning, a central deficit for children with FASDs (Mattson et al., 1998; Rasmussen, 2005). The intervention strategies developed for the program focused on the concept that children would be best equipped to improve their executive functioning deficits if they were better able to self-regulate. The program curriculum combined self-regulation techniques and strategies with tools for improving executive functioning skill sets: memory, cause and effect reasoning, sequencing, planning, and problem solving.

Many of the concepts for improving self-regulation that were used in the neurocognitive habilitation program curriculum were adapted from the *Alert Program*© (Williams & Shellenberger, 1996). The *Alert Program*© uses the metaphor of a car engine to describe the concept of self-regulation. Children are told that their brains are like a car's engine and can make their bodies run in high-, low-, or just-right gear. The

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

program is broken down into three stages: teaching children engine speed identification skills, offering children a variety of strategies to change their engine speeds to desired speed states, and learning to monitor sensorimotor input to regulate their state of arousal.

6.1. Method

6.1.1. Participants

A total of 78 foster and adopted children, 6–11 years 11 months of age, who had a confirmed history of prenatal alcohol exposure were recruited to participate in the study. Consents for participation were signed by the foster or adoptive parent(s) and, as appropriate, the Office of the Guardian of the Illinois Department of Children and Family Services (DCFS). Four children, all assigned to the treatment group, were eliminated from the sample because they and their parents did not participate in at least 4 of the 12 treatment sessions and did not follow through for exit and follow-up evaluations. These four children (three males, 1 female) did not differ from other children enrolled in the study or from other children assigned to the treatment group.

The Behavior Rating Inventory of Executive Function (BRIEF; Gioia, Isquith, Guy, & Kenworthy, 2000) is a questionnaire that assesses executive function behaviors in home and school environments. The BRIEF's internal consistency and test–retest reliability have been demonstrated to be adequate, while convergent and discriminant validity have been demonstrated with other measures of inattention, impulsivity, learning skill, and emotional and behavioral functioning.

The Roberts Apperception Test for Children (RATC) (McArthur & Roberts, 1982) is designed for children and adolescents 6–15 years of age to assess their perceptions of common interpersonal situations. Children's responses are scored on standardized scales measuring adaptive and maladaptive functioning (eight adaptive scales and five clinical scales) and providing *t* scores. The RATC scoring system has shown adequate interrater agreement and split-half reliability estimates have shown reasonable consistency. The validity of the RATC has been demonstrated in multiple ways (McArthur & Roberts, 1982.).

6.1.2. Measures and procedures

A total of 90 children and their families qualified for the study and were invited to participate; 12 declined because of geographical issues. From the 78 children who were enrolled in the study, 2 cohorts were developed via random table assignment after initial intake and a general treatment plan had been completed. The children in the intervention group ($N = 40$) received a full evaluation at Children's Research Triangle and participated in a course of 12 weekly 75-min neurocognitive habilitation group therapy sessions based on the *Alert Program*© (Williams & Shellenberger, 1996), while their parent(s) concurrently participated in a parent education group. The intervention lasted for 12 weekly sessions.

Control group children ($N = 38$) received a full evaluation at Children's Research Triangle, but were referred for services such as occupational therapy, physical therapy, or speech and language therapy through existing community- and school-based agencies, the community standard for service access and delivery at the time of the study. In contrast to children in the intervention group, children and their families in the control group did not participate in neurocognitive habilitation group therapy.

Children were enrolled in cohorts and, as much as possible, the intervention children were divided by chronological and developmental levels, with an optimal group size of five children. Licensed clinical psychologists and post-doctoral fellows under the direct supervision of a licensed psychologist conducted the assessments. Therapy services were provided by licensed clinical psychologists, licensed clinical social workers, and pre- and post-doctoral students under the direct supervision of a licensed psychologist. Outcome measures (BRIEF and RATC) were administered during the post-intervention period (following the approximately 12 weeks of intervention services) and after a comparable delay for children in the control group.

6.2. Results

Of the 40 families in the intervention group who began treatment, 4 were not able to complete the intervention or post-testing. None of the families in the control group were lost to follow-up. Because

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

the research design was a repeated measures design, a double multivariate analysis of variance approach to the data analysis–which is an extension of profile analysis–was used. The multiple subscales of a measure are considered a profile and three major questions must be addressed about this profile: (a) *Do different groups have parallel profiles* (parallelism question)? (b) *Does one group, on average, score higher on the combined subscales than another* (levels question)? and (c) *Are all the subscales the same at each time point of measurement* (flatness question)? In each analysis, all three of these questions were tested.

6.2.1. Brief

The multivariate omnibus test of significance that tested the effect of the treatment over time on the BRIEF was statistically significant ($p = .006$). Because the BRIEF has eight subtests, we conducted follow-up tests (Roy–Bargmann stepdown *F*-tests) to try to understand exactly how the treatment and control groups differed. There were no differences between the groups on any single subtest that were pronounced enough to reach statistical significance. These results suggest that the significant effect seen between the groups would be best understood as a combination of the subtests. That is, no single subtest independently would account for more of the variance between groups than any other subtest.

6.2.2. RATC

The multivariate omnibus test of significance that tested the effect of the treatment over time on the RATC adaptive scales was statistically significant ($p = .012$). There are eight adaptive scales, so again we conducted follow-up tests. One subtest did have a substantial difference that reached significance ($p < .01$): the Resolution 1 scale was the subscale that differentiated between the treatment and control groups. It appeared that children in the control group tended to narrate stories with more ease and identify unrealistic solutions to problems.

6.3. Discussion and conclusions

The results of this study suggested that children who participated in the neurocognitive habilitation program demonstrated significant improvement in executive functioning skills compared with the children in the control group. Because the treatment approach focused on the concept that children's self-regulatory problems contribute to executive functioning difficulties, the result suggested that the self-regulatory strategies and techniques taught to the children were beneficial from the parents' perspective; children appeared to learn the regulatory strategies and techniques taught in group and, as a result, parents saw improvements in the children's executive functioning skills.

The children in the treatment group at outcome also differed from those in the control group in their response to a projective storytelling test on the RATC: children in the treatment group told fewer stories that had unrealistic solutions to problems. This result might seem less intuitive than the first because the treatment approach clearly did not address directly storytelling or developing realistic solutions to stories specifically. However, one plausible explanation for this result would be related to the content of the groups. One component of the therapy focused on sequencing skills and cause-and-effect thinking. Thus, it was possible that the children internalized these concepts, as demonstrated through projective stories that had fewer unrealistic endings.

The results of this study suggested that the neurocognitive habilitation program is a promising approach to help foster and adopted children with FASDs improve their self-regulation and executive functioning skills. Further refinement of this curriculum and further investigation is needed to establish the treatment efficacy of this program.

7. Study 4. Parent–child interaction therapy: application of an evidence-based treatment to reduce behavior problems among children with fetal alcohol spectrum disorders (University of Oklahoma Health Sciences Center)

The aim of the study was to evaluate two group-based interventions for children with FASDs) that would reduce (a) behavior problems among children with FASDs and (b) decrease parenting stress

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

among caregivers. One treatment used a group adaptation of an evidenced-based behavioral parent training treatment, Parent-Child Interaction Therapy (PCIT) (Eyberg & Boggs, 1998) that provided both parents and children with a live, coached practice of behavioral parenting skills. The other was a parent-only Parenting Support and Management (PSM) program that comprised components from other effective behavioral programs (Barkley, 1997; Webster-Stratton, 2001).

Behavior difficulties are significant secondary disabilities among very young children with prenatal exposure to alcohol and other substances (Streissguth et al., 1996). According to research, caregivers' perceptions of children with prenatal exposure to alcohol and other drugs are more negative than those of children without exposure due to ongoing behavior problems that do not respond to traditional parenting (Griffith, Azuma, & Chasnoff, 1994; Paley, O'Connor, Frankel, & Marquardt, 2006). Furthermore, both biological and foster mothers of children with prenatal substance exposure have reported higher levels of parenting stress than have caregivers of children without prenatal exposure (Griffith et al., 1994). The difficult behaviors often seen among the children with FASDs together with the caregivers' negative perceptions and stress often have a detrimental impact on the child's development. Effective intervention programs to address the behavior problems of very young children with an FASD, and the distress experienced by caregivers, are essential for the overall well-being of the children and their caregivers (Bertrand et al., 2004; Streissguth et al., 1996).

Behavioral parent training is considered the single most effective method for ameliorating significant externalizing behavior problems among children in general (Brestan & Eyberg, 1998; Brinkmeyer & Eyberg, 2003). PCIT is an empirically supported intervention consisting of behavioral parent training to effect significant behavior change by the child. PCIT seeks to enhance the parent–child relationship, increase appropriate social skills, reduce inappropriate behaviors, and institute a positive discipline program (Eyberg & Boggs, 1998). PCIT is a short-term intervention, typically lasting 12–16 sessions. Decreases in conduct problems and noncompliant behaviors, as well as improvements in a child's self-esteem, have been found for those who complete PCIT (Eisenstadt, Eyberg, McNeil, Newcomb, & Funderburk, 1993). Although PCIT focuses on the parent–child relationship, research has found generalization of the positive effects to daycare, preschool, and elementary school settings (McNeil, Eyberg, Eisenstadt, Newcomb, & Funderburk, 1991).

A caveat is that behavioral parent training programs such as PCIT presume that disruptive childhood behavior originates in parent–child interaction patterns that inadvertently condition and reinforce disruptive behavior and create a negative parent–child relationship. However, the origin of the behavior problems for children with FASD are most likely rooted in the brain damage caused by prenatal exposure to alcohol. Thus the general PCIT intervention needs to be adapted to accommodate specific parenting skills that work within the learning and behavior skills of the child with an FASD who has brain damage.

7.1. Methods

7.1.1. Participants

A total of 58 children 3–7 years of age with an FASD and their caregivers were recruited for participation in this study. The FASD diagnosis was made by a clinical geneticist using a modified IOM criterion after a clinical dymorphia and CNS evaluation. Children participating had to have cognitive functioning at ≥30 months as measured by the *Bayley Scales of Infant Development*-second edition (Bayley, 1993) or the *Wechsler Preschool and Primary Scales of Intelligence*-third edition (WPPSI-III; Wechsler, 2002). Caregivers had to have an IQ of ≥65 on the K-BIT (Kaufman & Kaufman, 1990) to obtain reasonable comprehension of self-report measures. Sample characteristics are presented in Table 1. Of the 58 children recruited for the study, 46 entered treatment and were randomized.

7.1.2. Measures and procedures

The project used a randomized two-group longitudinal design. A blocked randomization pattern was used to ensure that both intervention conditions had equivalent proportions of biological versus nonbiological parents and equivalent proportions of male and female children. Following a comprehensive developmental and genetics evaluation to ascertain that FASD inclusion criteria were met, all families received a basic education/advocacy service prior to the parenting intervention.

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

Participant in both treatment and comparison conditions received 14 weeks of the assigned intervention (PCIT or PSM), with each weekly session lasting 90 min. Measures of child disruptive behavior problems and parenting stress were collected at each weekly treatment visit. A larger test-battery of measures was collected at baseline, mid-treatment, and treatment completion.

The PCIT intervention caregivers and children both were seen for treatment. Families were seen with their children for all but 2 of the 14 weekly sessions. Those two sessions focused on behavior education in general to orient families to the concept of behavior changes. In the remaining sessions, skills taught to the caregivers were practiced in session with their child with in vivo coaching via a one-way mirror and listening device placed in the parent's ear (bug-in-the-ear). Parent–child interactions were scored (coded) prior to treatment in order to assess areas most in need of intervention, as well as to establish a baseline of parent–child interaction pattern. At each of the sessions, an assessment of skills was obtained to focus the session in a family-specific manner. Families were provided feedback after each session regarding their progress in acquiring targeted skills and homework between sessions. They moved through the intervention based on skill acquisition.

The comparison program for this study also had a group format for parents only, intended to represent a plausibly beneficial but less costly and intensive intervention that could be easier to implement in community settings. It incorporated elements and approaches adapted from other supported behavioral programs shown to reduce behavior problems among children (Barkley, 1997; Webster-Stratton, 2001). The components included psychoeducation about development among children with an FASD, then moved families from awareness through acceptance and then to action, including ideas such as behavioral contracts and star charts. Discussions of implementation, challenges, and problem solving were part of each session with the group participants.

Prior to beginning the intervention, all parents completed a series of questionnaires. These included the *Parenting Stress Index third edition-Short Form* (PSI; Abidin, 1995), the Eyberg Child Behavior Inventory (ECBI; Eyberg & Pincus, 1999), and the CBCL. All of these measures have strong psychometric properties. An observation of parent–child interactions was completed and rated using the *Dyadic Parent–Child Interaction Coding System-II* (DPICS-II; Eyberg & Robinson, 2002) (presented elsewhere). The PSI and ECBI were completed each week. The ECBI shows good treatment sensitivity, such that any change is due to intervention rather than passage of time. All measures were administered again at the completion of treatment and at follow-up appointments.

7.2. Results

Approximately half (46%) of families in the study completed the entire 14-week treatment program (50% for PCIT, 42% for PSM). In general, an attrition rate of 50–75% has been reported for children referred for treatment associated with externalizing behavior problems (Brinkmeyer & Eyberg, 2003), so the observed rates were well within that range. Group differences in attrition were examined using a simple nonparametric survival analysis. This approach allows examination of dropout events and hazard rates across time. Group differences did not approach statistical significance and the survival and hazard functions visually appeared quite similar. Qualitative surveys of reasons for dropout were examined and, most often, dropout was reported to have little to do with the intervention and more to do with life circumstances (e.g., military deployment, serious illness, surgery, death in the family, removal of child from home, and job conflicts). The average number of sessions completed was 9.14 for the PCIT group and 8.92 for the PSM group.

Weekly PSI and ECBI measures were analyzed using growth models. Models for each of the two ECBI scale scores (Intensity and Problem scales) and the overall PSI score were executed. Each model treated intercepts and slopes as random effects and included tests for group differences in intercepts and slopes. Significant time (session) effects were observed for the PSI ($p < .05$), the ECBI Intensity score ($p < .001$) and the ECBI Problem score ($p < .001$). All effects were in the direction of significant reductions in scores across time. Group comparisons of time slopes (i.e., improvement rates) did not reach statistical significance for any of the three tests, although there was a nonsignificant trend favoring PCIT for the PSI ($p = .14$).

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

To estimate prescores and postscores from the growth models, estimated marginal means were generated for the pretime and posttime points. For children in the PCIT group, the mean EBCI pre-test standard score was 65, with a mean standard score of 58 post-test. For the PSM group on this measure, the mean pre-test standard score was 63, with a mean standard score of 57 post-test. Mean ECBI scores were in the clinically significant for both groups at baseline. At post-treatment, mean scores for both groups had dropped below clinical cutoffs. Examining variance components of the growth model suggested that there was very little case-to-case variation in rates of improvement across sessions.

For parents in the PCIT group, the mean PSI pre-test standard score was 97, with a mean standard score of 84 post-test. For the PSM group parents, on the PSI, the mean pre-test standard score was 88, with a mean standard score of 85 post-test.

7.3. Discussion and conclusions

Improvement over time was noted across outcome measures and across intervention conditions. No statistically significant differences in improvement between the two randomized intervention conditions were observed. Significant overall improvement in parent distress over time was noted across participants, and there were nonsignificant trends for group PCIT to yield somewhat greater rates of improvement. Child behavior problems also improved over time for both groups at rates that did not differ. Because the study did not include a placebo or no-treatment condition, spontaneous improvement, regression toward the mean or measurement artifact cannot be ruled out as explanations for improvement over time. Nonetheless, it is more likely that the improvements were to some extent the result of the interventions rather than simply the passage of time. As the measure of behavior problems, the ECBI has been found to be stable over timeframes comparable with those in this study, with change usually noted only in response to effective intervention (Eyberg & Pincus, 1999). Furthermore, research related to children with FASDs who have behavior difficulties in the significant range (as these children presented), generally do not show decreases in problems with time (Streissguth et al., 1996).

This study also found promise for reduction in behavior problems using a simple and easily implemented parent-only support and education intervention—PSM. This format might prove more cost effective in working with families with children with FASDs, given that it would require less effort and cost to deploy. Parents in both intervention programs were satisfied with treatment. All PCIT parents reported feeling positive about the program, and indicated that they would recommend it to a friend or relative. All parents enrolled in the PSM group also reported feeling positive about the program, and 80% indicated that they would recommend PSM to a friend or relative. In terms of behavioral change, 100% of PCIT parents felt that their presenting problems had improved, while 70% of PSM parents reported improvement. All parents felt neutral or confident that their child could manage future behavior problems using the skills from their respective programs. No significant differences in mean overall satisfaction were seen between groups.

In sum, the study generally supported both intervention models as viable alternatives for caregivers of children with FASDs, which was encouraging. Clear improvement can be observed using even brief behavioral interventions, using different types and intensities of behavioral interventions, even within the context of limited intervention dose and retention. This was particularly encouraging given that behavior problems among children with FASDs are generally viewed as strongly neurologically involved and not simply the product of parent–child interaction patterns.

A few limitations and corresponding directions for future research should be considered. First, the study sample was small and precluded examining potentially important case factors that might have suggested a differential benefit for one intervention model over the other. For example, it is possible that group differences might have existed depending on the initial level of a child's disruptive behavior or the parent's distress. Second, not all potentially important outcomes were examined. For example, it would have been important to learn whether the improvements noted on parent-report measures would translate to school or other environments. The nonsignificant trend favoring PCIT for reducing parent stress needs to be examined in a study with greater statistical power (i.e., having a larger sample size).

8. Study 5. Families moving forward: a behavioral consultation intervention to improve outcomes for families raising children with fetal alcohol spectrum disorders (University of Washington)

The overall goal of this study was to evaluate an intervention designed to improve caregiver self-efficacy, meet family needs, and reduce child problem behaviors. The specific aims of the study were: (a) to create a feasible, specialized behavioral consultation intervention – the Families Moving Forward (FMF) Program – for caregivers raising children with FASDs, based in part on positive behavior support techniques, and (b) to assess the efficacy of the FMF intervention, when compared with the community standard of care, using a randomized control trial design.

Most children with FASDs are identified in elementary school—a pivotal time when neurodevelopmental deficits and problematic, often disruptive behavior commonly emerge among children with prenatal alcohol exposure. What can be called "challenging behavior" is an important issue for this child population. In clinical data for 861 school-aged children referred to an FASD diagnostic clinic network in Washington State, a striking 82% showed a variety of behavior and learning problems. Parents raising children with FASDs often are highly stressed by these children (Paley et al., 2006) and these families have many unmet intervention and resource needs (Olson, Brooks, Davis, & Astley, 2004). Clinical experience and wisdom in the field suggest these parents struggle to attain positive parenting attitudes, find and use effective parenting skills, acquire needed specialized knowledge, and make effective linkages to appropriate school and community resources (Olson, Jirikowic, Kartin, & Astley, 2007).

Developmental systems literature and natural history research on individuals with FASDs has identified a cluster of factors describing a nurturing, appropriately structured, stable caregiving environment in childhood as an important protective influence for positive outcome (Streissguth et al., 2004). Translation of these concepts into tailored, useful, family-focused, scientifically validated parenting and behavior management intervention methods for use by clinicians is an important next step. Interventions are needed especially for use with caregivers raising children with FASDs who in the preschool and school years already show challenging behaviors of clinical concern, with inevitable signs of family and school disruption. Parenting intervention methods must be flexible enough to apply to the very diverse group of birth, foster, kinship, and adoptive families who raise children with FASDs. Intervention methods must also respond to the often complex psychosocial histories and circumstances of these children.

The FMF model was designed to modify specific parenting attitudes and parenting responses toward their child's problem behaviors. Through changed caregiving, the ultimate aim of FMF services was to reduce clinically concerning child problem behavior and improve other outcomes during the school years. The newly developed FMF model of behavioral consultation integrated several empirically supported child management and parent training techniques—and the clinical wisdom of "what works" in the field of FASDs (Kalberg & Buckley, 2007; Kleinfeld & Westcott, 1993; Streissguth, 1997). Most centrally, clinicians using the FMF intervention teach caregivers the skills involved in a "parent-friendly" positive behavior support approach to dealing with challenging child behaviors (called "brainstorming"). Developed in 2002, this approach is based on social learning theory and is congruent with evolving literatures on developmental disabilities and traumatic brain injury (e.g., Hieneman, Childs, & Sergay, 2006; Koegel, Koegel, & Dunlap, 1996; Lucyshyn, Dunlap, & Albin, 2002; O'Neill et al., 1997; Schoenbrodt, 2001; Ylvisaker et al., 2007). The FMF model simplifies and organizes the positive behavior support approach to make it systematic and usable for parents and clinicians. In the FMF intervention model, there is a strong emphasis on helping parents to learn and use antecedent-based behavior strategies, as well as on how to create and advocate for "accommodations" (modifications of the physical or caregiving environment) for their child. Clinicians using the FMF intervention assist caregivers in altering cognitions and attitudes, most centrally "reframing" their understanding of the behavior of the child with FASDs as affected by neurodevelopmental disabilities rather than as willful disobedience. The FMF intervention is hypothesized to improve parenting self-efficacy; meet family needs; reduce child-related stress; lead to other beneficial changes in parenting knowledge and behavior; and, ultimately, reduce "challenging" child disruptive behavior.

8.1. Methods

8.1.1. Participants

A sample of 52 children 5–11 years of age and their caregivers were enrolled from the Washington State FAS Diagnostic and Prevention Network (FAS DPN) of diagnostic clinics. Child participants all had measurable externalizing or attention problems, or both, of clinical concern at enrollment using an age-appropriate version of the CBCL (Achenbach and Rescorla, 2001b). All had evidence of variable but clear neuropsychological impairment and marked adaptive function problems seen in comprehensive test results across multiple developmental domains, yet were high-functioning enough to show a verbal IQ of $\geq$70 (and a group mean score well within the average range) on the K-BIT. There were other inclusion and exclusion criteria (e.g., living within driving distance of the University of Washington and no history of head injuries.). This sample was carefully selected to focus on children with FASDs who had demonstrated significant challenging behaviors at a young age, and were those most likely to show later costly secondary disabilities. See Table 1 for sample demographics.

8.1.2. Measures and procedures

A study was conducted using a stratified, randomized block design to assign families to either the FMF intervention group or to the community standard of care group, balanced on race or ethnicity, child sex, and birth or non-birth parent family structure. The community standard of care group received any of a range of services currently available in Washington State, which is a relatively well-served geographic area. This was a conservative intent-to-treat study design, so all participants enrolled in treatment were included in the analysis regardless of treatment dose received. Analyses revealed groups (each with $N = 26$) were well-matched on these variables, and on child age, alcohol-related diagnosis at enrollment, cumulative postnatal risk, and caregiver education.

The FMF intervention is a feasible, low-intensity, sustained model of supportive behavioral consultation lasting 9–11 months, with at least 16 every-other-week sessions typically lasting 90 min each. Services are carried out by mental health providers who receive affordable, specialized training to carry out the intervention. Limited and focused consultation with school staff and, when appropriate, community providers are available. This is an "added value" intervention, so FMF participation does not preclude families or children from receiving medication or other community services. In fact, interventionists also try to link families to needed resources in the community. The FMF intervention is manualized into a "flow" of sessions, but is also individualized for different families. There is a curriculum of easily readable, brief written materials to select from and use in sessions easily obtainable from the FMF training office. Checklists, now computerized, completed by providers after each session allow efficient monitoring of intervention fidelity. Interventionists have access to a supervisor, resource information from an FASD family advocacy group, and, if needed, brief expert consultation from a psychologist or occupational therapist, or both. In this initial efficacy trial, FMF services were provided in families' homes, but the intervention model was developed to be flexible enough for use in a variety of clinical settings.

The FMF intervention was newly developed, so some outcome measures were created for the study; and multiple aspects of sample characteristics, treatment process, and treatment outcome were examined. Primary outcomes discussed here include change from baseline to follow-up on: (a) parenting attitudes of efficacy and child-related stress as measured by the Parenting Sense of Competence (PSOC) Efficacy Scale score (Johnston & Mash, 1989); (b) stress levels as measured by the PSI Child Domain score (Abidin, 1995); and (c) caregiver ratings of child disruptive behavior immediately post-intervention as assessed by the ECBI Problem score (Eyberg & Pincus, 1999). Also discussed here are group differences at follow-up on: (a) perceived family needs met (a measure developed for this study assessing satisfaction with support received from child- and family-focused services) (family needs met, average of applicable needs met); (b) self-reported rating of change in parental self-care across the intervention period (a measure developed for the study); and (c) caregiver ratings of satisfaction with provider skill in caring for children with special health care needs using the Multidimensional Assessment of Parental Satisfaction (MAPS) score (Ireys & Perry, 1999). Results reported here were gathered immediately post-treatment, unless otherwise noted (e.g., PSI). The PSOC, ECBI, PSI, and MAPS all have very adequate psychometric properties.

8.2. Results

One hundred percent of children and 96% of caregivers completed baseline and follow-up assessments across both study groups. Of the 26 families enrolled in an intervention, 96% completed the full 9–11-month treatment (with one of the families completing a simplified intervention retaining all basic features of the model). Analyses were based on all 52 children (FMF group, $N = 26$; community standard group, $N = 26$).

Compared with caregivers in the community standard of care group, from baseline to follow-up, caregivers participating in the FMF intervention showed a significantly improved sense of parenting self-efficacy immediately post-treatment. A greater percentage of caregivers parents in the FMF intervention group reported engaging in more self-care behaviors than parents in the community comparison group (72% versus 44%, respectively; $p < .05$). No group differences emerged for change in child-related parenting stress, which was not surprising given the ongoing, marked executive functioning, other language and learning deficits or low adaptive function of these children.

A highly significant group difference ($p < .01$) revealed that the FMF intervention group reported their family needs were met more often than did the comparison families. In addition, provider satisfaction was significantly higher among those in the intervention group. On average, parents receiving the intervention also reported FMF services as highly acceptable (mean of 6.51 overall on averaged 7-point scales, where 7 is the highest score), and that they had received "just the right amount" of services for their child and themselves. Intervention was delivered with good fidelity.

Findings of perceived child behavior change were also observed. Caregivers receiving FMF services reported immediately after treatment that their children with FASDs showed a significantly decreased number of challenging disruptive behavior problems. On the ECBI, a parent report measure, children in the FMF intervention group achieved a mean standard score of 66.88 at pre-test, clearly in the clinical range. At post-test, these children showed a mean standard score of 60.54—a score just above the cutoff between the borderline clinical range and what is considered within normal limits. Among those in the community comparison group, scores at baseline and follow-up indicated clinical concern about child behavior, with the mean ECBI pre-test standard score at 64.38 and the mean post-test standard score at 63.20. The group difference was statistically significant ($p < .05$). Child behavior change over time, correlates of positive outcome, and group differences in parenting knowledge and behavior change will be discussed in future publications.

8.3. Discussion and conclusions

Children with FASDs and clinically concerning behavior problems, especially disruptive behavior and attention problems, place a heavy burden on caregivers at home and at school, and often come to the attention of mental health providers (Fryer, McGee, Matt, Riley, & Mattson, 2007; O'Connor et al., 2002; Streissguth & O'Malley, 2000). Preschool and school-aged children already struggling with clinically concerning behaviors are likely at highest risk for secondary disabilities in daily function later in life, which will require services that increase societal costs. The FMF model appears to provide a feasible, satisfying intervention with promising efficacy tailored to this high-priority group of children with FASDs and their caregivers. Data from this controlled study so far indicate a positive effect on parenting attitudes and headway on reducing child disruptive behaviors. More efficacy research is needed. Now under way in programmatic research is a project designed to streamline and transition the FMF training program and intervention from its use in a university setting to use by providers in a community setting. The current research will further assess FMF intervention feasibility and efficacy, examine program costs, ensure the FMF training program and intervention model are affordable, and make this scientifically validated intervention more widely available to families in need.

9. General discussion

Until now, information and strategies for interventions specific to individuals with FASDs have been gleaned from work with children having other disabilities (without appropriate adaptation) and

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

the practical wisdom gained by parents and clinicians through trial and error. Although informative to a limited degree, such evolving treatments have been implemented without systematic or scientific evaluation. The five interventions presented here are the first specifically designed and adapted for children with an FASD that have been scientifically tested.

These five diverse interventions uncovered basic ingredients that seem important to their success with individuals who have an FASD. Importantly, parent education or training was built into the general framework guiding all the studies. In two (Washington and Oklahoma) studies direct parent training was the primary intervention being assessed. In all studies, parents or caregivers showed improved knowledge about FASDs and applicable parenting issues. Also important was that a primary technique utilized was explicit instruction of the children (California, Georgia, and Illinois). That is, children with an FASD demonstrate a good capacity to learn new skills yet, because of underlying neurological impairment, must do so through explicit instruction rather than through observation and a process of abstracting rules, skills, and knowledge from ongoing situations as do children who are developing typically. Even those interventions focused on parent training included some amount of information on the efficacy of explicit instruction when working with their child with an FASD.

These five studies represent the wide range of possible treatments for children with cognitive, behavioral, or social problems resulting from prenatal alcohol exposure. It is essential to use programmatic research to develop multiple interventions that address the wide range of potential deficits associated with the FASD population. This approach to developing appropriate interventions is important because, as a group, children with FASDs are very heterogeneous in the nature and severity of their problems. The services needed for individuals with FASDs and their families vary according to differing neurological insults, the age or level of maturation of the child, the health or functioning of the family (see Streissguth, 1997; Streissguth et al., 1996), and the overall environment in which the child is living.

Another vital finding across the five reported interventions was that the individualized and targeted interventions specific to deficits among children with an FASD can be implemented within a framework of current community services typically available. Each project worked with already available resources such as special education, therapy services, or counseling to integrate value-added interventions specific to individuals with FASDs. As a result, these scientifically validated intervention projects moved the field forward within a community services context, rather than duplicating already available services.

As with any set of research projects, strengths and weakness were identified. Inclusion of parents as active participants and collaborators in the intervention process, either by direct intervention or adjunct parent training, was a tremendous strength of these research projects. Finally, these projects all benefited from the collaborative nature of the overall research consortium. The consortium allowed individual researchers to recognize problems common across all sites (e.g., recruitment or retention problems) and share solutions.

Intervention research is always a challenge with inherent weaknesses. First and foremost, these interventions were time-limited by funding constraints. A clear need remains to address the long-term effects and follow-up of each intervention. Whether children retained specific skills and knowledge beyond the intervention and follow-up periods could not be addressed in these studies. Further children's ability to generalize newly acquired skills could not be addressed either. For example, although they might learn a math skill or executive functioning technique appropriate for their current age, it is critical to know whether they retain that information as they enter the next developmental or academic stage. It is also important to know whether, once a skill is acquired within one domain, children are able to apply that skill to another domain. For example, if a child masters the skill of adjusting his or her readiness to learn through behavioral regulation techniques to complete mathematics assignments, will he or she be able to apply that skill to other assignments (such as writing) without specific instruction. Finally, because the overall population of children with FASDs is limited, the sample sizes in these studies were limited, although sufficient to demonstrate statistically significant effects. Thus, replication of these studies will be necessary to more solidly establish the reliability of the findings and strengthen their demonstrated effectiveness.

A major implication of these research studies for families dealing with FASDs is that they now have available tested interventions that can address their children's needs and that can be presented as

Please cite this article in press as: Bertrand, J. Interventions for children with fetal alcohol spectrum disorders (FASDs): Overview of findings for five innovative research projects. *Research in Developmental Disabilities* (2009), doi:10.1016/j.ridd.2009.02.003

scientifically validated and efficacious to intervention agents such as schools, social services, or mental health providers. A common theme reported by families is that clinicians and professionals have been reluctant to diagnose their children because there were no known effective treatments. Results of these five studies clearly dispel that concern. An important next step includes each site partnering with a community agency to adapt its intervention program to the resources, infrastructure, and personnel of its community partner agency.

PROFILE OF THE FIRST 1,400 PATIENTS RECEIVING DIAGNOSTIC EVALUATIONS FOR FETAL ALCOHOL SPECTRUM DISORDER AT THE WASHINGTON STATE FETAL ALCOHOL SYNDROME DIAGNOSTIC & PREVENTION NETWORK

Susan J Astley
Departments of Epidemiology and Pediatrics, University of Washington, Seattle, WA, U.S.A

ABSTRACT

Background
An interdisciplinary approach to fetal alcohol spectrum disorder (FASD) diagnosis using rigorously defined diagnostic guidelines has been adopted as best practice. Diagnostic clinics are being established worldwide. If these clinics are to successfully compete for limited health care dollars, it is essential to document their value.

Objective
The primary objectives were to document the value of the largest and longest standing interdisciplinary FASD diagnostic program; the Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network (WA FAS DPN). Now in its 17th year of operation, the WA FAS DPN is a statewide network of diagnostic clinics all using the 4-Digit Diagnostic Code and contributing to a centralized electronic database.

Methods
The clinical database was used to generate comprehensive profiles of all patients evaluated for FASD from 1993-2005. These profiles were used to answer a multitude of clinical, research, and public health questions including: What is the demand for FASD diagnostic services, who is referred to the clinics, and what are their FASD diagnostic outcomes? Can FAS/D prevalence estimates from this clinical population be used to estimate FAS/D prevalence estimates in the general population? Do FASD diagnostic outcomes vary by race, age or alcohol exposure? Does the presence of other adverse exposures/events lead to more severe outcomes? Does this approach to diagnosis meet the needs of families?

Results
Demand for diagnosis remains very high. Of 1,400 patients (newborn to adult) with confirmed prenatal alcohol exposure, 11% were diagnosed with FAS/PFAS, 28% with static encephalopathy, 52% with neurobehavioral disorder, and 9% with no evidence of CNS abnormality. FASD outcomes varied significantly by age, race, gender, alcohol exposure, and presence of other risk factors. Families reported high satisfaction with the diagnostic process, and receipt of information/services they were unable to obtain elsewhere.

Conclusions
This report documents the immense contribution of a statewide FASD diagnostic program, and underscores the extraordinary value of a comprehensive FASD clinical dataset.

Key Words: *Fetal Alcohol Spectrum Disorders (FASD), FASD 4-Digit Diagnostic Code*

The Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network (WA FAS DPN) is a network of statewide, fetal alcohol spectrum disorder (FASD) diagnostic clinics linked by the core clinical/research/training clinic located at the Center on Human Development and Disability at the University of Washington (UW) in Seattle

Washington. The FAS DPN began as a single CDC-sponsored clinic at the University of Washington in 1993 in response to a national request for proposals for FASD prevention. The philosophy behind the UW proposal was…If you build a clinical diagnostic program that meets the needs of the families raising children with FASD, they would seek out the services of the clinic. In so doing, each time you identified (diagnosed) a child with FAS/D, you had an opportunity to identify and potentially intervene with a woman at high risk for bearing subsequent children with FAS/D (the child's birth mother). The results of that FASD primary prevention effort are presented in Astley et al.[1,2] When the UW FAS DPN clinic first opened in 1993, it was the first to introduce an interdisciplinary approach to FASD diagnosis.[3] The interdisciplinary team included a medical doctor, two psychologists, a speech-language pathologist, an occupational therapist, a social worker, and a family advocate. A gestalt[4] approach to FASD diagnosis was initially used, reflecting the most current guidelines available at the time. This gestalt approach was replaced in 1995 by a more rigorous, case-defined FASD diagnostic system (the FASD 4-Digit Diagnostic Code[5-8]) developed by the UW FAS DPN. The 4-Digit Code was formally released to the public in 1997, with updates in 1999 and 2004. During the first two years of operation, the single UW FASDPN clinic was overwhelmed by demand for FASD diagnostic services, far exceeding its capacity. In 1995, the Washington Chapter of the National March of Dimes provided funding to establish two satellite FASD clinics in two large cities just north (Everett) and south (Federal Way) of Seattle. In 1995, the state legislature through Senate Bill SB5688 mandated further expansion of the program to six satellite clinics (located in Everett, Federal Way, Tacoma, Yakima, Pullman, and Spokane) linked by the core UW clinic in Seattle, establishing the WA FAS DPN.[9] The WA FAS DPN is now in its 17th year of funding support from the state.

The mission of the WA FAS DPN is FASD prevention through FASD screening, diagnosis, intervention, research, and training. To this end, the WA FAS DPN has created a myriad of diagnostic tools, training programs, and screening programs (FASD 4-Digit Diagnostic Code and Lip-Philtrum Guides[5-8] (1997,1999,2004), FAS Facial Analysis Software[10-12] (2003); Foster Care FAS Screening Program[13,14](1999); FASD 4-Digit Code Online Training Course[15](2004)), all of which are available to clinical professionals free or at cost to maximize access. Over the decades, this interdisciplinary approach to FASD diagnosis using the FASD 4-Digit Code has been adopted worldwide.

The core mission of the FAS DPN has always been the advancement of the field through translational research (the rapid translation of clinical research into practice). The foundation of translational research is data management. From the FAS DPN's first day of operation in 1993, all data from the diagnostic clinics have been methodically collected and entered into an electronic clinical/research database with patient consent and Human Subjects Review Board approval. Over the years, this dataset has grown to over 8,000 cases, each with up to 2,000 fields of information, providing a comprehensive documentation of statewide demand for FASD evaluations and extensive detail on the antecedents and outcomes of these evaluations. This dataset supported the development of the diagnostic tools, screening programs, and training programs listed above, and serves as one of the largest research registries of individuals with FASD (n = 2,000) for enrollment into research studies that directly benefit individuals with FASD and their families.[16-25]

Over the years, the clinical field of FASD has come to adopt, as best practice, an interdisciplinary approach to FASD diagnosis using more rigorous, case-defined diagnostic guidelines.[6,7,26,27] Interdisciplinary FASD diagnostic clinics are being established worldwide. If these clinics are to successfully compete for limited health care dollars, it is essential to document their value. To demonstrate the extraordinary and unique value of a statewide interdisciplinary FASD diagnostic clinical program (and the essential role of data collection), the outcomes of the first 13 years of operation of the WA FAS DPN are presented below. The primary objectives of this study were to:

1. Construct a comprehensive profile (based on factors A-K below) of all 1,400 Washington State residents who obtained an FASD diagnostic evaluation at one of seven

WA FAS DPN clinics between 1993 and 2005.

2. Divide the clinical population into four FASD diagnostic subgroups (ranging from no adverse outcomes to severe adverse outcomes), construct a comprehensive profile of each subgroup (based on factors A-K below), and identify risk and protective factors that differentiate the four groups.

Factors

A. Sociodemographics
B. Birth mother and birth father characteristics
C. Growth
D. FAS facial features
E. CNS structural, neurological, and functional outcomes
F. Patient's behavioral profile: Summary of Caregiver Interview and Child Behavior Check List
G. Prenatal alcohol exposure
H. Other prenatal and postnatal risk factors
I. Prevalence of other syndromes
J. Prevalence of mental health disorders
K. Patient satisfaction with the FASD diagnostic process and access to intervention services.

Primary objectives 1 and 2 allow a multitude of clinical, research, and public health questions to be addressed. For example, if a statewide FASD diagnostic program is built, what is the demand for services, who is referred to the clinics, and what are their FASD diagnostic outcomes? Are there individuals with prenatal alcohol exposure who present with no evidence of adverse outcome? Can FAS/D prevalence estimates from the clinical population be used to estimate FAS/D prevalence estimates in the general population? Do FASD diagnostic outcomes vary by race, age, or level of prenatal alcohol exposure? What is the prevalence of mental health disorders and other syndromes in this patient population? Does the presence of other adverse exposures/events (e.g., prenatal exposure to illicit drugs, poor prenatal care, multiple home placements, physical/sexual abuse) lead to more severe dysfunction? Growth deficiency has always been a hallmark of FAS/D. How prevalent is growth deficiency in this patient population? The FASD literature suggests that infants and adults are less likely to present with the full FAS facial phenotype than school-aged children? Is this true? Should a diagnosis of FAS be rendered in an infant who presents with structural evidence of CNS abnormality (microcephaly), but is too young to assess and confirm the presence of CNS dysfunction (intelligence, executive function, memory, language)? Does the presence of the full FAS facial phenotype increase the correlation between microcephaly and brain dysfunction? Who are the birth mothers and birth fathers of these children? What proportion of these patients are still in the care of their birth parents? How satisfied are patients with the services provided by the clinics? Are they provided information/services they were unable to obtain elsewhere? These questions and many more are answered in this report.

METHODS

The Washington State FAS DPN electronic clinical/research database was utilized to construct a comprehensive profile of all 1,400 Washington State residents (birth through adult) who received an interdisciplinary FASD diagnostic evaluation using the FASD 4-Digit Diagnostic Code at one of the seven WA FAS DPN clinics in the first 13 years (1993-2005) of operation. The protocol was approved by the University of Washington Human Subjects Review Board.

Interdisciplinary FASD Diagnostic Model.
All WA FAS DPN clinics use the same interdisciplinary approach[3] to FASD diagnosis using the FASD 4-Digit Diagnostic Code.[6,7]
Interdisciplinary Model. The WA FAS DPN interdisciplinary teams include a pediatrician, two psychologists, a speech-language pathologist, an occupational therapist, a social worker and a family advocate. The patient population served by the WA FAS DPN has expressed strong preference for an evaluation that can be completed in one visit. Thus, a diagnostic evaluation is conducted in one 4-hour session.[3] In preparation for the evaluation, the patient's birth, medical, school, psychological, and social service records are collected by the clinic coordinator and pre-reviewed by the lead psychologist. On the day of the evaluation, the lead psychologist presents the patient's case history, including the outcomes of

any prior medical/psychological assessments, to the team in a 30-minute case conference. While the case-conference is being conducted, the patient's growth is measured and facial photograph is taken for computerized analysis.[10] After the case-conference, the pediatrician and lead psychologist conduct an interview with the caregiver(s) while the child is assessed over a 2-hour period by the second psychologist, speech-language pathologist, and occupational therapist. The child receives a brief physical examination by the pediatrician at the end of their 2-hour assessment. The caregiver interview and child assessment sessions focus on gathering information that is needed for diagnosis and not already present in the child's records. The battery of assessments administered to each patient (both historically and on the day of the diagnostic evaluation) vary by patient age and area of developmental concern. The team reconvenes for 1 hour to derive the FASD 4-Digit Code and generate an intervention plan. The diagnosis and intervention plan are shared with the family in the final 30 minutes of the evaluation. A single comprehensive medical summary documenting the diagnostic outcome, all data used to derive the diagnostic outcome, and intervention recommendations are submitted to the patient's medical record.

The FASD 4-Digit Code. The 4-Digit Code was developed by the UW FAS DPN in 1997 with the most recent 3rd edition published in 2004.[5-8,23] Briefly, the 4 digits of the FASD 4-Digit Code reflect the magnitude of expression of the 4 key diagnostic features of FASD, in the following order: 1. Growth deficiency, 2. FAS facial phenotype, 3. CNS structural/functional abnormalities, and 4. Prenatal alcohol exposure (Figure 1). The magnitude of expression of each feature is ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong "classic" presence of the FASD feature. Each Likert rank is specifically case defined. There are 256 possible 4-Digit Diagnostic Codes, ranging from 1111 to 4444. Each 4-Digit Diagnostic Code falls into 1 of 22 unique clinical diagnostic categories (labeled A through V). Seven of the 22 diagnostic categories (4-Digit Categories A–C and E–H) fall broadly under the designation of FASD (A. FAS/Alcohol Exposed, B. FAS/Alcohol Exposure Unknown, C. Partial FAS/Alcohol Exposed, E-F. Static Encephalopathy/Alcohol Exposed, and G-H. Neurobehavioral Disorder/Alcohol Exposed).

FIG. 1A) FASD 4-Digit Diagnostic Code grid. FASD is defined by growth deficiency, specific FAS facial features, evidence of CNS damage/dysfunction, and prenatal alcohol exposure. The 4-Digit Code ranks each of these areas on 4-point, case-defined, Likert scales. The 4-Digit Code (3444) inserted in the grid is 1 of 12 codes that meet the diagnostic criteria for FAS. **B)** FASD 4-Digit Code FAS facial phenotype (**view image**). The Rank 4 FAS facial phenotype determined with the 4-Digit Diagnostic Code requires the presence of all 3 of the following anomalies: (1) palpebral fissure length 2 or more standard deviations below the norm; (2) smooth philtrum (Rank 4 or 5 on the Lip-Philtrum Guide), an (3) thin upper lip (Rank 4 or 5 on the Lip-Philtrum Guide). Examples of the full Rank 4 FAS facial phenotype for Caucasian, Native American, African American, and Asian American children are shown.

FIG. 1A FASD 4-Digit Diagnostic Code Grid

				3	**4**	**4**	**4**		
Severe	Severe	Definite	(4)		X	X	X	(4)	High risk
Moderate	Moderate	Probable	(3)	X				(3)	Some risk
Mild	Mild	Possible	(2)					(2)	Unknown
None	None	Unlikely	(1)					(1)	No Risk
	FAS			Growth	Face	CNS	Alcohol		
Growth Deficiency	**Facial Features**	**CNS Damage**							**Prenatal Alcohol**

Patient Referral Criteria and Diagnostic Capacity

The only criteria required for a patient to be seen in a WA FAS DPN clinic is a confirmed prenatal alcohol exposure history, at any level. The presence of the full FAS facial phenotype (4-Digit Face Rank 4) can be used in lieu of a confirmed alcohol history, since the Rank 4 facial phenotype, as defined by the 4-Digit Code is so specific to prenatal alcohol exposure.[11,12,14] The UW FAS DPN clinic provides evaluations to patients of all ages (newborn to adult). The other statewide FAS DPN clinics focus their services on pediatric populations. The diagnostic capacity of the WA FAS DPN has fluctuated over the years. Current funding levels support 130 evaluations per year: 80 at the UW FAS DPN and 50 at the four statewide FAS DPN clinics.

WA FAS DPN Electronic Clinical/Research Database

All data collected by the WA FAS DPN clinics since 1993 has been entered into an electronic clinical/research database with patient consent and Human Subjects Review Board approval. The majority of the data entered into the database come from two standardized data collection forms: 1) the New Patient Information Form, and 2) the FASD Diagnostic Form. These forms are provided in the Diagnostic Guide for FASD[6] and are posted on the FAS DPN website (**www.fasdpn.org**). The New Patient Information Form is completed by all families requesting an FASD diagnostic evaluation in a WA FAS DPN clinic. The form provides the clinic with key information regarding the patient's sociodemographics, growth, and development, lifetime prenatal and postnatal adverse exposures and events, including prenatal alcohol exposure, and social, educational, medical, psychological, psychiatric, and family history. The FASD Diagnostic Form is designed to capture all information required to derive and support the FASD 4-Digit Diagnostic Code (growth, facial features, CNS structural, neurological, functional measures, prenatal alcohol exposure, all other adverse prenatal and postnatal exposures, events, and conditions including all other physical anomalies and/or syndromes). The FASD Diagnostic Form is completed by the interdisciplinary team at the time of the FASD diagnostic evaluation. Data entered into the FASD Diagnostic Form include all data collected at the time of the FASD diagnostic evaluation as well as all information collected from previous records in preparation for the diagnostic evaluation (birth, medical, school, psychological, psychiatric, social service, placement, and legal records). All data collection forms are reviewed and prepared for data entry into an ACCESS[28] electronic database by SJA. Data is exported from ACCESS to SPSS[29] for statistical analysis. All 4-Digit Codes were upgraded to the most current 2004 version of the FASD 4-Digit Code.[6]

Study Population.

The following inclusion/exclusion criteria were applied to the WA FAS DPN database to establish the study population for this report.

Inclusion Criteria:

1. Received an FASD diagnostic evaluation at one of the seven WA FAS DPN clinics between 1993 and 2005.
2. Was a resident of Washington State at the time of their FASD diagnostic evaluation.
3. Had confirmed prenatal alcohol exposure, at any level. May have an unknown prenatal alcohol exposure history only if their FASD 4-Digit Code diagnostic outcome was full FAS (the Rank 4 FAS facial phenotype is so specific to prenatal alcohol exposure, it can be used in lieu of a prenatal alcohol exposure.[11,12,14,23])
4. Male or female, all ages, all races/ethnicities.

Exclusion Criteria:

1. None.

A total of 1,400 patients met the inclusion/exclusion criteria for this study. Patients evaluated in the WA FAS DPN after 2005 were not included in this study because their data are still in various phases of data entry, monitoring, and cleaning.

Study Groups

The study population was divided into four FASD diagnostic subgroups defined below. A recently completed FASD magnetic resonance study, conducted on a subset of this clinical population, confirmed these first three groups reflect three clinically meaningful and statistically distinct

FASD diagnostic subgroups.[16,23-25] Using the FASD terminology introduced by the Institute of Medicine[30], the SE/AE group most closely reflects 'severe Alcohol-Related Neurodevelopmental Disorder (ARND)' and the ND/AE group most closely reflects 'mild ARND'. The 4th group (Normal CNS/AE) by definition does not fall fully under the umbrella of FASD. This group represents individuals who have a confirmed prenatal alcohol exposure, but present with no evidence of adverse CNS outcomes. Some, but not all, present with growth deficiency and/or FAS facial features. The very existence of this group confirms that not all individual exposed to prenatal alcohol present with evidence of adverse outcomes. Inclusion of this group in this study presents an opportunity to identify potential 'protective' factors against prenatal alcohol exposure. The diagnostic features specific to each group were as follows:

1. *Patients in Group 1* had a 4-Digit diagnosis of **FAS or Partial FAS (FAS/PFAS)** (e.g., 4-Digit Diagnostic Categories A,B,C: with Growth Ranks 1-4, Face Ranks 3-4, CNS Ranks 3 and/or 4, Alcohol Ranks 2-4) (Figure 1). Alcohol Rank 2 (unknown exposure) could only be present if the patient had a diagnosis of full FAS because the Rank 4 FAS facial features are so specific to prenatal alcohol exposure.[11,12,14] In summary, patients in Group 1 had severe cognitive/behavioral dysfunction and the FAS facial phenotype.
2. *Patients in Group 2* had a 4-Digit diagnosis of **Static Encephalopathy / Alcohol Exposed (SE/AE)** (e.g., 4-Digit Diagnostic Categories E,F: with Growth Ranks 1-4, Face Ranks 1-2, CNS Ranks 3 and/or 4, Alcohol Ranks 3-4). In summary, patients in Group 2 had severe cognitive/behavioral dysfunction, comparable to Group 1, but did not have the FAS facial phenotype.
3. *Patients in Group 3* had a 4-Digit diagnosis of **Neurobehavioral Disorder / Alcohol Exposed (ND/AE)** (e.g. 4-Digit Diagnostic Categories G, H: with Growth Ranks 1-4, Face Ranks 1-2, CNS Rank 2, Alcohol Ranks 3-4). In summary, patients in Group 3 had prenatal alcohol exposure comparable to Groups 1 and 2, but in comparison to Groups 1 and 2 had only mild to moderate cognitive/behavioral dysfunction, and did not have the FAS facial phenotype.
4. *Patients in Group 4* had a 4-Digit diagnosis of **Sentinel Physical Findings/Alcohol Exposed** or **No Physical Findings or CNS Abnormalities Detected / Alcohol Exposed (Normal CNS/AE**) (e.g., 4-Digit Diagnostic Categories I and J: with Growth Ranks 1-4, Face Ranks 1-4, CNS Rank 1, and Alcohol Ranks 3-4. In summary, patients in Group 4 had prenatal alcohol exposure, no CNS abnormalities, and may or may not have had growth deficiency and/or FAS facial features.

Data Analysis

Objective 1: Descriptive statistics (means, SDs, proportions) were used to summarize the sociodemographic and clinical profiles of the clinical population as a whole, and each of the four diagnostic subgroups (1. FAS/PFAS; 2. SE/AE; 3. ND/AE; and 4. Normal CNS/AE). Proportions are expressed as valid column percents in all tables unless otherwise specified.

Objective 2: Empirical analyses were conducted to identify risk and protective factors that differentiated the four diagnostic subgroups. Chi-square tests (or Fishers Exact where appropriate) were used to compare proportions between 2 or more subgroups. T-tests were used to compare means between two groups. ANOVA was used to compare means between 3 or more groups. When ANOVA was employed, the overall f-statistic was used to test if differences existed among the group means. When the overall f-statistic was statistically significant, the Duncan post hoc range test was used to identify which group means differed. The Duncan test makes pairwise comparisons using a stepwise procedure. Means are ordered from highest to lowest, and extreme differences are tested first. The Duncan test sets a protection level for the error rate for the collection of tests. The Duncan test identifies homogeneous subsets of means that are not different from one another. For example, if the outcome of a Duncan test is presented as 1,23,4, this means the mean for groups 2 and 3 were comparable to one another, but significantly higher and lower than the means for groups 1 and 4 respectively. Two-tailed p-values of 0.05 were used throughout the analyses. Due to multiple comparisons, resulting p-values should be interpreted accordingly.[31,32] As a

general point of reference (since sample size varied with each analysis), this study had 80% power or greater to detect the following effect sizes (at a two-tailed alpha level of 0.05) when a study group had 65 or more subjects: 1) A difference in means one-half the standard deviation of the mean difference; 2) A 24-point or greater difference in proportions between two groups.

RESULTS

Demand for FASD Diagnostic Services and Ability to Meet the Demand

Although the WA FAS DPN provides FASD diagnostic evaluations to patients from all over the U.S., the vast majority (95%) reside in WA State. Demand for FASD diagnostic services has always exceeded the FAS DPN's capacity, but expansion from the single clinic to a statewide network of clinics doubled its capacity and increased access to FASD diagnostic services. The WA FAS DPN's current capacity is 130 diagnostic evaluations per year. A total of 6,586 families from WA State requested an FASD diagnostic evaluation between 1993 and 2005; on average 506 per year. Patients request an appointment by sending their name and address to the clinic via voicemail or email. All patients requesting an appointment are sent an information packet that includes a description of the clinical services and a New Patient Information Form (NPIF). Patients are requested to complete the NPIF and submit it to the clinic for review. The NPIF documents why a diagnostic evaluation is being requested, what the developmental concerns are, if any, and whether the patient has a confirmed prenatal alcohol exposure. Of the 6,586 requests, 3,004 (47%) completed and submitted the NPIF. In a survey conducted in the mid 1990's, the primary reason stated for not submitting the NPIF was lack of a confirmed prenatal alcohol exposure. Oftentimes, families are requesting evaluations because they are concerned about their child's development, have confirmation of maternal illicit drug use during pregnancy and therefore suspect prenatal alcohol exposure. It has become clear after 17 years of clinical record review that when women use illicit drugs and alcohol during pregnancy, their illicit drug use is far more likely to be documented in medical or social service records than their alcohol use. Of the 3,004 NPIFs submitted, 2,462 (82%) appeared to have a confirmed prenatal alcohol exposure and were thus eligible to be evaluated in clinic. The 18% without a confirmed prenatal alcohol exposure were referred to other appropriate clinics (typically neurodevelopmental clinics). Of the 2,462 patients deemed eligible to be evaluated in the FAS DPN clinics, 1,668 (68%) received a diagnostic evaluation between 1993 and 2005. The average wait to be seen in a clinic, from the time the NPIF was submitted, was 6.7 months. Of the 1,668 patients evaluated in the clinics, 268 were deemed to have an unknown prenatal alcohol exposure, despite what appeared to be a confirmed prenatal alcohol exposure at the time the evaluation was requested. Exclusion of the 268 patients with unknown alcohol exposure produced the sample of 1,400 patients summarized in this report.

FASD Diagnostic Outcomes (Table 1)

Of the 1,400 residents of WA state evaluated in the WA FAS DPN in the first 13 years of operation, 4% were diagnosed with FAS, 7% had PFAS, 28% had Static Encephalopathy (without the FAS facial phenotype), 52% had Neurobehavioral Disorder, 2% presented with growth deficiency and/or FAS facial features, but no evidence of CNS abnormalities, and 7% presented with no growth deficiency, no FAS facial features, and no evidence of CNS structural, neurological, or functional abnormalities, despite their prenatal alcohol exposure. The core clinic at the University of Washington provided diagnostic evaluations for 930 (66%) of the 1,400 patients. The remaining 470 were evaluated at one of the six other FAS DPN statewide clinics. The distribution of FASD diagnoses rendered by the core UW FAS DPN clinic was comparable to the distribution of FASD diagnoses rendered by the six other statewide FAS DPN clinics.

Sociodemographic Profile (Table 2)

Although patients of all races and ethnicities were evaluated in the FAS DPN clinics, the racial distribution of the clinical population was significantly different from the racial distribution of the state ($chi^2 = 100$, $p < 0.000$). The WA State 2000 census reported the following distribution of single races: White 82%, American Indian/Native

Alaskan 2%, Black 3%, Asian 6%).[33] By comparison, Caucasians (48.9%) and Asians (0%) were under-represented in the clinical population and Black (6.6%) and American Indian/Native Alaskan (8.2%) groups were over-represented. Males were significantly more prevalent (58%) than females (42%) (chi^2 18, $p< 0.000$). The vast majority of the population (90%) was under 16 years of age with a mean age of 9.9 years (6.2 SD) and an age range of 7 days old to 50.8 years old. Only 22% percent of the patients were accompanied to clinic by their birth mother. The vast majority (70.5%) were not residing with their birth mother or birth father at the time of their diagnostic evaluation.

Contrasts between FASD Diagnostic Subgroups

Factors A-K below are compared and contrasted between the four clinical subgroups (1. FAS/PFAS, 2. SE/AE, 3. ND/AE, and 4. Normal CNS/AE).

Factors

- **A.** Sociodemographics (Table 2)
- **B.** Birth mother and birth father characteristics (Table 3)
- **C.** Growth (Table 4)
- **D.** FAS facial features (Table 4)
- **E.** CNS structural, neurological, and functional outcomes (Tables 5 and 6)
- **F.** Patient's behavioral profile: Summary of Caregiver Interview and Child Behavior Check List[34] (Tables 7 and 8, Figures 2 and 3)
- **G.** Prenatal alcohol exposure (Table 9)
- **H.** Other prenatal and postnatal risk factors (Table 10)
- **I.** Prevalence of other syndromes (Table 10)
- **J.** Prevalence of mental health disorders (Table 11)
- **K.** Patient satisfaction with the FASD diagnostic process and access to intervention services. (Table 12)

Use of the FASD 4-Digit Code by seven statewide, interdisciplinary teams, over a period of 13 years, produced three clinically and statistically distinct FASD clinical subgroups. The three subgroups (ND/AE, SE/AE and FAS/PFAS) reflected a linear continuum of increasing neuropsychological impairment and physical abnormality, representing the full continuum of FASD.

DISCUSSION

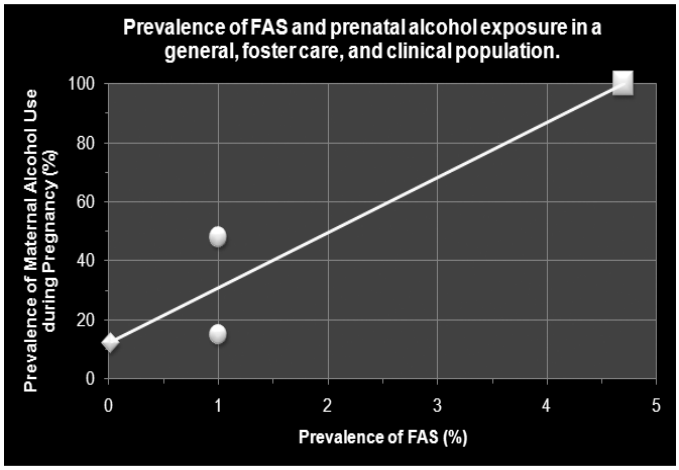
An infinite array of clinical, research, and public health questions can be addressed using the WA FAS DPN clinical dataset. The answers to a selection of questions are presented and discussed below to document the immense value and contribution of a statewide FASD diagnostic program, and underscore the extraordinary value of a comprehensive FASD clinical dataset.

1. Does the prevalence and distribution of the FASD diagnostic outcomes observed in this statewide *clinical* population reflect the prevalence and distribution one would expect to observe in the statewide *general* population?

No. The prevalence of FASD will be higher in this clinical population than in the general population for two reasons: 1) all individuals in this clinical population have a prenatal alcohol exposure, and 2) individuals experiencing difficulties are more likely to be referred to a clinic than those not experiencing difficulties. How much higher will the prevalence be? Below are some FASD prevalence estimates from other population samples (and their corresponding alcohol-exposure estimates) to compare to our clinical sample. The prevalence of FAS in our statewide clinical population was 4.2%. One hundred percent had a confirmed prenatal alcohol exposure. The prevalence of FAS in the King County subset of our statewide clinical population (were Seattle and the University of Washington are located) was 4.7%. Again, 100% had a confirmed prenatal alcohol exposure. In comparison, the prevalence of FAS in a foster care population residing in King County (as documented by a 10-year, active case-ascertainment FAS screening program) was 1.5%.[14] Fifteen percent of this foster care population had a documented prenatal alcohol exposure in their foster records. Forty-eight percent had a confirmed or suspected prenatal alcohol exposure in their foster records. Thus the true prevalence of prenatal alcohol exposure in this foster population was likely somewhere between 15% and 48%. The FAS prevalence estimates from these clinical and high-risk foster populations are 15 to 47 times greater than the FAS prevalence estimate often cited for the general U.S. population (0.1 – 0.3%).[35] National surveys of the general population

estimate 12% of women report drinking during pregnancy.[36] If one plots the prevalence of FAS to the prevalence of alcohol exposure across these three populations (clinical, foster care, and general), an interesting trend appears (Figure 4).

FIG. 4 Prevalence of FAS and prevalence of maternal alcohol use during pregnancy in three populations: ♦General U.S. population (FAS = 0.2%[35], alcohol use = 12.2%[36]). ●King County WA foster care population (FAS = 1%, alcohol use = 15% to 48%).[14] ■King County WA FAS Diagnostic & Prevention Network (FAS DPN) clinical population (FAS = 4.7%, alcohol use = 100%). Best fit linear trend line: y = 18.989x + 12.352; R-squared = 0.89. FAS: fetal alcohol syndrome.



Another related question that is often raised is: How much more prevalent is "ARND" than FAS? The prevalence of SE/AE and ND/AE combined (what other diagnostic systems refer to as ARND[27,30]) was 7.2-fold greater than the prevalence of FAS/PFAS in our clinical population. Does this mean there are 7 times more individuals with ARND than FAS in the *general* population? The true ratio is likely higher for the following reason. Since individuals with severe outcomes are more likely to be referred to a clinic than individuals with less severe outcomes, diagnostic subgroups with the most severe outcomes will likely be disproportionately over-represented in a clinical population. Thus, if FAS is more severe than SE/AE, the prevalence of SE/AE to FAS would likely be higher in the general population than was observed in this clinical population. The published literature suggests ARND is as least three times more prevalent than FAS.[37] Unfortunately, the published literature does not specifically case-define ARND or FAS, so it is difficult to know which of our clinical subgroups to compare them to. The ratio of ARND to FAS, generated from our clinical population, ranges from a low of 2.6-fold (if ARND is defined as SE/AE+ND/AE and FAS is defined as FAS+PFAS) to a high of 18.9-fold (if ARND is defined as SE/AE + ND/AE and FAS is defined as FAS). No matter how one chooses to define ARND and FAS, our clinical data strongly suggest "ARND" is at least 3-fold greater than FAS, but likely much higher. In summary, prevalence estimates derived from clinical populations will exceed those of the general population, but clinical estimates can play an important role in formulating estimates for the general population. An FASD diagnostic clinic is a form of passive population-based FASD screening. The individuals referred are the subset of the general population who were identified by community professionals as at-risk and in need of diagnostic and intervention services.

2. Did the prevalence estimates for FAS/PFAS, SE/AE, and ND/AE vary by race? Yes (Table 13). And these variations were correlated with racial variations in drinking patterns during pregnancy. The prevalence of FAS/PFAS was significantly higher among Caucasians (12.7%) and Blacks (18.5%) than among American/Alaskan Natives (5.2%) (Caucasian versus Native: Chi=5.4, p=0.02; Black versus Native: Chi=9.1, p=0.003). Caucasians and Blacks also reportedly drank significantly more days per week during pregnancy (on average 4.6 and 5.7, respectively) than American/Alaskan Natives (on average 3.6). Interestingly, the only measure of prenatal alcohol exposure that significantly differentiated FAS/PFAS from all other FASD diagnoses, across the entire study population of 1,400, was a higher mean number of days per week of drinking during pregnancy. This same finding was observed in the recently completed FASD magnetic resonance study.[24] Since the window of vulnerability for producing the FAS facial features appears to be very short in duration (a few hours in the mouse[38], a few days in the nonhuman primate[39]), perhaps the more days per week of drinking, the more likely drinking will occur during this narrow window of vulnerability. In contrast to FAS/PFAS, the prevalence of SE/AE "severe ARND without the FAS facial features" was significantly higher in American/Alaskan Natives (41.7%) than in Caucasians (26.6%) or Blacks (20.7%). American/Alaskan Natives reportedly drank a significantly higher number of drinks per drinking occasion during pregnancy than Caucasian or Blacks. Perhaps binge drinking places a fetus at greater risk for CNS structural/functional abnormalities, whereas more frequent drinking increases the odds of also having the FAS facial features.

3. Did the prevalence estimates for FAS/PFAS, SE/AE, and ND/AE vary by age? The prevalence of FAS/PFAS did not vary significantly by age at diagnosis: 0-3.9 yrs (15%), 4-5.9 yrs (9%), 6-10.9 yrs (11%), 11-15.9 yrs (9%), 16+ yrs (10%); Chi=6.3 (p=0.18). An infant was as likely to receive a diagnosis of FAS/PFAS as an adult. As a point of reference, the prevalence of FAS/PFAS across the entire study sample of 1,400 was 11 %. The prevalence of ND/AE varied from 45.3% to 58.4% across the age categories, but these variations were not statistically significant. Again, for reference, the prevalence of ND/AE across all 1,400 subjects was 51.6%. The prevalence of SE/AE did vary significantly by age. Children under the age of 6 years were significantly less likely to receive a diagnosis of SE/AE than older individuals. This may be explained, in part, by the fact that a key clinical feature of SE/AE is significant dysfunction across three or more domains of cognitive/behavioral function. A child typically is not old enough to engage in an assessment of higher level functioning (executive function, memory, language, etc) until they are 7 to 8 years of age. But an individual does not have to have significant dysfunction to meet the CNS criteria for SE/AE. They could meet the criteria with microcephaly. In fact, the CNS criteria for FAS/PFAS and SE/AE are identical (presence of a CNS structural/neurological abnormality and/or significant dysfunction across 3 or more domains of brain function).[6] So why are individuals with SE/AE significantly older (mean = 10.1 years) than individuals with FAS/PFAS (mean = 8.9 years) if the CNS criteria to achieve these two diagnoses are identical? Remember, the only feature that distinguishes FAS/PFAS from SE/AE is the FAS facial phenotype. As it turns out, those with the FAS facial phenotype are significantly more likely to have microcephaly (the prevalence of microcephaly among FAS/PFAS was 45%) than those with comparable brain dysfunction, but no FAS facial phenotype (the prevalence of microcephaly among SE/AE was 25%). This same finding was observed in the recently completed FASD MRI study.[16] More specifically, individuals with FAS/PFAS had significantly and disproportionately smaller frontal lobes than individuals with SE/AE. Since head circumference can be accurately assessed in children less than 8 years of age, but a comprehensive assessment of brain dysfunction cannot, the higher prevalence of microcephaly among the FAS/PFAS group produces a diagnostic subgroup that is significantly younger than the SE/AE subgroup. This observation leads to the next question.

4. Is it clinically cogent to render a diagnosis of FAS in an infant who presents with structural evidence of CNS abnormality (microcephaly), but is too young to assess and confirm the

presence of brain dysfunction (intelligence, executive function, memory, language, etc)? Is the presence of microcephaly in an infant with the FAS facial phenotype predictive of brain dysfunction that will not be revealed until an infant is old enough to participate in higher level functional assessments? The answers to both questions are yes. Among the 154 patients with FAS/PFAS, 69 (44.8%) had microcephaly (Table 5). Of the 69 with microcephaly, 36 (52%) had no evidence of brain dysfunction (Rank 1), 14 (20%) had moderate (Rank 2) brain dysfunction, and 19 (28%) had severe (Rank 3) brain dysfunction. Did the 52% with no evidence of brain dysfunction, truly have normal function, or were they too young to accurately/comprehensively assess function? The data would suggest they were too young to assess. The subset with no evidence of brain dysfunction (Rank 1) had a mean age of 4.7 (6.0 SD) years. The subset with Rank 2 moderate dysfunction had a mean age of 7.5 (5.9 SD) years. And the subset with Rank 3 severe dysfunction had a mean age of 10.3 (5.9 SD) years. The older the patient, the more likely they revealed evidence of moderate to severe dysfunction (ANOVA F=5.8 (df 2), p=.005). This data suggests rendering a diagnosis of FAS/PFAS in a newborn/infant that presents with microcephaly, but is too young to assess/confirm brain dysfunction, is clinically sound. The combined presence of the FAS facial phenotype, microcephaly, and prenatal alcohol exposure serves as a strong risk factor for (predictor of) brain dysfunction. The correlations between increasing magnitude of expression of the 4-Digit FAS facial phenotype and 1) increasing CNS dysfunction ,and 2) decreasing head circumference are quite high (Figures 5A,B).[11,16] Early diagnosis affords early intervention. Postponing a FAS/PFAS diagnosis in children with microcephaly, who were not old enough to participate in higher-level functional assessments to confirm brain dysfunction, could lead to missed opportunities for early intervention.

FIG. 5A) The mean Performance Intelligence Quotient (PIQ) standard score (WISC III [40]) decreased significantly as the FAS facial phenotype increased in magnitude from 4-Digit Face Rank 1 to 4 (ANOVA: F 2.7(3df), p =.046).

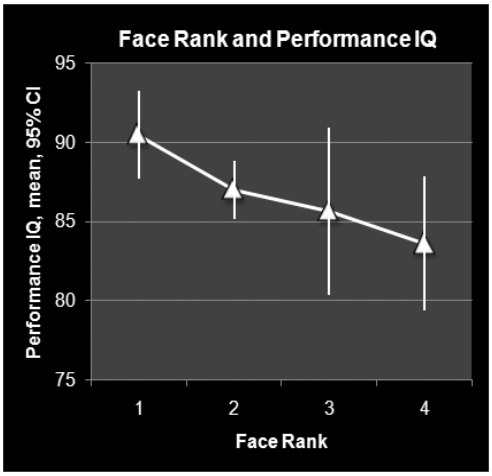


FIG. 5B) The mean occipital frontal head circumference (OFC) in centimeters (cm) decreased significantly as the FAS facial phenotype increased in magnitude from 4-Digit Face Rank 1 to 4 (ANOVA: F 26 (3df), p < .001).

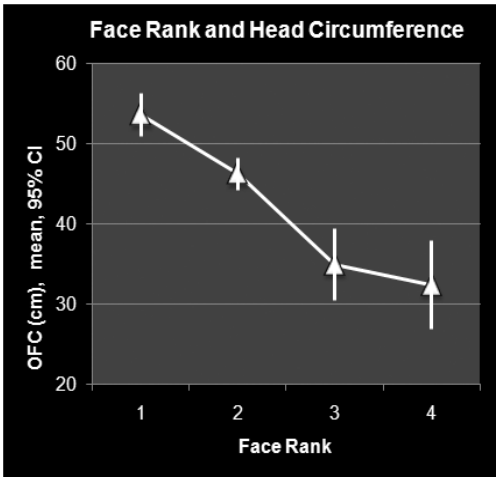


5. Do the CNS functional profiles of the FAS/PFAS, SE/AE and ND/AE groups differ when generated by a single, age-appropriate, comprehensive neuropsychological battery administered to all patients, as compared to when generated by variable neuropsychological batteries that may focus more on deficits than strengths (as is often the case in clinical settings)? The CNS functional profiles of the FAS/PFAS, SE/AE, and ND/AE groups presented in Table 6 were generated from two primary sources of data: 1) past school/psychological assessments, and 2) current assessments conducted at the time of the FASD diagnostic evaluation. These school and clinic-based assessment protocols are more likely to target areas of deficit (rather than areas of strength) because the primary goals of these assessments are to determine if an individual qualifies for school-based services or meets established FASD diagnostic criteria. As a result, no two patients in the FAS DPN clinical dataset necessarily received the same test battery, and their test batteries likely focused more on their deficits than their strengths. This could lead to group profiles that under estimate the mean performance levels of each group as a whole. If every patient received the same age-appropriate test battery, and the battery assessed all areas of function, not just the areas with perceived deficits, how different might the profiles be? The recently completed FASD magnetic resonance research study provided an opportunity to answer this question.[24] Sixty-five children across the full continuum of FASD were randomly selected for enrollment into the magnetic resonance study from among these 1,400 WA FAS DPN patients. As a standard of research protocol, a single, comprehensive neuropsychological battery was administered to all 65 children.[24] The CNS functional profiles generated by the single, comprehensive research battery[24] were near identical to the functional profiles generated by the more variable, less comprehensive clinical batteries (Table 6). For example, the mean FSIQ[40] standard scores for the FAS/PFAS, SE/AE, and ND/AE groups in the magnetic resonance study were 77.5, 79.3, and 99.2 respectively. The mean Visual Motor Integration[41] total standard scores for the FAS/PFAS, SE/AE, and ND/AE groups in the magnetic resonance study were 76.2, 81.4, and 90.9 respectively. The mean Rey Complex Figure Test[42] Copy Raw Scores for the FAS/PFAS, SE/AE, and ND/AE groups in the magnetic resonance study were 17.4, 20.5, and 25.6 respectively. These outcomes suggest the CNS profiles presented in Table 6 were not markedly influenced by the variable clinical batteries used to generate them.

6. Do FASD diagnostic outcomes vary by level of prenatal alcohol exposure? Yes (Table 9). Individuals with FAS/PFAS had a significantly higher mean number of days per week (5.6) of prenatal alcohol exposure than individuals with a comparable level of CNS dysfunction, but no facial features (SE/AE) (4.3 days/week) ,or individuals with less severe CNS dysfunction and no facial features (ND/AE) (4.4 days/week). This same finding was observed in the FASD magnetic resonance study.[24]

7. Is the presence of other adverse exposures/events (e.g., prenatal exposure to illicit drugs, poor prenatal care, multiple home placements, physical/sexual abuse) associated with more severe developmental outcomes? Yes (Table 10). Prenatal alcohol exposure was rarely, if ever, the sole risk factor present among patients evaluated at the WA FAS DPN. One third of the population had no documented prenatal care. Ninety-three percent had other adverse prenatal exposures (e.g., tobacco, illicit drugs). Seventy percent were no longer in the care of their birth parents and had on average three out-of-home placements. At least 34% were physically abused and 24% sexually abused. Seventy-five percent had one or more mental health disorders documented in their medical record. The prevalence of adverse exposures and events was for the most part, comparably high across the three FASD groups (e.g., tobacco, illicit drug use, neglect, out-of-home placements). Occasionally the prevalence increased incrementally with increasing severity of FASD diagnostic outcome from NE/AE to SD/AE to FAS/PFAS (e.g., no prenatal care). Most striking, however, were the contrasts observed between the three FASD groups and Group 4 (the group with no evidence of CNS abnormality). Physical and sexual abuse was 2- to 5-fold more prevalent in the FASD groups than in Group 4. Children in the FASD

groups were twice as likely to be in adoptive care and significantly less likely to receive prenatal care than children in Group 4. Prenatal exposure to alcohol and other illicit drugs was comparably high across all four groups.

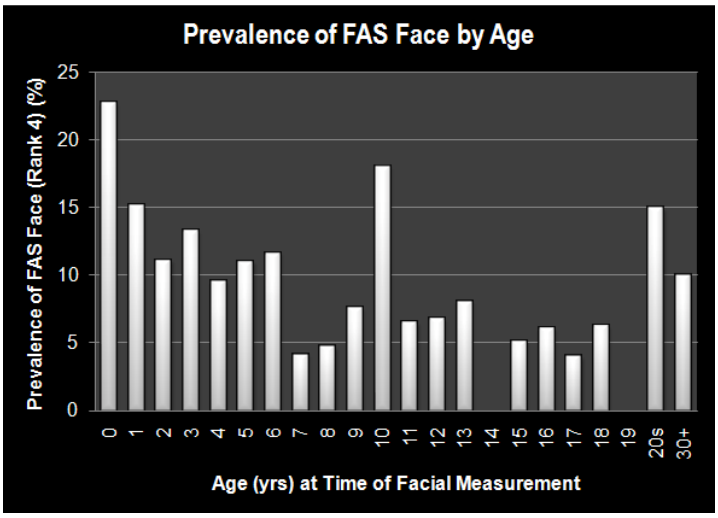
8. What proportion of individuals with prenatal alcohol exposure present with no evidence of CNS structural, neurological, or functional abnormalities? Were they exposed to less alcohol? Of the 1,400 subjects with prenatal alcohol exposure, 130 (9.3%) presented with no evidence of CNS abnormality (Table 1). Ninety-six of the 130 subjects in Group 4 presented with no growth or FAS facial features either. Although one might expect to see a lower reported alcohol exposure among this group, their reported level of exposure was comparable to that of the SE/AE and ND/AE groups. Three features that did distinguish this unaffected group from the other groups were their gender, age, and postnatal adverse experiences. The unaffected group was significantly more likely to be female (57.7%) than the other FASD clinical subgroup (FAS/PFAS 48.1%; ND/AE 41.6%; SE/AE 35.3%). And the unaffected group was significantly younger (46.2% were under 4 years of age) compared to 25.3% among the FAS/PFAS, 10.7% among the SE/AE, and 16.2% among the ND/AE. It is likely that some of the subjects in the unaffected group were classified as functionally within the normal range because they were too young to assess and rule-out higher level functional deficits. The only way an infant could meet the CNS functional criteria for SE/AE is with significantly delayed mental and motor development (e.g., Mental and Motor Developmental Index standard scores of 50 on the Bayley Scales of Infant Development[43]). But young age does not explain why the 130 patients in Group 4 did not meet the CNS functional criteria for ND/AE. A third factor that markedly differentiated the unaffected group from the three affected groups was adverse postnatal experiences. As reported above, the unaffected group was significantly less likely to experience high-risk (Rank 4) postnatal adverse events like physical or sexual abuse.

9. How often are other syndromes present in this patient population? Eighteen (1.3%) of the 1,400 subjects were diagnosed with other syndromes (Table 10). Only one of the seven clinics had a dysmorphologist on their interdisciplinary team. When the prevalence estimate was restricted to the 664 patients seen at the UW FAS DPN between 1993 and 1999 when a dysmorphologist served as the pediatrician on the team, 13 (1.9%) were identified with other syndromes. When syndromes other than FAS were suspected by the other pediatricians on the teams (the pediatricians who were not dysmorphologists or geneticists), the patients were referred to a geneticist. Of the 736 patients seen by the other pediatricians 5 (0.7%) were documented to have another syndrome and an additional 8 (1.1%) were suspected to have another syndrome and were referred to a geneticist. Thus, the pediatricians documented or suspected the same proportion of patients with other syndromes (1.8%) as was diagnosed when a dysmorphologist was on the team (1.9%). It is worth noting that one child diagnosed with FAS in the WA FAS DPN also had Down syndrome. Alcohol is a teratogen to all developing fetuses, including those with genetic disorders. The child presented with growth deficiency below the 2nd percentile on a growth chart for children with Down syndrome. The child presented with the facial features of Down syndrome and FAS. The facial features of Down syndrome are distinct from the facial features of FAS. The two phenotypes were readily apparent and easily distinguished. The child presented with microcephaly (3 SDs below the mean for boys with normal development, 1 SD below the mean for children with Down syndrome). The child presented with Bayley[43] Motor and Mental Index scores below 50; a level of developmental delay that can be observed in both Down syndrome and FAS. The birth mother was reported to have consumed alcohol daily throughout pregnancy.

10. The FASD literature suggests that infants and adults are less likely to present with the full FAS facial phenotype than school-aged children. Is there evidence of this in this dataset? No. The proportion of subjects who presented with the full FAS facial phenotype (Rank 4) by age group was as follows: birth to 3.9 yrs (36/258, 14%), 4 to 16.9 years (78/1001, 7.7%), and 17 to 53 years (12/141, 9.5%). The age group with the highest prevalence of the FAS facial phenotype was infants under one year of age (23%) (Figure 6).

Profile of the first 1,400 patients receiving diagnostic evaluations for fetal alcohol spectrum disorder at the Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network

FIG. 6 Proportion of patients in each age group who presented with the full Rank 4 FAS facial phenotype at the time (age) of their FASD diagnostic evaluation.



11. Growth deficiency has always been a hallmark of FAS/D. How prevalent is growth deficiency in this patient population? Only 34.1% of the 1,400 subjects presented with height and/or weight below the 10th percentile (Growth Ranks 2, 3 or 4). Only 7.9% presented with height and weight below the 3rd percentile (Growth Rank 4). Of the patients with FAS/PFAS, 35.7% presented with no growth deficiency (Growth Rank 1: height nd weight above the 10th percentile) and thus received a diagnosis of PFAS.

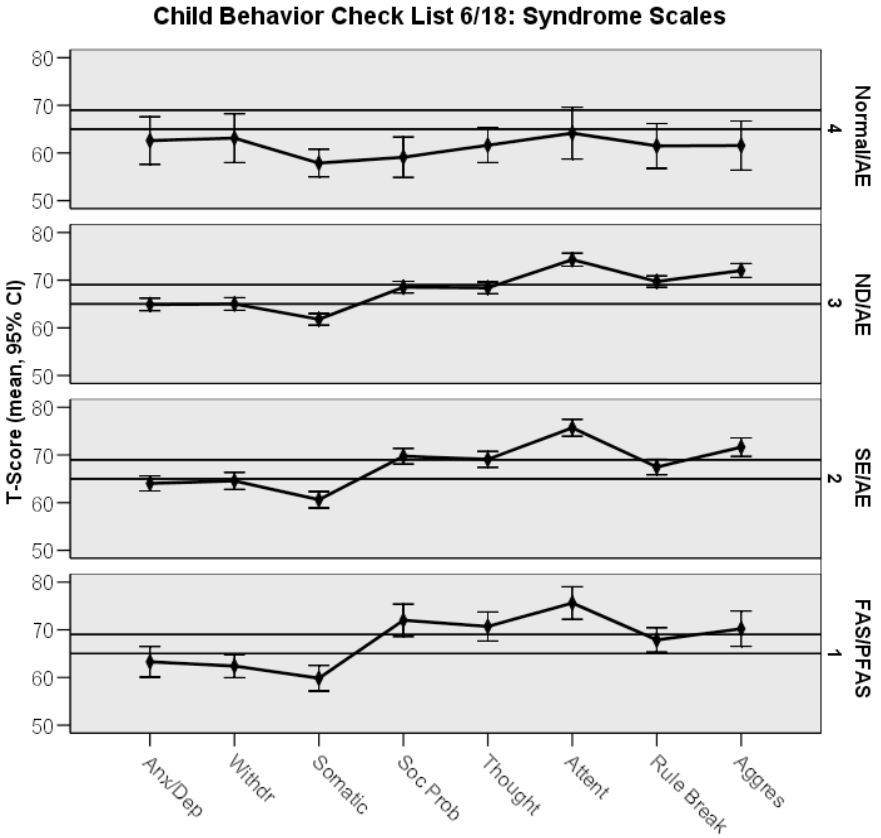
12. Who are the birth fathers of these children? The names of 76% of the birth fathers were known, compared to 95% of the birth mothers. The more severe the FASD diagnostic outcome, the less likely the birth father's name was documented in the child's records. Only 7.6% of them accompanied their child to the FASD diagnostic evaluation. The fathers were on average 29 years old at the birth of their child with FASD and 38 years old at the time the child was being diagnosed with FASD (Table 3). Thirty-nine percent did not finish high school, 45% completed high school, and 16% attended college. They were in general, older and more highly educated than the birth mothers. Approximately half of them reportedly had learning disabilities.

13. What proportion of patients were no longer in the care of their birth parents at the time of their FASD diagnostic evaluation? Seventy percent of the patients were no longer in the care of either birth parent at the time of their FASD diagnostic evaluation (Table 1). The average number of home placements across the 1,400 patients was 2.9 $\pm$ 3.1. Nineteen percent had four or more home placements.

14. Does a caregiver's impression of their child's behavior differ between FAS/PFAS, SE/AE, and ND/AE? Yes and No. Among the 1,270 caregivers who completed the Child Behavior Checklist[34] (for children 6 to 18 years of age), the prevalence and magnitude of behavior problems was comparably high across all FASD subgroups. Attention problems were reported most often (Table 7, Figure 2). When the results of the 2-hour, structured interview with the caregiver(s) (conducted by the medical doctor and psychologist on the day of the FASD diagnostic evaluation) were tabulated (Table 8, Figure 3), the

prevalence and magnitude of behavioral concerns often increased significantly and incrementally as one advanced from the ND/AE to SE/AE to FAS/PFAS group. It is important to note that these parent impressions of their child's behavior were recorded before the parent or the clinicians knew the FASD diagnostic outcome of the child.

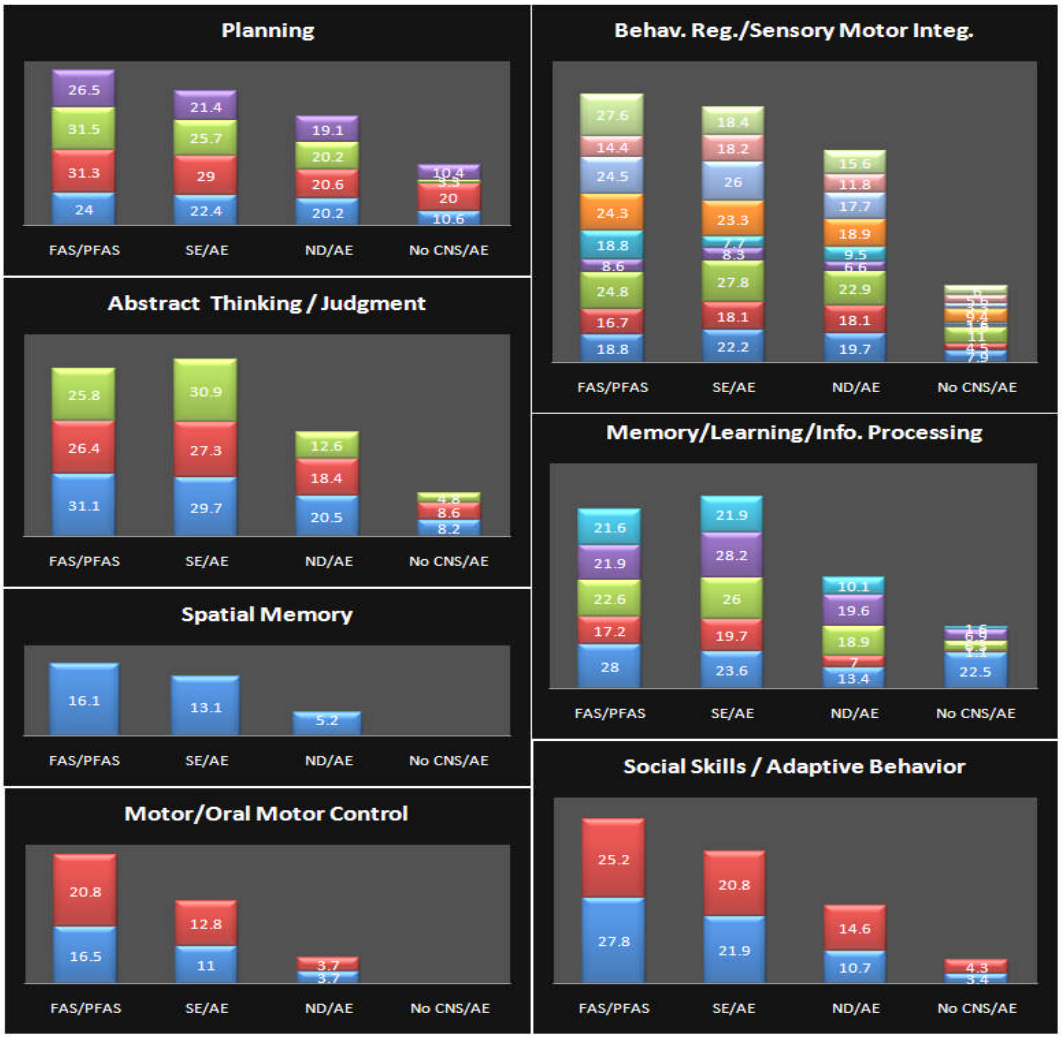
FIG. 2 Child Behavior Check List[34] (CBCL/ 6-18) Syndrome Scales (*see* Table 7) among the 516 patients administered a CBCL when they were between 6 and 18 years of age. All abbreviations are defined in Table 7.



Profile of the first 1,400 patients receiving diagnostic evaluations for fetal alcohol spectrum disorder at the Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network

FIG. 3 Proportion of patients classified by the pediatrician as 'significantly delayed/impaired' in behaviors addressed in a 2-hour, structured caregiver interview administered jointly by the pediatrician and psychologist during the FASD diagnostic evaluation. This is a graphical presentation of the data presented in Table 8 to illustrate the cumulative increase in impairment as one advances across the study groups. Each color in a bar reflects the behaviors listed in Table 8 under each Domain. Abbreviations are defined in Table 8. The number printed in each colored section is the proportion of patients with significant impairment for that behavior. For example, the bar for the FAS/PFAS group in the Planning Domain reflects the following: blue square (24% present with significant impairment for "Needs considerable help organizing daily tasks"); red square (31.3% present with significant impairment for "Cannot organize time"); green square: (31.5% present with significant impairment for "Does not understand concept of time"); and purple square (26.5% present with significant impairment for "Difficulty carrying out multistep tasks").

.



15. What is the prevalence of other mental health disorders in this patient population? Among the 1,064 patients, five or more years of age at the time of their FASD diagnostic evaluation, 82% had one or more mental health disorders documented in their medical records (Table 11). The most prevalent was ADD/ADHD (53.9%). Despite this high overall prevalence, the prevalence estimates for each disorder (based on review of medical records available to the FASD clinics) may substantially under-estimate the true prevalence of each disorder. Many of these disorders fail to be formally diagnosed and recorded in the medical record. When a representative subset of these children (n=65) were administered the Computerized Diagnostic Interview Schedule for Children[44] during their enrollment in the FASD magnetic resonance study[24], the prevalence estimates for many disorders were substantially higher. For example, Oppositional Defiant Disorder was reported in 6.8% of this clinical population, but was diagnosed in 52% of the subset that participated in the magnetic resonance study. Obsessive compulsive disorder was reported in 0.7% of this clinical population, but was diagnosed in 9.2% of the subset that participated in the magnetic resonance study.

16. Were patients satisfied with the interdisciplinary FASD diagnostic evaluation process? Were they provided information they were unable to obtain elsewhere? Was the 4-Digit Code approach to diagnosis easy to understand? Was their ability to access and benefit from recommended intervention services influenced by what diagnosis their child received under the umbrella of FASD? Would they recommend the clinic to other families with similar needs? A 10-question patient satisfaction survey has been sent to all patients evaluated at the UW FAS DPN clinic since 1993. The survey may be completed anonymously and comes with a stamped-addressed return envelope to maximize participation in the survey. Patients universally expressed high satisfaction for the FASD diagnostic services provided by the University of Washington (Table 12). Ninety-nine percent would recommend the Clinic to other families with similar needs. Ninety-one percent said they received information they were unable to obtain elsewhere, despite the fact the clinic is located in a large metropolitan area (Seattle) with many genetic, neurodevelopmental, and psychological evaluation services available. Eighty-six percent found the explanation of the diagnosis using the 4-Digit Code easy to understand. And perhaps most informative; family's whose child received a diagnosis of SE/AE or ND/AE were as likely to report successfully accessing and benefiting from recommended intervention services as family's whose child received a diagnosis of FAS/PFAS. This is in contrast to the oft stated belief that a family will not qualify for services if the diagnosis is not FAS/PFAS or at least given a name that implies alcohol is the causal agent (e.g., ARND). Overall, 82.1% of families reported being somewhat to very successful in finding the recommended intervention services and 83.7% reported these services met some to all of their needs.

Strengths and Limitations

The outcomes presented in this report reflect a very large, 13-year, statewide, clinical population of patients (newborn to adult) who all received an identical, interdisciplinary approach to FASD diagnostic evaluation using the FASD 4-Digit Code. By virtue of this, the outcomes presented in this report are highly representative of the study's intended target population (a statewide clinical population of individuals with prenatal alcohol exposure seeking an FASD diagnostic evaluation). The outcomes presented in this report should not be construed to represent the population of *all* individuals exposed to prenatal alcohol exposure. Even though the only requirement to obtain an FASD diagnostic evaluation in the WA FAS DPN is a confirmed prenatal alcohol exposure, alcohol-exposed individuals with developmental concerns are more likely to be referred to the clinic than alcohol-exposed individuals with no developmental concerns. Other features inherent to this clinical dataset should also be taken into consideration when interpreting the reported outcomes. 1) Data in the FAS DPN clinical dataset are obtained from a variety of sources (medical/educational/social service record review,

caregiver interview, and direct clinical evaluation). The accuracy of the data will vary by source. 2) No two patients have an identical dataset. The amount and type of data available on each patient varies by their age and the existence and availability of previous medical/educational assessments. 3) Prior medical and educational assessments may focus more on areas of concern than areas of strength. As a result, inclusion of these data sources could generate group profiles that over represent deficits. Overall, clinical datasets are an invaluable, ubiquitous resource that, when interpreted in the proper context can greatly inform and advance a field.

CONCLUSION

In summary, the existence of the WA FAS DPN diagnostic program and electronic database over the past 17 years confirms it is possible to establish and maintain a comprehensive statewide FASD diagnostic program and dataset. As demonstrated in this report, a broad array of clinical, research, and public health questions can be addressed with a FASD clinical dataset. The outcomes presented in this report reflect the experience of WA State. With the worldwide replication of this interdisciplinary approach to FASD diagnosis using the 4-Digit Code, the opportunity now exists, for the first time ever, to construct and validly compare clinical profiles across very diverse, geographically dispersed populations. This report serves as a formal appeal to FASD clinical programs worldwide to do just that. The benefits to individuals with FASD and their families would be immense.

Acknowledgements

The WA FAS DPN has been supported over the past two decades by the following organizations: Centers for Disease Control and Prevention (1992-1997, U84/CCU008707); Western Washington Chapter of the National March of Dimes Birth Defects Foundation (1995); Washington State Department of Social and Health Services, Division of Alcohol and Substance Abuse through the passage of Senate Bill SB5688 (1997-present, 0965- 69095); and the Chavez Memorial Fund (2002-present). Support has also received from the Center on Human Development and Disability, University of Washington since 1993 (National Institute of Child Health and Human Development grant P30 HD02274). The creation of this clinical dataset would not have been possible without the extensive clinical efforts and support of the interdisciplinary diagnostic teams and community health/social service agencies in Seattle, Everett, Federal Way, Tacoma, Yakima, Spokane, and Pullman. And finally, special thanks are extended to the patients and their families for their benevolent contributions to the WA FAS DPN dataset.

SE/AE: Static encephalopathy/alcohol exposed. Wgt: weight. Wks: weeks.
Notations: A. Numerator degrees of freedom = 3; denominator df = total sample size minus 4. B. The Duncan multiple comparisons range test is reported if the overall ANOVA is statistically significant; commas separate groups with homogeneous means at $p < 0.05$. C. All 55 Rank 1 growths are PFAS. D. All 69 Rank 3 faces are PFAS; E. 25 too young to rule out CNS Rank 3 (< 8yrs). F. All 7 are too young to rule out CNS Rank 3 (<8yrs). G. All 30 Rank 3 philtrums are PFAS. H. All 30 Rank 3 lips are PFAS.

Abbreviations: Chi: chi-square test statistic across Groups 1, 2 and 3. FAS: fetal alcohol syndrome. P: p-value. PFAS: partial FAS. ND/AE: Neurodevelopmental disorder/alcohol exposed. Normal CNS/AE: No central nervous system abnormalities/alcohol exposed. SE/AE: Static encephalopathy/alcohol exposed. Notations: Not all patients are old enough to demonstrate each of the behaviors listed above. Thus the valid % reflects the proportion of patients with significant impairment among those old enough to demonstrate the behavior.

Observation of Classroom Social Communication: Do Children With Fetal Alcohol Spectrum Disorders Spend Their Time Differently Than Their Typically Developing Peers?

Lesley B. Olswang
University of Washington, Seattle

Liselotte Svensson
Karolinska University Hospital, Stockholm, Sweden, and Karolinska Institute, Stockholm, Sweden

Susan Astley
University of Washington

Purpose: In this research, the authors examined how social communication profiles during classroom activities differed between children with fetal alcohol spectrum disorders (FASD) and typically developing pair-matched peers.
Method: Twelve pairs of children were observed in their classrooms 20 min a day for 4 days across 2 weeks. Coders documented classroom social communication by recording performance on handheld computers using the Social Communication Coding System (L. B. Olswang, L. Svensson, T. E. Coggins, J. Beilinson, & A. L. Donaldson, 2006). The Social Communication Coding System consists of 6 behavioral dimensions (prosocial/engaged, passive/disengaged, irrelevant, hostile/coercive, assertive, and adult seeking) that account for all verbal and nonverbal productions during a specified timeframe. The frequency of occurrence and duration of each dimension (as measured by proportion of time and average length of time spent performing each dimension) were recorded.
Results: Children with FASD had significantly more occurrences of passive/disengaged and irrelevant behavior, and the proportion and average length of time in these behaviors were larger and longer than those of their peers. Further, children with FASD had significantly more occurrences of prosocial/engaged behavior; however, the proportion and average length of time that they spent being prosocial were smaller and shorter than those of their peers.
Implications: Results suggest children with mild FASD performed differently than their peers in regard to classroom social communication, which was consistent with parent and teacher behavioral reports.

KEY WORDS: fetal alcohol syndrome, observation, school-age children, elementary schools

School-age children who have been diagnosed with fetal alcohol spectrum disorders are frequently noted to have difficulty interacting with peers in classroom situations. Teachers as well as parents have expressed concerns about social communication for these children, along with their other behavioral and academic problems (see, e.g., Jacobson & Jacobson, 2002, for a review). Yet, for these children, the nature of the social communication problems has been difficult to portray and even more challenging to document. Standardized tests do not capture the nature of the problems, and teacher ratings yield a more global view of performance. Researchers who are interested in social

communication that occurs during dynamic, interactive events in natural contexts have long been vigorous advocates of using authentic, real-time observation (Damico, 1992; Dodge, McClaskey, & Feldman, 1985; Fujiki, Brinton, Isaacson, & Summers, 2001; Lund & Duchan, 1993; Olswang, Coggins, & Timler, 2001; Prutting & Kirchner, 1987; Rice, Sell, & Hadley, 1990). Continuous recording of ongoing verbal and nonverbal behaviors offers an opportunity to document not only individual, momentary behaviors quantified as frequency of occurrence but also behavior states or behavioral dimensions quantified using duration measures (Bakeman & Gottman, 1997; Olswang, Coggins, & Svensson, 2007; Olswang, Svensson, Coggins, Beilinson, & Donaldson, 2006). For children who are at risk for social communication problems, this perspective can provide a unique and valuable insight into classroom performance as the children interact with others. In the present study, we examined the social communication of children with fetal alcohol spectrum disorders and matched peers by documenting frequency of occurrence and duration of behavioral dimensions as they were observed in classroom settings. The purpose is to document the social communication profile of children with fetal alcohol spectrum disorders and to determine whether their profile differs from that of matched, typically developing peers.

Prenatal Alcohol Exposure and Social Communication Problems

Fetal Alcohol Spectrum Disorders

Children with prenatal alcohol exposure range in their diagnoses, from the full diagnosis of fetal alcohol syndrome (FAS) to the classification of alcohol-related neurodevelopmental disorders (ARND; Stratton, Howe, Battaglia, & the Committee to Study Fetal Alcohol Syndrome, Institute of Medicine, 1996). The label *fetal alcohol spectrum disorders (FASD)* has been used to cover this range. At one end of the continuum, FAS is characterized by growth deficiency, a unique set of minor facial anomalies, documented central nervous system (CNS) structural and/or functional abnormality, and confirmed prenatal alcohol exposure. Children with FAS may demonstrate an array of neurobehavioral problems, including cognitive, social, and language deficits that range in severity and that challenge the children's success in school and beyond. At the other end of the continuum, children with ARND are known to have been exposed to alcohol prenatally, yet they do not show the growth or facial features associated with FAS. They, too, exhibit a range of neurobehavioral problems reflecting some type of CNS damage, but typically, deficits are less severe, and a causal link to their prenatal alcohol exposure cannot be confirmed or ruled out. The documented array of disabilities in children with FASD likely contributes to social communication problems being one of the most prevalent characteristics of this population (Coggins, Olswang, Carmichael Olson, & Timler, 2003).

Social, Behavioral, Language, and Neuropsychological Characteristics of Children With FASD

Children with FASD who are enrolled in regular and special classrooms are frequently described as having difficulty managing social interactions, including notable behavior problems. Because prenatal exposure to alcohol can interfere with the developing brain at multiple levels and can alter the coordinated developmental schedule of the CNS, it can have long-term consequences for several domains of development that impact social performance and, ultimately, learning (Carmichael Olson, Morse, & Huffine, 1998; Streissguth & Kanter, 1997).

Data from teacher and parent questionnaires as well as anecdotal and clinical reports abound in reference to social and behavioral problems that these children exhibit (Brown et al., 1991; Carmichael Olson, Feldman, Streissguth, Sampson, & Bookstein, 1998; Coles et al., 1997; Kleinfeld & Wescott, 1993; Mattson & Riley, 2000; Steinhausen, Willms, Metzke, & Spohr, 2003; Streissguth & Kanter, 1997; Thomas, Kelly, Mattson, & Riley, 1998). The authors of these studies have used a variety of methodologies and terminology to describe performance; the focus in this review is on those characteristics that likely pertain to social communicative interactions. In research based on teacher and parent ratings of adaptive behavior, children with prenatal alcohol exposure are viewed as having difficulty managing social situations (e.g., Mattson & Riley, 2000; Steinhausen et al., 2003). For example, using the Vineland Adaptive Behavior Scales (Sparrow, Balla, & Cicchetti, 1984) to examine adaptive functioning of children with FASD as reported by their parents, Thomas et al. (1998) found that children diagnosed with the full FAS exhibited significant deficits across the three domains of communication, socialization, and daily living skills compared with typically developing children. Children with FAS were most impaired in the subdomain measuring interpersonal relationships. These researchers noted that the social problems associated with prenatal alcohol exposure did not appear to be solely the result of decreased cognitive functioning, suggesting that social abilities may be of particular concern (Thomas et al., 1998). Other researchers, using The Child Behavior Checklist (CBCL; Achenbach, 1991a, 1991b) to examine social skills and behavior problems as reported by parents or teachers, have found similar outcomes. Brown et al. (1991) discovered that children who had been exposed to alcohol throughout pregnancy were rated by

their teachers as showing more problem behaviors than children whose mothers never drank or stopped drinking by the second trimester. Likewise, using CBCL parent ratings, Mattson and Riley (2000) found that children with FASD were more impaired on the Total Problem scale than children who were not exposed to alcohol and who were matched for verbal IQ. Clinical observational reports also refer to social and behavioral problems as being commonly exhibited by children with FASD. For example, it has been reported that many children with FASD display impulsive, aggressive, assertive, and unpredictable behaviors (Aronson, 1997; Streissguth, 1997; Tanner-Halverson, 1997), and difficulty with peer interactions is a recurring theme (Kleinfeld & Wescott, 1993).

Researchers have noted that children with prenatal alcohol exposure have difficulty resolving conflicts and anticipating the consequences of their actions (Caldwell, 1993; Timler & Olswang, 2001; Timler, Olswang, & Coggins, 2005). Related specifically to the challenges that children with FASD face in interacting with peers, Timler and colleagues (Coggins et al., 2003; Timler, 2000) examined nine children with prenatal alcohol exposure using social conflict vignettes. The vignettes described a conflict with a peer that a child was asked to resolve. In comparison with typically developing peers, children with FASD produced fewer prosocial/engaged strategies for resolving conflicts and more passive/disengaged, hostile/coercive, assertive, and adult-seeking strategies. Even when the children were given choices for how they might resolve the conflicts, the children with FASD still selected fewer prosocial/engaged strategies and more hostile/coercive ones. These data are notable, suggesting that children prenatally exposed to alcohol would be at risk for problems in their social interactions.

In addition to social and behavioral problems being characteristic of this population, language difficulties have been repeatedly observed. Although language deficits have been hard to consistently document using standardized tests, problems using language in conversation and narratives appear prevalent (Coggins, Friet, & Morgan, 1998; Coggins et al., 2003; Thorne, Coggins, Carmichael Olson, & Astley, 2007). In particular, the challenges include difficulty producing language that takes into account the listener's perspective and responding appropriately to assumptions about shared knowledge. Recently, Thorne and colleagues (2007) found difficulties with the production of cohesive narratives by children with FASD resulting, in part, from errors with a syntactic element marking nominal reference. This error illustrates the link between syntax and language use, which is notable because it could disrupt communication during social interactions.

Further evidence on specific neuropsychological limitations exhibited by children with FASD may contribute to the challenges these children demonstrate during social interactions. Various studies have documented deficits in executive function, including limitations in planning, inhibition, self-regulation, attention, and memory (Coles et al., 1997; Kodituwakku, Handmaker, Cutler, Weathersby, & Handmaker, 1995; Mattson, Calarco, & Lang, 2006; Mattson, Goodman, Caine, Delis, & Riley, 1999). It appears that these deficits are manifested in performance decrements that are frequently accompanied by behavior problems and social ineptitude. Furthering the challenge for these children, Kodituwakku (2007) observed that the children's behavior suffers when task complexity increases—which, of course, is a hallmark of advancement in school and participation in academic and social situations.

Summary—Child Characteristics and the School Setting

In summary, the phenotype of children with FASD is characterized by social, behavioral, and language problems that disrupt interactions with peers and that appear to be influenced by task complexity. These characteristics—along with neuropsychological problems in planning, inhibition, self-regulation, and attention and memory—arguably contribute to the challenges facing these children in school settings. In particular, children with FASD may suffer in social and academic situations because their deficits interfere with their ability to be as engaged as they need to be. Student engagement, inferred from performance (attention, work completed, appropriate participation), is key to motivation and, ultimately, learning or mastering knowledge or skills (Newmann, Wehlage, & Lamborn, 1992). A number of researchers have shown the value of observation in addition to teacher report in identifying factors that might impact engaged performance in the classroom (Fredricks, Blumenfeld, & Paris, 2004; Powell, Burchinal, File, & Kontos, 2008). These studies, using an eco-behavioral approach, have begun to isolate factors (e.g., teacher talk, activity type) that can facilitate children's engaged performance. This approach has great appeal for examining the performance of children with FASD as they struggle with their deficits and strive to meet classroom expectations. However, prior to determining what factors might be influencing performance, first we need to (a) better understand and document the performance of children with FASD as they interact in classroom settings and (b) examine the differences between children with FASD and their typically developing peers. Determining the nature of performance in the classroom will not only reveal more about the phenotype but also provide implications as to how to better work with these children to improve social communication and, ultimately, school outcomes.

Social Communication—Observation

Social communication, which is viewed as ongoing verbal and nonverbal behaviors during interactive contexts, allows for the observation of behavioral states or dimensions as well as the observation of discrete, momentary behaviors. This approach has been advocated by several researchers interested in social interactions (Bakeman & Gottman, 1997) and classroom performance, particularly behavioral engagement (Fredricks et al., 2004). The value in viewing and coding states versus individual, momentary behaviors comes, in part, from research on peer relations, particularly in regard to peer acceptance and rejection. Specifically, Bierman (2004) argued that a child's social behaviors that are clustered into the dimensions of prosocial/cooperative, aggressive/disruptive, inattentive/immature, and anxious/avoidant provide the best empirical evidence that reflects peer social status and problematic peer relationships. These behavioral dimensions, or variations on these particular categories, have been used with different methodologies, such as peer nomination tasks or ratings (e.g., Pope, Bierman, & Mumma, 1991), teacher ratings (e.g., Flanagan, Bierman, & Kam, 2003), and observational rating scales (e.g., Ladd & Profilet, 1996). Recently, this dimensional view of performance was adopted for use in observational methodology designed to describe the frequency of occurrence of behavior states and their durations performed by children in classrooms (Olswang et al., 2006).

The Social Communication Coding System (SCCS; Olswang et al., 2006) was designed to capture how children spend their time as they interact with others in the classroom. Using a dimensional perspective based on the work by Bierman (2004) as well as by Asher and colleagues (e.g., Chung & Asher, 1996), a child's social communication status can be coded into one of six mutually exclusive categories suggesting manner of performance: prosocial/engaged, passive/disengaged, irrelevant, hostile/coercive, assertive, or adult seeking. For example, the dimension of *prosocial/engaged* is defined by verbal and nonverbal behaviors reflecting that a child is engaged in a task, such as a child's commenting, raising his or her hand, watching a demonstration, and/or asking a question. *Passive/disengaged* includes behaviors such as looking out the window or moving away from a group activity. The *irrelevant* dimension captures behaviors that are out of place, unrelated, extraneous, or odd according to what is expected at the time. The *hostile/coercive* dimension is defined by a child's verbal and nonverbal behaviors that reflect aggressive or intimidating actions, such as hitting, pushing, or teasing, versus the *assertive* dimension, which reflects a child's being firm or outspoken about an opinion but without crossing a line that is perceived as threatening. Finally, *adult seeking* refers to verbal and/or nonverbal communication that solicits help or attention from an adult. In the classroom, social communication as measured by dimensions is conceptualized as always occurring, with categories being mutually exclusive. As such, during a classroom activity, all categories of behavioral dimensions may occur, but research has indicated that these behavioral dimensions are not expected to be equally occurring. As identified by Powell and colleagues (2008), who recently examined engagement in early childhood classrooms, children spend their time primarily being engaged (47% of the time) or attentive (40% of the time).

An advantage of conceptualizing social communication behavioral dimensions is that performance may be analyzed as a function of occurrence as well as duration. Historically, frequency of occurrence has been useful in describing the individual behaviors that a child is demonstrating to illustrate his or her consistency or variety in performance during classroom interactions. For example, Damico (1992) counted frequency of illocutionary acts. Although informative, frequency of occurrence captures only part of the picture. Critical to the profile of children is the amount of time that they spend demonstrating each of the social communication behavioral dimensions; thus, duration becomes important to measure.

Two valuable types of duration data are the proportion of time and the average length of time that children spend demonstrating different social communication behavioral dimensions. *Proportion of time* reveals how much of a given time period (e.g., specific activity or part of a school day) a child spends demonstrating each social communication behavioral dimension (i.e., prosocial/engaged, passive/disengaged, irrelevant, hostile/coercive, assertive, adult seeking). *Average length of time* reveals the mean duration of each occurrence of a particular dimension. Across activities and/or days, an observer could create a profile of performance capturing how a child primarily performs. For example, a child who spends a relatively large proportion of an activity demonstrating irrelevant performance would likely be of concern, considering irrelevant behaviors are typically off task. Thus, for a thorough look at classroom performance, both frequency and duration measures are critical.

Purpose of the Research

The increasing difficulties that children with FASD exhibit in social situations as they grow older no doubt result from greater societal demands to be responsive to a variety of individuals across a variety of situations. Managing social interactions becomes increasingly

important and challenging when children enter school (Campbell & Siperstein, 1994). To date, research has not documented real-time social communication performance for this population in natural settings, such as school, to validate teacher and parent concerns. The overall sense is that social/behavioral problems exist, but the nature and extent of these problems as they are manifested in everyday settings during social communication interactions are not well understood. Specifically, research has not quantitatively documented the classroom performance of children with FASD, particularly those on the mild end of the continuum who are enrolled in regular education classrooms.

The purpose of this research was to examine the social communication performance of children with FASD compared with their matched, typically developing peers during classroom activities. In the study, we used an observational methodology that employed a behavioral dimensional coding taxonomy yielding frequency and duration data. The following general question was addressed: When social communication performance is divided into six mutually exclusive dimensions (prosocial/engaged, passive/disengaged, irrelevant, hostile/coercive, assertive, and adult seeking), do two groups of children (i.e., a group diagnosed with FASD and a group of matched, typically developing peers) demonstrate different profiles of social communication in regard to frequency of occurrence and duration (proportion and average length of time) of each dimension in a classroom setting?

Method

Participants

In this paired, case-control study, participants consisted of 12 children with FASD (cases) and 12 typically developing (TD) children (controls), ages 7;5–11;8 (years;months). Each child with FASD was pair matched on gender and age to a TD classmate in the same regular education classroom; therefore, this study included 12 classrooms. Each matched pair was observed alternately in their classroom to document social communication performance using the SCCS (Olswang et al., 2006), a behavioral dimensional coding system. The children with FASD were previously diagnosed and recruited through the Washington State Fetal Alcohol Syndrome Diagnostic and Prevention Network (FAS DPN) at the University of Washington (described in the sections that follow). The TD children were identified by their respective teachers. For all children, consent to enroll was obtained from the caregiver, the child's teacher, and the child (i.e., informed assent) following the University of Washington Human Subjects Institutional Review Board approval policy. Demographic data were obtained from the caregiver.

Identification and Selection of FASD Participants

For this study, we recruited children with FASD who met the inclusion/exclusion criteria detailed in the subsections that follow.

Inclusion Criteria

Each child had to meet six criteria for inclusion in the study:

1. Child was age 7;0–12;0.
2. Child had an FASD diagnosis of FAS, partial FAS, static encephalopathy/alcohol exposed, or neurobehavioral disorder/alcohol exposed. The last two diagnoses are comparable to the U.S. Institute of Medicine (Stratton et al., 1996) diagnostic criteria for ARND with confirmed prenatal alcohol exposure. More specifically, they would be equivalent to severe and mild ARND, respectively.
3. Child performance was in the clinical range on the Problem Behaviors subscale (i.e., standard score > 115) of the Social Skills Rating System (SSRS)–Teacher Form (Gresham & Elliott, 1990). Sample items from the Problem Behaviors component of the SSRS include fights with others, threatens or bullies others, appears lonely, appears easily distracted, interrupts conversations, disturbs others, does not listen to what others say, has temper tantrums, and acts impulsively. We included this criterion to further ensure that the children identified by the FAS DPN met the description of the FASD phenotype as described previously.
4. Child had a composite IQ score of no more than 1.0 *SD* below the mean (i.e., a standard score $\geq$ 85) on the Kaufman Brief Intelligence Test (Kaufman & Kaufman, 1990; administered by a certified speech-language pathologist [SLP]).
5. Child had been mainstreamed in a regular education classroom.
6. Child was residing in the greater Seattle area.

Exclusion Criteria

Children were excluded if they met any of the following five criteria:

1. Eligible comparison classroom peer could not be identified.
2. There was a confirmed presence of severe psychiatric condition (e.g., schizophrenia, pervasive developmental disorder, etc.).
3. There was a confirmed presence of severe physical or motor handicaps.

4. Child had hearing or vision impairment.
5. English was not used as primary language at home.

Identification and Selection of TD Participants

The TD control participants were identified by the regular education teacher in the classroom of the experimental participant with FASD. For this study, we recruited TD control participants who met the inclusion/exclusion criteria detailed in the subsections that follow.

Inclusion Criteria

Children had to meet the following five criteria for inclusion in the study:

1. Child was enrolled in the same classroom as the pair-matched child with FASD. The teacher was asked to select a child who was as close a cognitive match as possible.
2. Child performance was not in the clinical range on the Problem Behaviors subscale (i.e., standard score < 115) of the SSRS–Teacher Form (Gresham & Elliott, 1990).
3. Child had a composite IQ score of no more than 1.0 *SD* below the mean (i.e., a standard score $\geq$ 85) on the Kaufman Brief Intelligence Test (Kaufman & Kaufman, 1990).
4. Child was the same gender as the child with FASD to whom he or she was matched.
5. Child's chronological age was within ±6 months of the chronological age of the matched child with FASD.

Exclusion Criteria

Children were excluded if they met any of the following four criteria:

1. There was a confirmed presence of severe psychiatric condition (e.g., schizophrenia, pervasive developmental disorder, etc.).
2. There was a confirmed presence of severe physical or motor handicaps.
3. Child had hearing or vision impairment.
4. English was not used as primary language at home.

Table 1 presents the sociodemographic and clinical description of the study population. The FASD group consisted of one child with partial FAS, two with severe ARND, and nine with mild ARND. The FASD–control pairs were effectively matched on age and gender. IQ was also comparable between the two groups. By design, the FASD group had a significantly higher mean score on the Problem Behaviors subtest of the SSRS.

Equipment

Data on social communication behavior dimensions and type of situation in which they occurred were collected in real time in the classroom using the SCCS (Olswang et al., 2006), which is a handheld computer–based (Palm, M100) coding system developed by the Child Language Laboratory at the Department of Speech and Hearing Sciences, University of Washington. The sessions were not videotaped. This technology allowed for coding the duration of social communication behavioral dimensions. Specifically, as the researcher observed the child in the school environment, data were entered by tapping a stylus on specific entries via drop-down menus.

Selecting a child social communication behavioral dimension started a time code for that dimension. On selecting a new dimension, the duration of the previous dimension ended, and the duration for the new code started. The dimensions were mutually exclusive, and only one could be selected at a time. As long as the observation was occurring, a code was entered into the Palm device. The data were coded by subject number and observer number and were later sent to a secure central database for analysis (American Head and Neck Society Speech and Language Otobase; Coltrera, 2002).

SCCS: Behavioral Dimensions

The SCCS included six *behavioral dimensions*—that is, clusters of discrete behaviors to describe state or manner of performance (based on Bierman, 2004; Chung & Asher, 1996)—which are described in the text that follows.

Prosocial/engaged. This dimension reflected a child being engaged in a social interaction or the school activity relative to teacher's expectations, school rules, or the surrounding context (e.g., peer behaviors). Examples include listening attentively, on-task work or conversations, helping, sharing, compromising, and making an appropriate request or comment. For instance, during a cooperative group work activity, a child may constructively interact with his or her peers using appropriate language and staying on task, thus displaying prosocial/engaged behavior.

Passive/disengaged. This dimension reflected a child's lack of involvement in the situation or activity and/or physical disengagement from the activity. Examples include staring into space, putting his or her head down, or walking away from an activity without a clear

Table 1. Clinical and sociodemographic description of the study population: Children with fetal alcohol spectrum disorders (FASD) and their typically developing (TD) matched peers.

Characteristic	FASD (*n* = 12)	TD (*n* = 12)	Stat	*p*
Age in years: *M (SD)*	9.2 (1.1)	9.1 (1.3)	paired $t = 0.32$	.75
Gender—Females: *n* (%)	6 (50)	6 (50)	χ^2 Yates = 0.17	.68
Race—Caucasian: *n* (%)	6 (50)	4 (33)	χ^2 Yates = 0.67	.41
SSRS Problem Behavior Standard Score: *M (SD)*	122.8 (7.4)	92.5 (9.0)	paired $t = 10.23$	.000
K-BIT IQ Standard Score: *M (SD)*	109.8 (12.5)	114.7 (10.8)	paired $t = -1.36$	.20
FASD 4-digit code diagnosis: *n*			N/A	
Full FAS	0	0		
Partial FAS	1	0		
Static encephalopathy/alcohol exposed[a]	2	0		
Neurobehavioral disorder/alcohol exposed[b]	9	0		
Typical development/no alcohol exposure	0	12		
Grade level: *n* (%)			$\chi^2 = 0.0$	1.0
Grade 2	5 (42)	5 (42)		
Grade 3	2 (17)	2 (17)		
Grade 4	4 (33)	4 (33)		
Grade 5	1 (8)	1 (8)		
Home placement: *n* (%)			$\chi^2 = 12.6$	.000[c]
Birth family	1 (8)	10 (82)		
Adoptive family	8 (67)	1 (8)		
Foster family	3 (25)	0 (0)		

Note. SSRS = Social Skills Rating System–Teacher Form (Gresham & Elliott, 1990); K-BIT = Kaufman Brief Intelligence Test (Kaufman & Kaufman, 1990); Stat = statistic; N/A = not applicable. Blank cells indicate xxxxxxxxxxxxxxxxxxxx.

[a]Equivalent to Institute of Medicine (IOM) severe alcohol-related neurodevelopmental disorder (ARND). [b]Equivalent to IOM mild ARND. [c]Birth family versus other placement.

purpose or instruction. For instance, when working together with peers on solving a problem, a child may become passive/disengaged and put his or her head down instead of actively participating in the ongoing discussion.

Irrelevant. This dimension reflected (a) a child being actively engaged in an off-task behavior in which the child says or does something that he or she is not supposed to do according to teacher instructions and classroom rules or (b) behaviors that are out of place, unrelated, extraneous, or odd. Examples include starting an activity that is different from the teacher-directed task, fiddling with objects as a main focus of attention, engaging in goofy or silly behaviors, or saying something that bears no relationship to the task at hand. For instance, during a class discussion, a child may engage in irrelevant behavior by leaning back and whispering to a peer.

Hostile/coercive. This dimension reflected a child's aggressive behavior or ridicule of another child; typically, these behaviors would be considered unacceptable in a social situation, according to the teacher and the rules of the school. Examples include grabbing, hitting, pinching, kicking, pushing, taunting, provoking, yelling, and screaming. For instance, during negotiating a conflict with peers, a child might get hostile and hit or scream.

Assertive. This dimension reflected a child stating a position, opinion, or idea in a firm, persistent, or bold way. Examples include stressing a point, demonstrating an assertion of rights or beliefs (verbally or nonverbally), and persuading or directing another person. For instance, when a peer leans over and whispers something during quiet independent work, a child may firmly state, "Stop whispering! I have to finish this," thus displaying assertive behavior.

Adult seeking. This dimension reflected a child making an effort to seek assistance or attention from an adult. Examples include requesting help from an adult, summoning the teacher from across the room, and moving to the teacher to initiate an interaction. For instance, during a small-group discussion, a child goes to find the teacher and asks the teacher if he or she will tell the child's peers that they need to listen to the child's ideas.

Classroom Setting and Specific Data Collection Procedures

Within 2 weeks of qualifying for entry into the study, data on the children's social communication performance were collected in the children's classroom. Observations

were conducted 20 min per day for each child, on 4 separate days, occurring within 2 weeks whenever possible. The time period of 4 days was selected for three major reasons: (a) representativeness—recommendations that observational data be collected for at least two or three sessions in the setting of concern (following Walker, Ramsey, & Gresham, 2004); (b) feasibility—challenges associated with arranging and scheduling observations in the schools; and (c) maturation effects—intent of capturing performance within a short enough period of time to avoid child maturation/development or changes that might occur in the classroom over time. Each observation was conducted in the respective classrooms of each child pair. Children were observed in their classrooms at times that were convenient to the teacher. However, the teachers made an effort—at the request of the study team—to include two major types of activities: (a) small-group, cooperative work among students and (b) large-group work involving the teacher as leader. The former included math, science, and art activities, in which the students worked in small groups to complete a specific task. The latter involved the teacher at the "head of the class" giving instructions, leading a discussion, or giving a test. Because the intent of this study was to observe children in their natural environment, requests to the teacher to alter his or her typical day were held to a minimum. To account for day and activity effect, data were collected for the TD-matched peer on the same days as for the child with FASD. The coder alternated between observing the child with FASD and his or her matched peer in 5-min sessions (20 min per child) as they participated in classroom activities. Order of coding was counterbalanced by alternating which child was coded first on the different observation days. The coder observed for 5 min before starting the actual coding in order to reduce subject reactivity. The child was allowed to interact with any peer(s) or with the teacher during the observations. The goal was to be an unobtrusive observer.

Observational data were collected by three trained observers. Observer training is described in the section that follows. All observers were female certified SLPs with an average of 12.3 years of clinical experience (3, 5, and 29 years, respectively). These observers were different from the SLP who conducted initial testing. Because the informed assent was obtained from the children at the time of initial testing, the children were aware of the observers' participation in a study but had not met the observers.

Before the observations started, the observer(s) spent a few minutes talking to the teacher to get further information about the classroom (e.g., activity), how the experimental and control children were doing that day, best positions for observing, restrictions about walking around the room, and reminding the teacher about how to introduce the observers. The teacher subsequently introduced the observer(s) by telling the class: "We have one (two) visitors from the University of Washington who will be watching our class today. They will be staying a while today and other days. They will be sitting or walking around quietly taking some notes."

Observers arranged themselves as close to the target child as possible in order to hear conversations and see the target child's gestures and nonverbal cues from a front or side angle view. Often, this entailed some quiet moving around the classroom, especially during small-group activities. In order to be as unobtrusive as possible, observers looked at a variety of children in the classroom or the teacher during the first 5 mins before actual coding started and during intermissions between coding sessions.

Observer Training

Training of the three observers occurred over 3 months for approximately 30 hr (see Olswang et al., 2006, for details). Training involved a series of phases including discussing relevant articles addressing social communication; reading the *SCCS Procedural Manual* (Olswang & Svensson, 2005), which included definitions of behavioral dimensions, examples, and short written quizzes; and then practicing and being tested on coding of children in a variety of classroom settings via videotape. Video coding was done independently by observers and then was compared using the Kappa (κ) coefficient. Live coding was not allowed until interobserver agreement testing achieved a κ value of .60 or better on at least one set of ten 2-min video segments. Guidelines for interpreting κ values were borrowed from Cicchetti and Sparrow (1981).

Observer Agreement for In-Class Observation

To examine interobserver agreement during the live observations, approximately 25% of the data were coded concurrently by two independent observers. Eighteen children were observed simultaneously by two observers (nine children with FASD and nine TD children) for 1 or 2 days. Following Olswang and colleagues (2006), interobserver agreement was assessed using time-interval analysis. This procedure—which was based on the work of Cordes, Ingham, Frank, and Ingham (1992)—divides an observation period into fixed time-interval units, which allows for comparison across observers. Time-interval analysis is an effective and appropriate strategy that can be applied to analyzing agreement of occurrence and duration judgments (Cordes et al., 1992; Olswang et al., 2006). Agreement is determined by dividing the actual time frame of observation into fixed time-interval units for comparison across observers. Breaking down the entries into preset intervals allows for an interval-by-interval comparison of type of behavior present; the continuous,

real-time duration data may now be manipulated and analyzed for agreement in the same way as data collected using interval recording. In the present research, time-interval units for examining reliability were set to 5 s because this is the shortest duration in which any coding entry can be conducted and based on the results by Olswang and colleagues (2006). For each interval, the dimension that was coded defines the interval. If two behaviors occur during the interval, the one with the longest duration defines the interval. Using the interval data, Cohen's κ was calculated to provide a summary agreement score between observers for coding the six SCCS behavioral dimensions for each child whose data were included in this analysis. In addition, to provide another index of agreement, point-by-point percent agreement between intervals was calculated using the same data set for each child. Table 2 provides a list of children with number of observation days, number of 5-min observation sessions, and number of intervals included in agreement analyses. This table also presents the κ values and point-by-point percent agreement for the independent observers' coding of the agreement data set for each child using an interval-by-interval analysis. Guidelines for "acceptable" κ values followed the recommendations of Cicchetti and Sparrow (1981): κ < .40 = poor agreement; κ between .40 and .59 = fair agreement; κ between .60 and .74 = good agreement; κ > .75 = excellent agreement. For percent agreement, an "acceptable" agreement level was defined as at least 80% agreement (following Cordes et al., 1992). Using these guidelines, the data of five children stood out as below the acceptable level of agreement either by virtue of their overall κ value or point-by-point percent agreement. For these children, point-by-point percent agreement, including chance, was calculated for all codes that the children demonstrated. These data are presented in Table 3. The results presented in this table indicate high point-to-point agreement for each of the behavioral dimensions. In all cases, percent agreement is equal to (i.e., TD11: passive/disengaged) or better than chance when the behavioral dimension occurred. It is worth noting the high levels of chance; this reflects, for some categories, extremely high levels of occurrence or nonoccurrence of entries, which is known to increase chance (McReynolds & Kearns, 1983). This is particularly noteworthy for the categories of hostile/coercive, assertive, and adult seeking. These data indicate that the agreement analyses, which were conducted live in the school setting, were comparable to the agreement that was achieved via videotapes (Olswang et al., 2006), confirming the success of the training and SCCS coding.

Data Reduction

Children's social communication performances in classrooms were coded into the six mutually exclusive social communication behavioral dimensions via the SCCS, as described previously. These coded data were

Table 2. Live observation (Social Communication Coding System) interobserver agreement using time-interval analysis: Overall κ (all codes) and point-by-point percent agreement between coded intervals.

Participant	Days	Number of 5-min observation sessions	Number of total 5-s intervals	κ	% point-by-point agreement between coded intervals
FASD1	2	6	382	.69	82
TD1	2	8	510	.49[a]	96
FASD2	1	5	321	.66	95
TD2	1	4	254	.85	99
FASD4	2	8	510	.67	87
TD4	2	8	504	.29[a]	89
FASD5	2	8	509	.62	87
TD5	2	7	401	.56[a]	85
FASD8	1	4	257	.74	83
TD8	1	4	255	.67	87
FASD9	1	5	318	.69	89
TD9	1	4	250	.65	97
FASD10	1	3	191	.84	95
TD10	1	3	193	.90	98
FASD11	1	5	254	.66	84
TD11	1	4	249	.48[a]	92
FASD12	1	4	236	.58[a]	78[a]
TD12	1	4	254	.70	90

[a]For overall κ < .60 and/or percent agreement < 80%, point-by-point agreement—including chance—was calculated for each of the social behavioral dimensions (see Table 3).

Table 3. Point-by-point agreement (and chance) for all behavioral dimensions.

		% point-by-point agreement (and chance)						
Participant	κ all codes	All codes	Prosocial/engaged	Passive/disengaged	Irrelevant	Hostile/coercive	Assertive	Adult seeking
TD 1	.49	96	96 (92)	99 (98)	97 (94)	99 (99)	99 (99)	No occurrence
TD 4	.29	89	91 (86)	97 (94)	94 (93)	99 (99)	98 (98)	No occurrence
TD 5	.56	85	90 (68)	91 (86)	93 (82)	99 (99)	99 (99)	97 (97)
TD 11	.48	92	93 (85)	97 (97)	94 (87)	No occurrence	No occurrence	No occurrence
FASD 12	.58	78	86 (57)	93 (87)	85 (68)	No occurrence	No occurrence	97 (93)

used for data reduction and analysis. As a reminder, actual coded data, not interval data, were used for data reduction and analysis; intervals were used only for examining interobserver agreement. Coded data were summed across the four observation days to ensure representativeness of child performance (note that day-to-day performance variation was examined in a separate study; see Svensson, 2006). Four primary outcome measures were computed to document the performance based on the six social communication behavioral dimensions, as follows: (1) number of children exhibiting each of the behavioral dimensions, (2) frequency of occurrence of each behavioral dimension that was coded, (3) proportion of time spent in each coded dimension, and (4) average length of time (in seconds) spent in each coded dimension. Number of children exhibiting each type of social communication behavioral dimension was used descriptively to compare the groups of children based on the array of behaviors that they demonstrated. Frequency of occurrence indicated the total number of times that each behavioral dimension was coded for each child. *Proportion of time* was defined as the total duration (in seconds) of a behavioral dimension totaled across the 4 observation days divided by the total duration of the observation (typically 80 min; i.e., 20 min per observation day) multiplied by 100. *Average length of dimension occurrences* was defined as the total duration of a behavioral dimension (in seconds) divided by the total number of occurrences of that dimension totaled across the 4 observation days.

Data Analysis

Differences with regards to frequency, proportion of time, and average length of time spent in each behavioral dimension were compared between the FASD and TD groups using the paired t test. The number of children presenting each behavioral domain was compared between the FASD and TD groups using the χ^2 or the Fisher exact test. Effect sizes were examined using Glass's d (Glass, McGaw, & Smith, 1981), a standardized mean difference derived by dividing the difference between the FASD group's mean and the TD group's mean by the *SD* of the TD group's scores. A d of ≥ 0.80 has been suggested as reflecting a large effect size—that is, a large magnitude of an effect/difference (Cohen, 1988).

Results

Table 4 presents the results for all aspects of the data analysis. First, to examine diversity of performance using the SCCS, we examined the data to determine the number of children exhibiting each of the behavioral dimensions. Most children in both groups presented at least one occurrence of prosocial/engaged, passive/disengaged, irrelevant, and adult-seeking behavior (see Table 4). No more than half the children in each group presented with any hostile/coercive behavior. The number of children presenting one or more occurrence of each behavioral domain was comparable between the two groups.

In the second part of the analysis, we examined frequency of occurrence of each behavioral dimension that was coded. As displayed in Figure 1, children in the FASD group, on average, exhibited more occurrences of each behavioral dimension than children in the TD group: prosocial/engaged (FASD = 50.0 occurrences, TD = 39.0 occurrences); irrelevant (FASD = 27.8 occurrences, TD = 14.9 occurrences); passive/disengaged (FASD = 14.8 occurrences, TD = 6.3 occurrences); adult seeking (FASD = 3.3 occurrences, TD = 2.8 occurrences); assertive (FASD = 4.1 occurrences, TD = 3.3 occurrences); and hostile/coercive (FASD = 1.1 occurrences, TD = 0.4 occurrences). Frequency of occurrence was significantly different between the groups for the following dimensions: prosocial/engaged, $t(11) = 6.1, p < .001, d = 1.9$; irrelevant, $t(11) = 4.9, p = .001, d = 1.9$; and passive/disengaged, $t(11) = 8.1, p < .001, d = 3.2$. Although children in the FASD group were more likely to exhibit more occurrences of adult-seeking, assertive, and hostile/coercive performances relative to the children in the TD group, these differences were not statistically significant (see Table 4).

In regard to proportion of time spent in each coded dimension, the observations revealed that both groups spent the majority of their time (over 76%) in prosocial/engaged behavior (see Figure 2). Moreover, on average, children in both groups spent most of their time

Table 4. Comparison of the frequency, proportion, and average length of time for each behavioral dimension between the FASD and TD groups across all 4 observation days.

Behavioral dimension	FASD (*n* = 12) *M (SD)*	TD (*n* = 12) *M (SD)*	Statistic	*p*
Prosocial/engaged

Average length of time (in s)	6.0 (7.8)	3.4 (5.7)	0.9[a]	.399

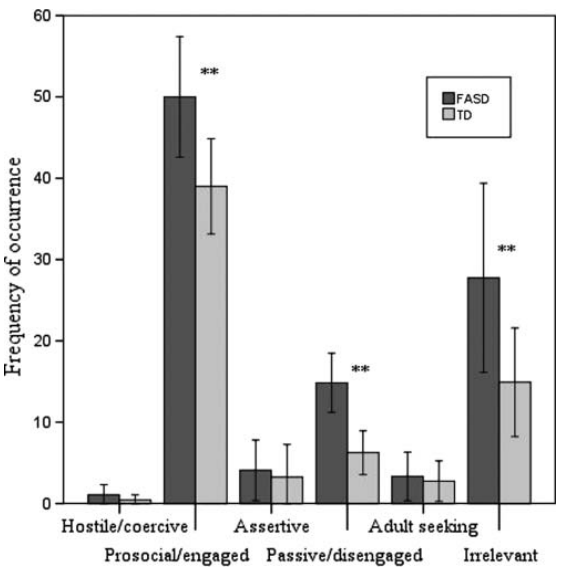
Note. s = seconds.

[a]statistic = paired *t* test. [b]statistic = chi-square. [c]statistic = Fisher exact test. [d]The .1 difference in values between Table 4 and Figure 2 reflect a rounding artifact.

exhibiting three of the dimensions: prosocial/engaged (FASD = 76.7%, TD = 89.3%); irrelevant (FASD = 15.8%, TD = 7.2%); and passive/disengaged (FASD = 5.4%, TD = 1.8%). Results of the paired *t* tests confirmed the pattern seen in the descriptive data for these three major dimension categories. Children with FASD spent significantly less time demonstrating prosocial/engaged performance than did TD children, $t(11) = -4.6$, $p = .001$, $d = -2.3$. In contrast, children with FASD spent significantly more time than their matched peers in irrelevant, $t(11) = 4.3$, $p = .001$, $d = 1.7$, and passive/disengaged, $t(11) = 4.4$, $p = .001$, $d = 3.2$, performances. Although children with FASD spent more time demonstrating adult-seeking, assertive, and hostile/coercive behaviors relative to the children in the TD group, these differences were slight and not statistically significant (see Table 4).

Finally, when examining average length of time (in seconds) spent in each coded dimension, Figure 3 shows

Figure 1. Mean frequency of occurrence of the Social Communication Coding System behavioral dimensions for children with fetal alcohol spectrum disorders (FASD) and typically developing (TD) children. Error bars denote ± 1 *SD*. Group differences were examined using the paired *t* test. $^{**}p < .01$.



that instances of the three dimension types in which the children spent most of their time, on average, also were the longest: prosocial/engaged (FASD = 88.6 s, TD = 127.5 s); irrelevant (FASD = 32.3 s, TD = 25.0 s); and passive/disengaged (FASD = 20.8 s, TD = 14.7 s). Results revealed that instances of prosocial/engaged behavior were significantly shorter for children with FASD when compared with instances of coded prosocial/engaged behavior exhibited by children in the TD group, $t(11) = -7.2$, $p < .001$, $d = -1.4$. On the contrary, instances of irrelevant behavior were significantly longer for the children with FASD than for TD peers, $t(11) = 2.3$, $p = .044$, $d = 0.8$. This pattern was observed for passive/disengaged performances as well, $t(11) = 2.3$, $p = .044$, $d = 1.1$. Although not significant, the average length of time for occurrences of assertive and hostile/coercive behavior was longer for children with FASD than for TD matched peers (see Table 4). Average length of time for adult-seeking occurrences was comparable across the two groups of children.

Discussion

Summary of Findings

Data revealed that children with FASD and TD children display a similar array of behavioral dimensions

Figure 2. Mean proportion of time spent in the Social Communication Coding System behavioral dimensions by children with FASD and TD children.

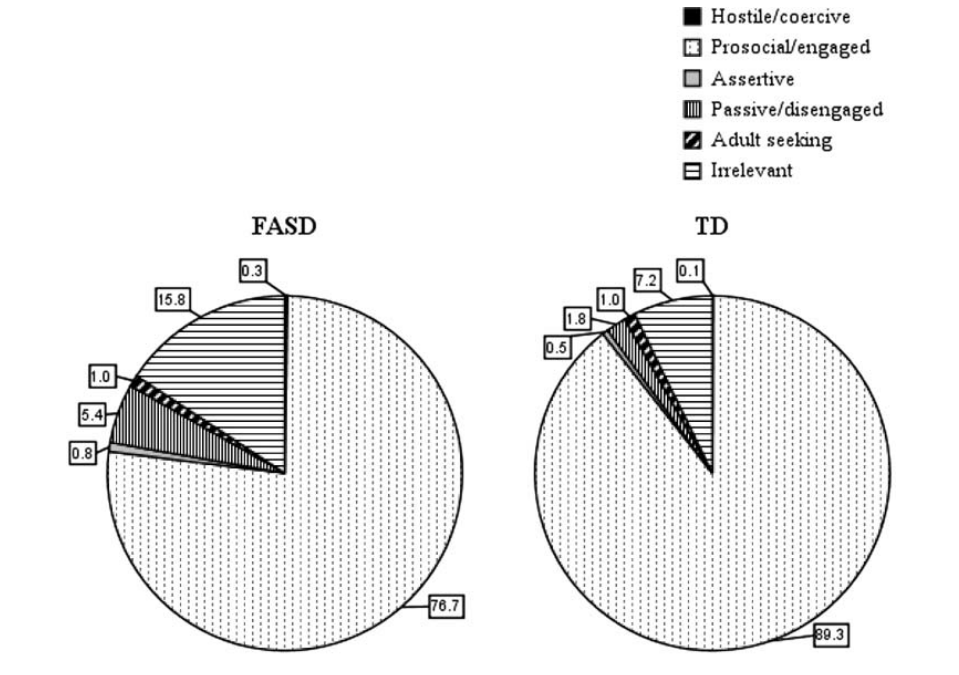


Figure 3. Mean average length of time of Social Communication Coding System behavioral dimension instances for children with FASD and TD children. Group differences were examined using the paired *t* test. $*p < .05$. $**p < .01$.

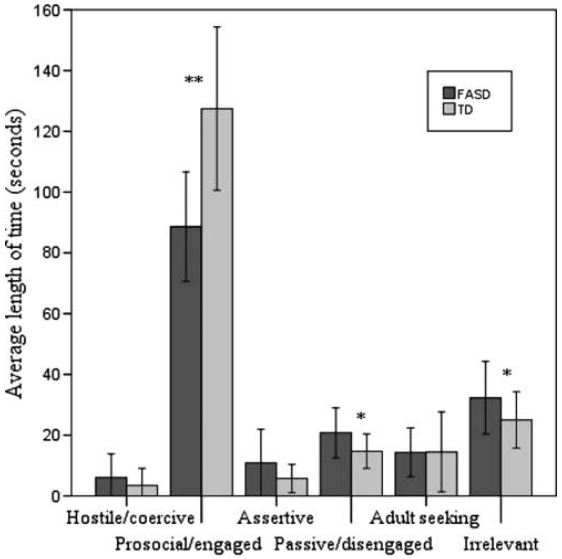

during classroom activities. During the course of a 4-day observation, both groups of children demonstrated performances that could be categorized into the six social communication behavioral dimensions. The predominant performances in terms of proportion of time displayed in the classroom were prosocial/engaged, irrelevant, and passive/disengaged, with both groups of children spending most of their time demonstrating prosocial/engaged performances. The predominance of prosocial/engaged performance corresponds to the results reported by Powell and colleagues (2008). Compared with their matched TD peers, children with FASD spent a smaller proportion of their time displaying prosocial/engaged performance and a larger proportion of their time displaying passive/disengaged and irrelevant performances. With regard to the average length of occurrences of the predominant dimensions, the results revealed that for children with FASD, prosocial/engaged occurrences were shorter than those of their matched peers, and passive/disengaged and irrelevant occurrences were longer than those of their matched peers. Taken together, the frequency and duration data suggest that children with FASD have more occurrences of prosocial/engaged behavior than do their TD peers; however, overall, the proportion of time that they spend being prosocial/engaged is smaller, and the average length of each such instance is shorter than that of their TD peers. Further, they have more passive/disengaged and irrelevant occurrences than do their TD peers, and the proportion and average length of time in these off-task behaviors are larger and longer, respectively, than those of their peers. The previously discussed differences between the groups concerning frequency, proportion of time, and average length of time with regard to the prosocial/engaged, irrelevant, and passive/disengaged dimensions are not only statistically significant but also important in magnitude, as reflected by large effect sizes. Hence, they are likely to be clinically relevant.

This study was designed to explore the social communication performance of children with FASD as they participated in their classrooms as a way to further understand the nature of their problems. We accomplished this objective by examining the differences in social communication profiles between children with FASD and their matched peers in the classrooms. The research successfully revealed new information about the nature of social communication problems that characterize children with prenatal alcohol exposure, particularly those who are on the mild end of the continuum and who are enrolled in regular education classrooms. Further, surprising similarities—as well as differences—emerged as the two groups were compared.

Classroom Performance From a Dimension Perspective: Children With FASD and TD Children

The observational data from this research indicate that children diagnosed with FASD and their TD matched peers spent most of their time demonstrating prosocial/engaged behaviors, followed by irrelevant and passive/disengaged performances. This is a significant finding, particularly for the sample of children with FASD. These data reveal that in general, children with mild FASD perform similarly to their peers in the classroom during both small-group and large-group activities with regard to behavior states/dimensions. Perhaps the message is "children are children" and that school performance of children between the ages of 7 and 12 involve both on-task and off-task performance throughout the day—and even children who are identified as having problem behaviors do not exhibit large extremes in their performance. Both groups spent most of their time being prosocial/engaged—well over 70% of the time across all days and classroom activities—as was expected. Yet, all of the children spent some proportion of their time exhibiting irrelevant and passive/disengaged performances. Until now, this degree of similarity has not been documented. This finding seems particularly revealing in light of the extensive literature describing the social/behavioral problems of children with FASD.

The observational data enlighten our understanding of the nature of the problems that have been noted in the FASD population. Findings from this study validate other literature indicating that children with FASD are characterized by problems interacting with others, yet this study reveals important nuances. Notably, the children with FASD did not demonstrate a significant number of hostile/coercive or assertive behaviors during the observation period, as might have been expected given the literature cited earlier, particularly Aronson (1997), Streissguth (1997), Tanner-Halverson (1997), and Timler (2000). Perhaps this finding reflects the influence of a relatively structured classroom environment on the children's performances. As shown in a case study of a school-age boy with FAS, Timler and Olswang (2001) explained that the boy's behavioral and social performance varied between the school and home environment, seemingly as a result of the difference in structure between the two settings. Another possibility for the limited occurrence of hostile/coercive and assertive behaviors is that the children with FASD in this study were on the mild end of the continuum and were enrolled in regular education classrooms. The research cited earlier in regard to hostile, assertive, and aggressive behavior included children across the FASD continuum. The results from our research suggest that "standout" hostile/coercive or assertive performance as defined by the SCCS protocol may not be accounting for the problem-behavior status of the children with FASD as noted by teachers. In fact, as noted earlier, items from the Problem Behaviors component of the SSRS involves a range of behaviors, including "is easily distracted," "interrupts conversations of others," "acts impulsively," and "disturbs ongoing activities," along with more aggressive and assertive behaviors such as "fights with others" and "threatens or bullies others" (Gresham & Elliot, 1990). High ratings by teachers (i.e., the behavior occurs very often) on the former (less aggressive and assertive) type of items could result in categorizing a child as having problem behaviors according to the SSRS rather than high ratings for the latter (more aggressive and assertive) items.

The results from this observational study serve to enlighten our understanding of why children on the mild end of the FASD continuum may be described as exhibiting problem behaviors. Recall that during the observation period, the children with FASD demonstrated predominantly prosocial/engaged behavior during classroom activities; in fact, frequency of occurrence for this coded dimension was larger for the children with FASD than for their typical peers. However, the proportion of time and average length of each occurrence were shorter than those demonstrated by TD children. These data suggest that children with FASD—particularly on the mild end of the continuum—may have problems sustaining attention, and this, in turn, may lead to their increased challenges in learning and behaving appropriately in class rather than to extremes in behavior (such as those viewed as hostile/coercive or assertive).

Contributing to the profile of children with FASD in this study are the behaviors exhibited that were coded as irrelevant and passive/disengaged. All children act irrelevant or disengage during the school day, but what seems to be true for the children with FASD is that they did so more often (frequency of occurrence data) and for a greater proportion of the day than their peers. Further, when the children with FASD were irrelevant or passive during the observations, these "bouts" lasted longer than the "bouts" of their peers. These factors—in combination with the shorter periods of prosocial/engaged performance—seemingly could account for why these children are notable to their teachers as exhibiting "behavior problems" and why these children are less successful in school. This study revealed that although in large part, children at the mild end of the continuum for FASD act like their peers in the classroom from a social communication behavioral dimensional perspective, they are, in fact, different in regard to being engaged versus disengaged. Their documented performance differences are ones that could call attention to themselves and, perhaps, even be disruptive—or at least counterproductive—in the classroom. These results suggest that the differences noted between groups in the performance of prosocial/engaged, irrelevant, and passive/disengaged dimensions could be accounting for at least part of the problem-behavior status of the children with FASD rather than more conspicuous behaviors, such as those categorized as hostile/coercive or assertive.

The children included in the experimental group in this research were selected because of their prenatal alcohol exposure and behavior problems to confirm the characteristics of the phenotype for FASD. These inclusionary criteria did not allow us to argue convincingly that prenatal alcohol exposure was solely responsible for differences between groups. Nevertheless, the data granted us the opportunity to suggest that children with FASD—even those on the mild end of the spectrum—show differences in their performance in the classroom when compared with peers. The results from this research validate the findings by several researchers (Carmichael Olson, Feldman, et al., 1998; Kodituwakku, 2007; Mattson & Riley, 2000; Thomas et al., 1998) indicating that the social/behavior problems associated with prenatal alcohol exposure do not appear to be solely the result of decreased cognitive functioning. This is the case because the children with FASD in the present research were matched with TD peers in their classrooms, and paired analysis revealed no significant differences between the groups with regard to IQ. Perhaps the children with FASD had other deficits that contributed to

their social communication problems tapped by the observational data. These deficits might have been in any number of areas, as discussed by Coggins and colleagues (2003) and Svensson (2006), such as deficiencies in language, attention, self-regulation, problem solving, and/or memory. We do know that for almost half the children with FASD in our sample, caregivers had noted some language and academic concerns. In a study by Greenbaum, Nulman, Rovet, and Koren (2002), 52 children who had been referred to a hospital-based outpatient program because of learning and behavior problems were split into two groups: 28 children with prenatal alcohol exposure (ARND group) and 24 children without prenatal alcohol exposure. Group comparisons revealed that the ARND group had lower scores on standardized measures of intelligence, language, and memory abilities than the nonalcohol group. Yet, the groups did not differ in the frequency of behavior or social problems as measured by The CBCL (Achenbach, 1991a). Greenbaum and colleagues' (2002) data suggest that children with ARND are likely to have neuropsychological deficits that characterize them but that social problems may not be significantly different from those of other children with learning and behavior problems. Our study isolated and documented the social differences between children with FASD and TD matched peers. Considering the findings of these two studies, perhaps the CNS involvement related to alcohol exposure can be manifested in a variety of ways, one of which is neuropsychological deficits with concomitant social problems. For children with language-learning problems or attention-deficit/hyperactivity disorder, studies suggest that their neurological impairments may contribute to problems in social interactions (Brinton & Fujiki, 1993; Bruce, Thernlund, & Nettelbladt, 2006; Fujiki, Brinton, Morgan, & Hart, 1999; Redmond & Rice, 1998). Children with FASD may share this characteristic. Clearly, future research is needed to address the underlying cause of social performance problems. Be that as it may, some children with FASD seem to stand out in regard to their interaction abilities with children, and this becomes an important aspect of their profile.

Clinical Implications

The data from this study provide a picture of performance of children with FASD as they interact with teachers and peers in the classroom. The data demonstrate the value of using a dimensional approach for documenting performance that might otherwise be challenging to depict. In turn, the results begin to explain why children with FASD—even those on the milder end of the continuum—are conspicuous to their teachers and why they may struggle in school. Direct observation served to enlighten the teacher report and, as such, contributed important information to the assessment process.

An important outcome of the observational methodology was recognizing the strengths as well as weaknesses of children with FASD as they interacted with others in the classroom. Prosocial/engaged behaviors were most common for children with known behavior problems. This directly speaks to the need for an ecobehavioral analysis of classroom performance for children with FASD—that is, determining those activities and factors that appear to facilitate prosocial/engaged performance. Such research would yield important information in regard to how teachers might engineer their classrooms to better support desired, on-task performance for children who face significant challenges in being successful. In regard to the children's off-task behaviors, such as irrelevant and passive/disengaged behaviors, investigating specific classroom factors that may influence performance would be a valuable exercise. As a component of intervention, classroom management, as suggested by Watson and Westby (2003), seems important. Without a doubt, the nature of the neuropsychological deficits that characterize children prenatally exposed to alcohol will create ongoing challenges to engagement in the classroom and deserve careful analysis.

Children and Youth With Fetal Alcohol Spectrum Disorders: Summary of Intervention Recommendations After Clinical Diagnosis

Tracy Jirikowic, Julie Gelo, and Susan Astley

Abstract

Children with fetal alcohol spectrum disorders (FASDs) present with a wide range of developmental disabilities; however, clinical standards of care after a diagnosis are not well established. This retrospective review summarizes the types of intervention recommendations generated by an interdisciplinary FASD diagnostic team for 120 children ages 0.2 to 16.5 years receiving an FASD diagnosis at the University of Washington FAS Diagnostic & Prevention Network Clinic. Intervention recommendations documented in a FASD diagnostic summary report and submitted to each patient's medical record were subject to masked review and content analysis. Intervention recommendations were compared across 3 FASD diagnostic groups and selected demographic variables. The results show the type and frequency of services, supports, and resources recommended to a clinical sample of children with FASD.

DOI: 10.1352/1934-9556-48.5.330

Prenatal alcohol exposure has a well-established and wide-ranging teratogenic impact on the central nervous system (CNS), with resultant impairments in learning, development, and adaptive function (Astley et al., 2009a; Riley & McGee, 2005). Fetal alcohol syndrome (FAS), a permanent birth defect characterized by a unique cluster of minor facial anomalies, CNS structural and/or functional abnormalities, and growth deficiency, is one of the more widely recognized outcomes of prenatal alcohol exposure. At 0.2 to 1.5 cases per 1,000 live births, FAS is the leading known preventable cause of developmental and intellectual disability (U.S. Centers for Disease Control and Prevention, 2006). However, FAS represents a relatively small proportion of children affected by prenatal alcohol exposure. The continuum of birth defects and developmental disabilities associated with alcohol exposure, currently referred to under the umbrella term of *fetal alcohol spectrum disorders* (*FASD*), may occur up to eight times as often as FAS among clinical populations of individuals with prenatal alcohol exposure (Astley, 2006). As such, FASD remains a significant public health concern that places substantial social and financial burdens on communities (Lupton, Burd, & Harwood, 2004).

A number of intervention guidelines and treatment strategies have been identified as useful for individuals with FASD and their families (Bertrand et al., 2004; Clarren, 2004; Kalberg & Buckley, 2007). Recently, several important evidence-based interventions also have emerged or are forthcoming (see Bertrand, 2009; Peadon, Rhys-Jones, Bower, & Elliott, 2009, for review). However, evidence-based standards of care for children and families following a diagnosis on the fetal alcohol spectrum remain limited (Olson, Jirikowic, Kartin, & Astley, 2007; Premji, Benzies, Serret, & Hayden, 2006). Moreover, caregivers continue to describe treatment barriers, unmet needs, and high levels of parenting stress (Olson, Oti, Gelo, & Beck 2009; D.M. Ryan, Bonnett, & Gass, 2006; S. Ryan & Ferguson, 2006). Difficulty qualifying for services, poorly coordinated services across systems and providers, gaps in the continuum of care, and a general paucity of specialized interventions for individuals affected by prenatal alcohol exposure are among the specific challenges reported.

Access to appropriate services and supports across all systems of care is a clearly stated need and a high priority among caregivers raising children with FASD and community professionals (Bertrand et al., 2004; Olson et al., 2009; D. M. Ryan et al., 2006; S. Ryan & Ferguson, 2006; Streissguth et al., 2004; Streissguth & O'Malley, 2000). Yet, the full scope of supports, services, and resources most needed by individuals who receive a diagnosis on the fetal alcohol spectrum have not been systematically described among large, clinically referred populations. As such, examining the type and frequency of clinical recommendations received by children and youths following a systematic diagnosis on the fetal alcohol spectrum is one means to better understand the unique needs of this population and to inform program development, research, and policy efforts.

The Washington state Fetal Alcohol Syndrome Diagnostic and Prevention Network (FAS DPN) was established in 1993. The network consists of four Washington-state, community-based clinics linked by the core research and training clinic at the University of Washington. The FAS DPN provides diagnostic evaluations using the FASD 4-Digit Diagnostic Code (Astley, 2004) administered by an interdisciplinary diagnostic team (Clarren, Olson, Clarren, & Astley, 2000). Currently, the FAS DPN clinical database contains more than 2,000 patient records with patient consent and institutional review board approval. With over 2,000 fields of information recorded per patient, the FAS DPN database is one of the largest and most comprehensive repositories of sociodemographic, cognitive–behavioral, and physical information for individuals of all ages and races–ethnicities with prenatal alcohol exposure, their families, and birth parents. Thus, it provides a rich source of information for a statewide clinical population of individuals systematically evaluated for FASDs.

An important component of the diagnostic process is to provide patients with a comprehensive set of intervention and/or follow-up recommendations specific to their needs. These recommendations are collectively generated by the interdisciplinary diagnostic team as part of the clinic visit after the FASD diagnostic evaluation. These recommendations include resources, referrals, and strategies that address presenting clinical concerns in areas such as health, behavior, social welfare, and education. Team members share these intervention recommendations with caregivers during a brief care conference and include the recommendations in the patient's FASD medical summary note that is submitted to the medical record.

A description of these recommendations, which have not been comprehensively analyzed to date, serves to provide insight into the types of interventions that may support the needs of children with FASDs and their caregivers at the time of diagnosis. The primary purposes of this study were to (a) describe the type and frequency of intervention recommendations provided to patients receiving a FASD diagnosis at a FASD diagnostic clinic and (b) determine if recommendations varied by FASD diagnostic groups and selected sociodemographic characteristics (e.g., age, gender, and caregiver status).

Method

Study Design

We completed a retrospective review of patient records from the University of Washington FAS DPN clinical database. The University of Washington Institutional Review Board approved the study.

Diagnostic Method

An interdisciplinary team (pediatrician, 2 psychologists, occupational therapist, speech–language pathologist, family advocate, and social worker) used the FASD 4-Digit Diagnostic Code to derive the FASD diagnoses (Astley, 2004; Astley & Clarren, 2000). Table 1 outlines key phases of the diagnostic process and primary sources of clinical data used to derive the diagnoses (Clarren et al., 2000). Although the FAS DPN database is a clinic-referred sample, the only requirement for obtaining a diagnostic evaluation is confirmed prenatal alcohol exposure of any quantity, frequency, or duration.

The FASD 4-Digit Diagnostic Code is an objective, case-defined diagnostic system. The four digits of the code reflect the magnitude of expression of the four key diagnostic features of FASD in the following order: (a) growth deficiency, (b) FAS facial features, (c) CNS structural–functional abnormality, and (d) prenatal alcohol exposure. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic"

Table 1. Overview of FAS DPN Diagnostic Process and Sources of Clinical Data

Phase	Description
Phase 1	*Clinical intake:* Caregivers complete a comprehensive "New Patient Information Form" prior to the clinic visit to report current concerns and developmental, social and alcohol exposure history. Past medical, educational, psychological, social, and legal records are also obtained.
	Record review: Psychologist reviews all available medical, developmental, and educational records and presents a case summary to the FASD diagnostic team on the day of the diagnostic evaluation.
Phase 2	*Psychometric screening/evaluation*: Diagnostic team members (occupational therapist, psychologist, speech–language pathologist) screen/assess the patient's current neurobehavioral performance (e.g., language and communication, executive function, cognition, sensory–motor skills).
	Physical examination: Physician examines diagnostic parameters of growth and facial dysmorphology (and general health).
	Caregiver(s) interview: Pediatrician and psychologist conduct a 2-hr caregiver interview to query about past and present child behavior, developmental concerns, and the child's current level of function.
Phase 3	*Diagnosis and intervention recommendations*: Diagnostic team reviews and synthesizes data, derives the 4-Digit Code, and generates intervention recommendations.
	Diagnostic summary: Diagnostic team shares the diagnosis and intervention recommendations with caregiver(s) in a brief case conference.
	Diagnostic summary report: Diagnosis, assessment results, and intervention recommendations are integrated into a comprehensive 6–8-page diagnostic summary report and submitted to the patient's medical record.

Note. FAS DPN = Washington state Fetal Alcohol Syndrome Diagnostic and Prevention Network; FASD = fetal alcohol spectrum disorders.

presence of the FAS feature. There are 256 possible 4-Digit Diagnostic Codes, ranging from 1111 to 4444. Each 4-Digit Diagnostic Code falls into 1 of 22 (labeled A–V) unique clinical diagnostic categories. Seven (A–C; E–H) of the 22 diagnostic categories fall broadly under the designation of FASD (A. FAS–alcohol exposed; B. FAS–alcohol exposure unknown; C. partial FAS–alcohol exposed; E and F. static encephalopathy–alcohol exposed; G and H. neurobehavioral disorder–alcohol-exposed). See Astley (2004) for a full description of the 4-Digit Diagnostic Code and diagnostic categories.

Study Population

We applied the following inclusion criteria to the FAS DPN clinical database to establish the study sample: (a) chronological ages, birth through 18.9 years; (b) received a FASD diagnostic evaluation at the core University of Washington FAS DPN clinic between January 2001 and June 2007; (c) received a 4-Digit Diagnostic classification of FAS with confirmed or unknown alcohol exposure, partial FAS–alcohol exposed (pFAS), static encephalopathy–alcohol exposed (SE/AE), or neurobehavioral disorder–alcohol exposed (ND/AE); and (d) signed a consent to allow the use of their clinical data for research purposes. We used records from the core University of Washington FAS DPN clinic because they represented a patient group with clinical recommendations that were procedurally consistent and fully documented in the patients' diagnostic summary reports. Records from 2001 to 2007 contained the most current intervention needs and service availability. Initially, we considered adult patient records for the study but ultimately excluded them because of the relatively small proportion of patients older than 18 years of age seen in the diagnostic clinic.

One hundred ninety patient records met eligibility criteria. From these records, we established three study groups based on 4-Digit Code

diagnostic outcomes. Children in Group 1 had FAS or partial FAS (FAS/pFAS): significant cognitive–behavioral dysfunction with the FAS facial phenotype (n = 40). Children in Group 2 had static encephalopathy, alcohol exposed (SE/AE): significant cognitive–behavioral dysfunction broadly comparable with Group 1 but no FAS facial phenotype (n = 65). Children in Group 3 had neurobehavioral disorder, alcohol exposed (ND/AE): mild to moderate cognitive–behavioral dysfunction and no FAS facial phenotype (n = 85). Previous research has confirmed these three diagnostic subgroups are clinically distinct and span the full continuum of FASD (Astley et al., 2009a).

To balance age, gender, and race–ethnicity across the three FASD study groups, we started with the smallest of the three study groups (FAS/pFAS; n = 40) and selected an equal number of records (40 per group) from the eligible SE/AE and ND/AE groups by pair matching on age (within 6 months), gender, and race–ethnicity to each case in the FAS/pFAS group. If multiple records met matching criteria we randomly selected a single record.

Content Analysis

For each patient record reviewed, we examined only the portion of the FASD diagnostic summary report containing the clinical intervention recommendations. We used masked review and content analysis to develop a standard coding scheme for categorizing recommendations (Waltz, Strickland, & Lenz, 2005). The first two authors (T. J. and J. G.), both FASD diagnostic team members for over 13 years, developed the first draft of the coding scheme by reviewing 20 randomly selected, eligible patient recommendation reports (not included in the final study sample). Three additional diagnostic team members from different professional disciplines (e.g., psychology, social work) provided expert review of the clinical relevance, clarity, and completeness of the coding scheme. The first two authors (T. J. and J. G.) revised the coding scheme and assessed interrater reliability on 20 additional eligible patient records (not included in the final sample). After the coding scheme was finalized, the first author (T. J.) used it to code all 120 patient recommendation records (masked to their diagnostic outcome) in the study. Table 2 illustrates the coding scheme with category and subcategory definitions and examples of coded text from the diagnostic summary reports.

Data Analysis

The primary focus of the analysis was to determine if intervention recommendations differed significantly among FASD diagnostic groups, caregiver status, and across age groups. Descriptive statistics (Ms, *SD*s, and proportions) were used to summarize sociodemographic and cognitive variables, and intervention recommendation categories across study groups. Analyses of variance (ANOVAs) and chi-square tests were used to compare means and proportions, respectively, among the study groups. Significance levels were set at a conventional two-tailed alpha (α = .05). Analyses were exploratory, with no adjustment for multiple comparisons, thus p values should be interpreted accordingly.

Results

Sociodemographic Characteristics

The mean age of the total sample was 6.5 years (*SD* = 4.1), with a range of 0.2 to 16.5 years; 53% were male and 60% were Caucasian. Sociodemographic characteristics of this sample were comparable with the entire statewide sample of FAS DPN patients (N = 1,235) less than 19 years of age seen since 1993 with similar FASD diagnostic classifications (M age = 8.0 years, *SD* = 4.1; 59% male; 49% Caucasian). Sociodemographic and clinical characteristics of the study sample by FASD diagnostic group are presented in Table 3.

At least 56% of children in the sample had confirmed exposure to high levels of alcohol (i.e., 4-Digit Code, Alcohol Scale Rank 4, indicating an exposure pattern consistent with the medical literature placing the fetus at high risk. The remaining 44% of the sample had confirmed exposure, but the actual levels of exposure were low to moderate or unknown (i.e., 4-Digit Code, Alcohol Scale Rank 3; Astley, 2004). Other reported prenatal risk factors included in utero exposure to illicit drugs (70%) and/or tobacco (71%). Eighty-five (71%) children also experienced notable postnatal risk factors. For example, among these 81 children, 55% experienced physical abuse and 31% had been in one or more out-of-home placements. Approximately 30% of the sample had a reported diagnosis of attention deficit disorder with or without hyperactivity. In general, these other risk factors were distributed comparably across the three diagnostic study groups, with one

Table 2. Coding Scheme and Sample Recommendations From Diagnostic Summary Report

Recommendation category and definition	Subcategories	Sample content from diagnostic summary report
1. *Accommodations:* Specific adaptation or modification to environment/routine to be implemented in home, school, or other setting.	1. Behavior/emotional regulation (e.g., supports for group participation, enhancing environmental structure) 2. Communication (e.g., visual schedules, cues for social interaction) 3. Executive function, organization, memory (e.g., memory aids, checklists) 4. Sensory–motor (e.g., headphones, reducing sensory input, keyboarding) 5. Team communication (e.g., communication between home, school, and other providers)	Code: 1.1 "Based on observations made in clinic today, this team recommends the use of visual strategies and supports to help James maintain attention and manage his behavior."
2. *Anticipatory guidance/prevention*: Prevention oriented recommendations based on developmental risk factors for future problems.	1. Substance abuse prevention 2. Learning problems/behavior risks (awareness of potential for school/learning difficulties and/or mental health problems) 3. Reproductive health (e.g., pregnancy and STD prevention)	Code: 2.1 "James is at high risk for substance abuse later in life, developmentally appropriate substance abuse education that occurs early and often is critical for future prevention.
3. *Community-based:* Leisure or recreation recommendations for specific, community-based activities/programs that are prosocial, recreational, extracurricular in nature and include appropriate developmental and social supports.	1. Prosocial extracurricular/play activities (e.g., Boys and Girls Club; community social skills groups) 2. Physical/movement (e.g., noncompetitive sports; therapeutic horseback riding; Special Olympics) 3. Special interest groups (e.g., focused leisure, religious, or cultural activities) 4. Adult mentor (e.g., Big Brother/Big Sister)	Code: 3.2 "Structured physical activity, such as swimming lessons and/or gymnastics is recommended to help develop balance and gross motor skills."
4. *Education/assessment:* Referral, advocacy, or support for a specific educational program or service, psychoeducational assessment, or specific skill area that requires educational monitoring.	1. Referral/support for educational service (e.g., special education, life skills training, birth to 3 year program) 2. Monitor a specific area of performance (e.g., fine motor, language) 3. Psychoeducational–neuropsychological assessment to determine special education eligibility, re-examine individual education plan or advocate for continued eligibility	Code: 4.1 "Sarah's level of adaptive functioning remains quite low. Continued attention to adaptive living skills is strongly recommended. We strongly recommend that Sarah's special education services remain intact as she moves into middle school as we anticipate that this transition will require increased support."

Table 2. Continued

Recommendation category and definition	Subcategories	Sample content from diagnostic summary report
5. *Family support–resources:* Referral/ recommendations for educational materials (e.g., books, Web sites) community support groups, advocacy training, or caregiver education or support.	1. Books, Web-based resources (e.g., attachment, sleep, FASD) 2. Personal/peer support (e.g., National Organization or Fetal Alcohol Syndrome [NOFAS], grandparent support group) 3. Advocacy/education (e.g., parent advocacy group, parent education, community training) 4. Respite/self-care for caregiver	Code 5.2 and 5.4 "We recommend continued personal, professional and peer support for parents through organizations such as NOFAS Washington for advocacy and training. We strongly encourage parents to pursue avenues for self-care, including respite care to help them continue parenting as effectively as possible."
6. *Medical:* Recommendation/referral to medical specialist or current provider for evaluation or follow-up care regarding a specific medical problem or issue.	1. Psychiatric services and/or medication management/consultation 2. ADHD evaluation 3. Sleep evaluation 4. Vision/hearing evaluation 5. Growth 6. Neurological evaluation/consultation 7. Genetic work up or consultation	Code 6.3 "Consultation with a sleep specialist with an overnight sleep study may reveal primary sleep issues impacting late bedtimes, nap refusal and sleep behaviors. Code 6.5 A thorough nutritional assessment to assess failure to thrive is recommended."
7. *Mental health:* Support/referral for mental health services to address individual and/or family needs around behavior, development, or mental health problem.	1. Behavioral consultation or specialist (e.g., behavior management, home-based intervention services) 2. Individual counseling 3. Family counseling 4. Case management	Code 7.3 "Beth and her family may benefit from counseling. They have done a wonderful job with this complex child but may need support for her behavioral and cognitive issues as she goes through adolescence."
8. *Developmental therapy:* Referral/recommendation for occupational therapy, physical therapy, speech–language therapy, or specific therapeutic program.	1. Referral/recommendation for occupational, physical, or speech language therapy evaluation or treatment 2. Referral to a therapeutic social skills group	Code 8.1 "Language assessment indicates difficulties with unstructured communication, increasing risk for future academic and social problems. An evaluation by an SLP can help determine if reading and writing difficulties have a basis in language impairment."

Table 2. Continued

Recommendation category and definition	Subcategories	Sample content from diagnostic summary report
9. *Safety* Recommendations/resources to address home, school, or community safety concerns.	1. Personal ID/safety (e.g., ID bracelet, wallet card 2. Environmental modification/supervision (e.g., alarms, line-of-sight supervision)	Codes 9.2 and 9.1 "Because of personal safety issues we recommend that Mary should be in line of sight supervision at all times, in all settings and we recommend that she wear an ID bracelet."
10. *Social service/child welfare:* Resources/support for children in out of home placements, including caregiver support and funding resources.	1. Placement advocacy (e.g., stable, safe, structured, supportive home environment; movement towards long-term permanency) 2. Caregiver resources to support appropriate placements and long-term needs (e.g., adoption support, supplemental security income eligibility, family support program)	Code 10.1 "Chris would benefit from a stable home environment with structured daily activities. The new foster, and prospective adoptive parents, will need support and education for complex health and behavioral needs.
11. *Other*	1. Substance abuse recommendations supporting treatment or recovery (caregiver or patient). 2. FASD re-evaluation 3. Other	Code 11.1 "The team highly recommends that Eric's mother continue to access her social and sobriety supports."

Note. FASD = fetal alcohol spectrum disorders; ADHD = attention deficit hyperactivity disorder.

Table 3 Sociodemographic and Cognitive Profiles by Diagnostic Group

*$p < .05$. **$p < .01$.

exception. Children with SE/AE (42%) and ND/AE (36%) were significantly more likely to present with other psychiatric diagnosis (e.g., oppositional defiant disorder, reactive attachment disorder) compared with those with FAS/pFAS (13%), $\chi^2(2, N = 114) = 8.49$, $p = .01$. The high prevalence of other prenatal and postnatal adverse exposures and events observed in this study sample were comparable with the prevalence observed in the entire FAS DPN clinical sample.

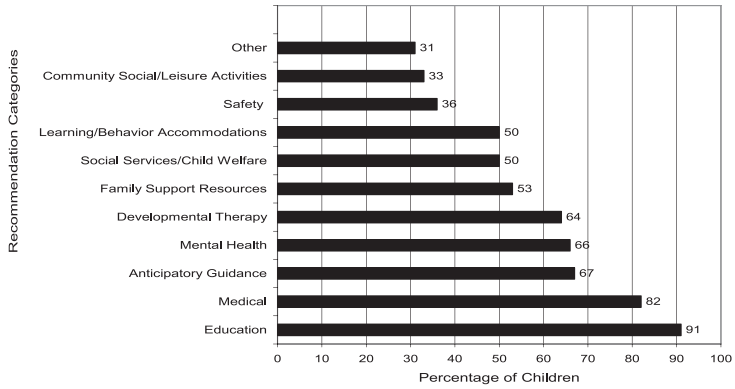

Figure 1 Percentages of children and youths with fetal alcohol spectrum disorders (FASD; $n = 120$) receiving one or more recommendations by category.

Coding Scheme and Interrater Agreement

The final coding scheme (see Table 2) consisted of 11 primary intervention categories each with respective subcategories. Interrater agreement between the first two authors (T. J. and J. G.) on the 11 primary categories exceeded 90%. Intrarater agreement on 11 (10%) records from the final sample was 94%; interrater agreement compared with a masters-level clinical trainee (who was not a diagnostic team member) was 90%.

Primary Intervention Recommendations

The proportion of children with FASD from the entire sample receiving one or more recommendations across each of the 11 primary intervention categories is profiled in Figure 1. The majority of children in this sample received one or more recommendations targeting educational needs. Comprehensive psychoeducational or neuropsychological assessments (50%); special education programs, services, or eligibility (40%); or advocacy to enhance or modify existing educational programs or services (28%) were the most frequent recommendations in the education category. The medical needs of children with FASD in this sample were also high. Medical referrals and recommendations reflected needs for psychiatric care and/or medication management (35%); vision and/or hearing screening (30%); neurological consultation or treatment (22%); attention deficit disorder/attention deficit hyperactivity disorder evaluation or treatment (20%); and growth–small stature (17%), sleep medicine (14%), or genetic (13%) evaluation or consultation.

Approximately two thirds of children and youth in this sample received mental health, developmental therapy, and/or anticipatory guidance recommendations. Individual counseling (33%), family counseling (20%), or specialized behavior management support (18%) constituted the majority of mental health recommendations. Speech–language assessment or intervention (50%), occupational therapy or physical therapy assessment or intervention (50%), or therapeutic social skills groups (12%) were the most frequent types of developmental therapy services recommended. Substance abuse prevention (51%), prospectively monitoring risks for learning and/or behavioral problems (32%), and attention to reproductive health and safety (e.g., pregnancy prevention; 13%) were the anticipatory guidance recommendations provided most often.

About half of the children and youths received one or more recommendations for family support resources, social service–child welfare support, or learning or behavior accommodations. Caregiver support groups (36%), printed or electronic resources (20%), advocacy training and education (16%), and respite or "self-care" (10%) were the most frequent family resource recommendations. Supportive fiscal resources for caregivers (30%) and advocacy for stable, timely, and appropriate home placements (26%) composed most of the social service or child welfare recommendations. Instructional or behavioral accommodations included

Table 4 Percentages of Children and Youths Receiving One or More Intervention Recommendations by Category Across Diagnostic Groups

Recommendation category	FAS/pFAS (n = 40): n (%)	SE/AE (n = 40): n (%)	ND/AE (n = 40): n (%)
Accommodations[a]	26 (65)	21 (53)	13 (33)
Anticipatory guidance	25 (63)	24 (60)	31 (78)
Community-based program	17 (43)	10 (25)	13 (33)
Education[b, c]	40 (100)	36 (90)	33 (83)

Medical	33 (83)	32 (80)	33 (83)
Mental health	28 (70)	24 (60)	27 (68)
Developmental therapy	26 (60)	25 (63)	26 (65)
Safety	14 (35)	15 (38)	14 (35)
Social services/child welfare	22 (55)	19 (48)	19 (48)
Other[d]	18 (45)	8 (20)	12 (30)

Note: FAS/pFAS = fetal alcohol syndrome/partial fetal alcohol syndrome; SE/AE = static encephalopathy, alcohol-exposed; ND/AE = neurobehavioral disorder, alcohol-exposed
[a]Significant contrast, FAS/pFAS vs. ND/AE: $\chi^2(1, N = 80) = 8.45$ $p = .004$. [b]Significant contrast, FAS/pFAS vs. ND/AE: $\chi^2(1, N = 80) = 7.67$ $p = .006$. [c]Significant contrast, FAS/pFAS vs. SE/AE: $\chi^2(1, N = 80) = 4.21$ $p = .04$. [d]Significant contrast, FAS/pFAS vs. SE/AE: $\chi^2(1, N = 80) = 5.70$ $p = .02$.

recommendations for team communication among caregivers and providers (25%) and specific strategies to support learning or behavior in response to executive function (17%), behavior regulation (16%), sensory–motor (14%), or communication (7%) challenges or impairments.

Strategies to enhance personal safety or participate in community-based recreation or leisure activities were important but less frequent recommendations. Procuring personal identification (e.g., ID bracelet; 21%) or enhancing features of the physical (e.g., alarms) or social environment (e.g., line-of-sight supervision; 20%) were among the primary safety interventions made by this team. Referrals to local youth groups, clubs, or programs to facilitate prosocial and/or leisure skill development (23%), physical development (e.g., Special Olympics) (18%), or provide opportunities for adult mentorship (6%) constituted community-based leisure or recreation recommendations.

Primary Intervention Recommendations: Group Contrasts

Table 4 presents the percentages of children receiving one or more primary intervention recommendations by FASD diagnostic group. Intervention recommendations were relatively comparable across the three diagnostic groups, with three exceptions. Children with FAS/pFAS or SE/AE were significantly more likely than children with ND/AE to receive specific instructional or behavioral accommodations. Significantly more children with FAS/pFAS than children with ND/AE received education recommendations. Last, significantly more children with FAS/pFAS than SE/AE received recommendations categorized as *other* ($p <$ .05). Recommendations coded as *other* included substance abuse treatment or recovery support for the patient or caregiver, referrals for research studies, or consultation with a diagnostic team member.

Important developmental trends emerged when recommendations were analyzed across four age categories. Figure 2 illustrates recommendations that were significantly different across age groups. A higher proportion of children in the youngest age group (birth–2 years) received recommendations for family support resources, $\chi^2(3, N = 120) = 11.37$, $p = .010$, and social service–child welfare interventions, $\chi^2(1, N = 120) = 20.79$, $p = .000$, compared with children in older age groups. Mental health recommendations and referrals to community-based programs for prosocial recreation or leisure activities, $\chi^2(3, N = 120) = 16.27$, $p =$

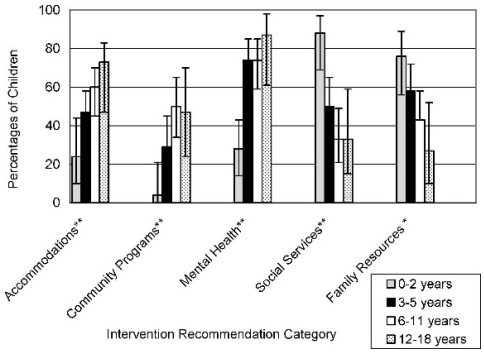

Figure 2 Percentages of children and youth receiving one or more intervention recommendations: significant trends by age group. Error bars indicate 95% confidence interval. *$p \leq .01$. **$p \leq .001$.

.001, were notably higher among children 3 years and older than infants and toddlers (birth–2 years), $\chi^2(3, N = 120) = 11.57$, $p = .009$. Specific behavioral or instructional accommodations also increased with age, with the highest proportion seen among children in the oldest age group (12–18 years), $\chi^2(3, N = 120) = 11.57$, $p = .009$. Figure 3 illustrates recommendations that were comparable across age groups.

Overall, intervention recommendations were relatively consistent across caregiver status (i.e., biological mother, foster parent, adoptive parent, or other) with two exceptions. Children with a foster caregiver were significantly more likely to receive social service–child welfare recommendations than children with adoptive parents, $\chi^2(1, N = 74) = 15.48$, $p = .001$; birth parents, $\chi^2(1, N = 57) = 6.00$, $p = .014$; or other caregivers, $\chi^2(1, N = 75) = 3.83$, $p = .05$. In addition, children in the care of an adoptive parent were significantly more likely to receive recommendations for community-based leisure or prosocial recreational activities than foster caregivers, $\chi^2(1, N = 74) = 4.94$, $p = .03$, although more than half of children living with their birth mothers also received recommendations in this category. The type and frequency of recommendations were generally consistent across gender for the entire sample. One exception was that females were significantly more likely (82%) to receive one or more recommendations categorized as anticipatory guidance than males (53%), $\chi^2(1, N = 120) = 11.32$, $p = .001$.

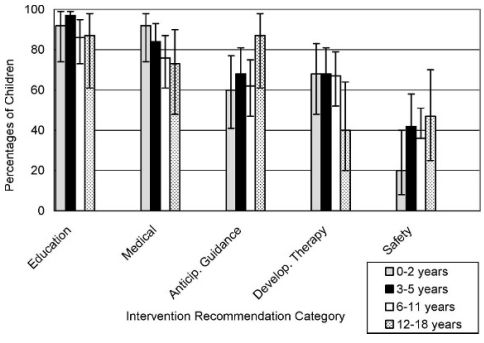

Figure 3 Percentages of children and youth receiving one or more intervention recommendations: nonsignificant trends by age group. Error bars indicate 95% confidence interval.

Discussion

This retrospective analysis sheds light on the type and frequency of supports, services, and referrals recommended by an interdisciplinary diagnostic team for children and youths who received a FASD diagnosis. Findings indicate that children with FASD, like children with other neurodevelopmental disabilities, have a wide range of complex and specialized needs that span across systems of care. Although FAS has historically been considered among the most severe outcomes of prenatal alcohol exposure, these data show that similar intervention recommendations and needs were seen for children across the fetal alcohol spectrum, regardless of diagnosis.

Several important developmental trends also emerged. Though not surprising, this is notable because children with FASD are often diagnosed at different ages, and some disabilities associated with prenatal alcohol exposure may not be evident until school age. Furthermore, a large proportion of children in this sample experienced other prenatal (e.g., exposure to tobacco or illicit drugs) and postnatal (e.g., multiple home placements, abuse, neglect) risks. Although these children received a diagnosis under the umbrella of FASD, prenatal alcohol exposure was clearly not the only risk factor that may have impacted their development and needs at the time of diagnosis. Detailed neuropsychological, behavioral, and mental health profiles

of children from the same clinical population with the same FASD diagnostic classifications (FAS/pFAS, SE/AE, and ND/AE) have been described by Astley et al. (2009b) and provide more perspective on the needs and developmental challenges underlying these clinical recommendations.

The large percentage of children receiving educational recommendations reflects the well-substantiated and elevated risks associated with prenatal alcohol exposure and learning and academic achievement for individuals across the fetal alcohol spectrum (Riley & McGee, 2005; S. Ryan & Ferguson, 2006). Comprehensive developmental or educational assessments were frequently recommended as a means to more thoroughly evaluate neurobehavioral or neurocognitive concerns impacting school performance. Although the amount of neuropsychological and behavioral assessment data available at the time of the diagnostic evaluation is sufficient to render an accurate diagnosis, a child will often benefit from additional neuropsychological–behavioral assessments to guide individualized intervention efforts. Special education programs and services were also noticeably perceived as necessary sources of academic support for many children with FASD, but the need to consider alternative instructional approaches, monitor academic risks, or advocate for specific interventions (e.g., transition support, functional behavior analysis) was evident.

The learning and behavior accommodations we provided these children give additional insight into the neurobehavioral challenges experienced by children with FASD. The types of accommodation strategies recommended were congruent with domains (e.g., communication, executive function, sensory–motor, and behavior regulation) commonly associated with the adverse effects of prenatal alcohol exposure (Astley et al., 2009b, Church & Kaltenbach, 1997; Coggins, Olswang, Olson, & Timler, 2003; Jirikowic, Olson, & Kartin, 2008; Rasmussen, 2005; Riley & McGee, 2005). The scope and variability of the accommodation strategies identified within each neurobehavioral domain also underscore the need for interdisciplinary approaches to diagnosis, assessment, and intervention.

Service providers should be aware of and prepared to consider an array of educational resources, supports, and services for children with FASD. Emerging evidence supports the use of targeted instructional strategies for children with FASD (e.g., for mathematics, safety, and social skills; Kable, Coles, & Taddeo, 2007; O'Connor et al., 2006) as well as behavioral interventions that provide caregiver education, behavioral reframing, and environmental accommodations (Olson et al., 2005). Differentiated instruction, accommodations that enhance external structure and environments (e.g., visual supports), and learning and functional expectations congruent with neurobehavioral abilities appear to be meaningful and important treatment considerations for children with FASD (Clarren, 2004; Kalberg & Buckley, 2007).

Referrals for primary and specialized medical care also constituted a large proportion of the intervention recommendations we made. Several concomitant health, developmental, and psychopathological concerns among this group of children with FASD were revealed. The types of referrals and services that were often advised reflect body structures and functions reported as more vulnerable to the teratogenic impact of prenatal alcohol exposure (e.g., vision, hearing, CNS) as well as the adverse and cumulative impact of other prenatal and postnatal risk factors (Stratton, Howe, & Battaglia, 1996). As such, these findings alert providers to areas of health and development that may benefit from screening, as well as referrals to, and/or treatment by appropriate medical specialists.

A clear need for mental health services, particularly for children older than 3 years of age with an upward trend through adolescence, also emerged. As in other studies of individuals with FASD, mental health or psychiatric conditions were reported across the full range of diagnosis in this sample (Astley et al., 2009b; Streissguth & O'Malley, 2000; Streissguth et al., 2004). Prenatal alcohol exposure has also been considered a risk factor for attachment problems and later psychopathology (O'Connor et al., 2002; O'Connor & Paley, 2006). As such, infant mental health interventions, which have been found useful among other biologically and ecologically vulnerable children (Fisher, Gunnar, Dozier, Bruce, & Pears, 2006) warrant more attention and research among young children with prenatal alcohol exposure and FASD.

Despite a lack of formal infant mental health services, advocacy for important protective factors early in life (Streissguth et al., 2004) were among the social service– or child welfare–related recommendations received by many of the youngest children. As expected, a higher proportion of these

recommendations were received by children in foster care at the time of the diagnostic evaluation, presumably to optimize responsive and stable caregiving environments.

Although parent education and family support resources were a clear priority for caregivers of young children, the frequency of these recommendations did not occur uniformly across older age groups in this sample. This is surprising because education and resources to support and empower caregivers and families are important considerations for parents of children with disabilities across all ages and through different stages of development (Douma, Dekker, & Koot, 2006). One possible explanation is that caregiver education and support are inherent throughout the diagnostic process of this clinic; therefore, the breadth of caregiver support provided was not formally documented for all patients.

Last, diagnosis also serves as an important point of intervention for anticipatory guidance and primary prevention. Although most children and caregivers received some type of anticipatory guidance during their clinic visit, only about half of the children and youth across the entire sample received specific recommendations for substance abuse prevention. As a recognized and critical need with this population, developmentally appropriate substance abuse education that occurs early and often in life has since become a standard recommendation for all patients in this diagnostic clinic.

Findings need to be considered within the context of several study limitations. The recommendations were generated by a diagnostic team within the context of a tertiary care setting. Recommendations were made in the geographic context of a large metropolitan area; therefore, they reflect, in part, the availability of local programs, services, and resources at the time of diagnosis. These factors may limit generalizability of findings. However, this study is the first to describe clinically derived intervention recommendations using a large, representative, clinical sample of children from a Washington-state FASD diagnostic specialty clinic. As such, these results profile and benchmark child and family needs and priorities identified during a FASD diagnostic assessment, a critical point in the continuum of care for individuals affected by prenatal alcohol exposure.

Results from this descriptive study raise several questions regarding the outcomes of these intervention recommendations. Future research should investigate the success with which families access and implement the recommended services, resources, and supports after receiving an alcohol-related evaluation and diagnosis. The perceived short- and long-term value of the intervention recommendations should also be investigated, as developmental needs often change over time. Furthermore, the supports and services needed by adults with FASD remain important to examine, given the lifelong disabilities associated with FASD.

ENCYCLOPEDIA on Early Childhood Development

FETAL ALCOHOL SPECTRUM DISORDERS (FASD)

Clinical Assessment of Individuals with Fetal Alcohol Spectrum Disorders (FASD)

Susan Astley, PhD

Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network (FASDPN), USA

February 2011

Introduction

Fetal Alcohol Syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The condition is characterized by growth deficiency, a unique cluster of minor facial anomalies and central nervous system (CNS) abnormalities.[1] The prevalence of FAS is estimated to be 1-3/1,000 live-births[1] in the general population, and as high as 10-15/1,000 in high-risk populations like foster care.[2] Not all individuals exposed and damaged by alcohol have FAS. Most present neuropsychological impairments without the physical findings. The condition is now recognized as a spectrum of disorders, FASD. Diagnoses like FAS, Partial FAS (PFAS), Alcohol-Related Neurodevelopmental Disorder (ARND), Static Encephalopathy/Alcohol - Exposed (SE/AE) and Neurobehavioural Disorder/Alcohol-Exposed (ND/AE) fall under the umbrella of FASD.[1,3]

Subject

Although reference to the harmful effects of maternal drinking on infant outcome date back to biblical times,[4,5,6] the term FAS was not coined until 1973.[7-9,10,11] Diagnostic guidelines were developed and refined through the 70s and 80s,[7,12,13,14] culminating in 1996 with the publication of the Institute of Medicine (IOM) guidelines.[1] While the IOM guidelines reflected an important advancement, the IOM committee continued to feel: 1) "a medical diagnosis of FAS remained the purview of dysmorphologists and clinical geneticists," and 2) the guidelines remained intentionally broad and conceptual (gestalt) rather than specific and operational (case-defined).[15,16] For example, the guidelines for CNS dysfunction did not address how many areas of deficit must be present or how severe the deficits must be. The guidelines for the facial phenotype did not address how many features must be present, how severe each feature must be, or what measurement scales should be used to judge their severity. And introduction of the term ARND ran counter to the retraction of the term Fetal Alcohol Effects (FAE) the year prior.[17] Overall, guidelines through 1996 were not sufficiently specific to ensure diagnostic accuracy (the ability to derive the correct diagnosis) or diagnostic reproducibility (the ability for two different clinicians to derive the same diagnosis in a given patient).[18]

Problems

In the absence of an accurate/reproducible method of diagnosis, diagnoses continued to vary widely between clinics.[1,18,19] From a clinical perspective, diagnostic misclassification leads to inappropriate patient care, increased risk for secondary disabilities[20] and missed opportunities for prevention.[15,21,22] From a public health perspective, diagnostic misclassification leads to inaccurate prevalence estimates.[15] Inaccurate estimates thwart efforts to allocate sufficient social/educational/medical services to this high-risk population and preclude the accurate assessment of prevention efforts. From a research perspective, diagnostic misclassification prevents detection of clinically-meaningful contrasts between groups and valid comparisons of outcomes between studies.[23]

Research Context

To overcome the limitations of the physician-focused gestalt approach to FASD diagnosis, the FASDPN introduced an interdisciplinary team approach in 1993 (medical doctor, psychologist, speech-language pathologist and occupational therapist)[24,25] guided by a rigorous, case-defined set of guidelines (FASD 4-Digit Diagnostic Code) in 1997.[15,16] Briefly, the 4 digits of the 4-Digit Code reflect the magnitude of expression of the 4 key diagnostic features of FASD in the following

order: 1) growth deficiency, 2) FAS facial phenotype, 3) CNS structural/functional abnormalities, and 4) prenatal alcohol exposure (Fig. 1).[15] The magnitude of expression of each feature is ranked on a 4-point scale, with 1 reflecting complete absence of the feature and 4 reflecting severe presence of the feature. Each rank is specifically case-defined. The 4-Digit codes range from 1111 to 4444. To date, every combination of Code has been observed in the FASDPN clinics, reflecting the true diversity of outcome associated with prenatal alcohol exposure. The subset of 4-Digit Codes that fall under the umbrella of FASD can be grouped into three clinically meaningful and distinct diagnostic subgroups:

1. FAS/PFAS (severe neuropsychological impairment with the FAS facial phenotype);
2. SE/AE (severe neuropsychological impairment without the facial phenotype); and
3. ND/AE (moderate neuropsychological impairment without the facial phenotype).[23,26,27]

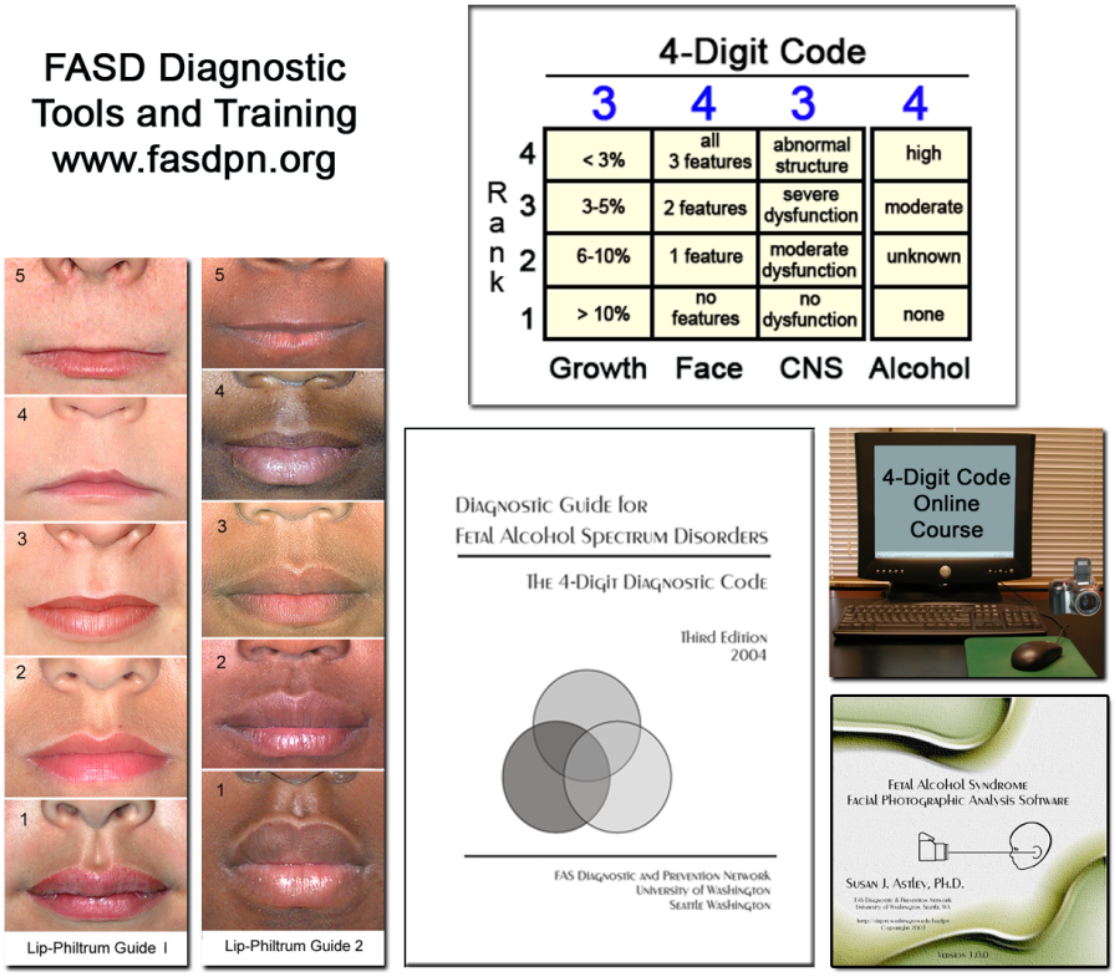

Figure 1. Fetal Alcohol Spectrum Disorders: 4-Digit Diagnostic Code: guide, tools and training.

Key Research Questions

Requisite to the development of diagnostic guidelines is validation of their performance, both before and after their release. Performance should be authenticated through published empirical studies. Measures of performance include accuracy, reproducibility, validity, and practicality.[28] Diagnostic teams should look for the following benchmarks in current FASD diagnostic guidelines:[1,3,28-32]

1. Are the guidelines evidence-based and developed from a broad, representative population-base? The evidence-base should include validation of performance prior to the guideline's release.
2. Do the guidelines endorse an interdisciplinary approach to diagnosis?
3. Are the diagnostic criteria specifically and comprehensively case-defined?
4. Do the diagnostic tools maximize measurement accuracy and precision?
5. The features that characterize FASD (growth, face, CNS, alcohol) are not simply present or absent. Each present along separate, clinically meaningful continua. Are these continua reflected in the guideline's measurement and classification scales?
6. The validity of an FAS diagnosis rests entirely on its unique facial phenotype. Therefore, the sensitivity and specificity of the FAS facial phenotype must be high (>90%) and empirically confirmed. Do the guideline's facial criteria meet these criteria?
7. Do the guidelines identify diagnostic subgroups that are: a) clinically and statistically distinct from one another, b) reflect a continuum of increasing neuropsychological and physical abnormality, and c) span the full continuum of FASD?
8. Does the diagnostic nomenclature assert clinical integrity?
9. The validity of the scales used to measure and classify exposures and outcomes is demonstrated by their ability to detect statistically-significant, physiologically meaningful correlations between physical outcomes, functional outcomes and alcohol exposure levels. With the scales: Does face predict brain? Does neurofunction correlate with neurostructure? Do diagnostic subgroups have unique alcohol-exposure patterns?
10. Are the guidelines readily adoptable into clinical practice? Their practicality should not be at the expense of their accuracy and precision. Training should be expedient, affordable, universally available and competency-based.

Recent Research Results

Below are examples of how the FASD 4-Digit Code meets all 10 benchmarks.

1. *Evidence-based*: The medical records of 1,014 patients (newborn-adult, all races) receiving FASD diagnostic evaluations in the statewide FASDPN were used to develop the 4-Digit Code. Its performance was validated prior to its release through both empirical analysis and

a two-year trial of use by an interdisciplinary team.[15]

2. *Interdisciplinary approach*: The guidelines necessitate the measurement and differential interpretation of physical (growth and dysmorphology) and functional (psychological, language, motor-sensory) outcomes, often in the context of complex social/environmental settings. This requires the expertise of an interdisciplinary team.[25,26]
3. *Case-definitions, measurement tools*: Continuum of exposure and outcome: Case-definitions, measurement tools: All criteria are specifically/operationally case-defined. For example, in contrast to the IOM definition of the FAS facial phenotype ("a characteristic pattern that includes features such as short *palpebral fissure length (PFL)*, flat upper lip, flattened *philtrum* and flat midface"),[1] the 4-Digit Code defines how short, how thin, and how smooth these first three features must be, and provides tools (Lip-Philtrum Guides and FAS Facial Photographic Analysis Software[33]) to accurately measure these features along their full continuum. The 4-Digit Code also recognizes the FAS facial phenotype is not simply present or absent. Its magnitude of expression is measured on a 4-point scale.[15]
4. *Continuum of exposure and outcome*: All FASD features are measured and classified on continuous or ordinal scales. Lips and philtrums are measured on 5-point *Likert scales*. Growth, face, CNS and alcohol are ranked on 4-point scales (Fig. 1). Even the diagnostic subgroups (ND/AE, SE/AE, and FAS/PFAS) reflect three distinct groups with increasing physical/functional impairment.[15,23,26,27,34,35]
5. *Specificity of FAS face*: The Rank 4 FAS facial phenotype is over 95% sensitive and specific to FAS and prenatal alcohol exposure.[2,36,37]
6. *Distinct diagnostic subgroups*: *MRI* /*MRS* /*fMRI* [23,26,27,34,35] have confirmed ND/AE, SE/AE and FAS/PFAS are three clinically distinct, increasingly more severe diagnostic subgroups with unique alcohol exposure patterns. For example, although FAS/PFAS and SE/AE both present with severe dysfunction and disproportionately smaller *caudates*, only FAS/PFAS has the full FAS facial phenotype, disproportionately smaller frontal lobes, significantly lower neurocholine levels, and a significantly higher frequency and duration of alcohol exposure. And although neither SE/AE nor ND/AE present with the full FAS facial phenotype, SE/AE presents with more severe dysfunction, disproportionately smaller caudates and a significantly higher quantity of alcohol exposure. And despite ND/AE's moderate dysfunction, MRI confirms a high prevalence of underlying neurostructural abnormality.

7. *Nomenclature integrity*: The terms SE/AE and ND/AE replace the terms ARND and FAE to accurately document an individual's outcomes and exposure without implying a causal association has been confirmed (or ruled-out) between the two.[15,17,28,29]
8. *Validity*: Published empirical studies[2,15,23,26,27,34-37] document a broad array of physiologically cogent relationships between exposures and outcomes. A few examples: Face predicts brain: IQ and regional brain volumes decrease incrementally and significantly with increasing expression (Ranks 1-4) of the FAS facial phenotype. Neurofunction correlates with neurostructure: The 3-point scale for CNS dysfunction (Rank 1=none, Rank 2=moderate, Rank 3=severe) is significantly associated with decreasing caudate volume.
9. *Readily adoptable into practice*: The guidelines and tools are distributed free or at cost via the web. Training is online, accredited, low-cost and can be completed in a weekend.[38]

Research Gaps

The problems (outlined above) that initially hindered FASD diagnosis have now been overcome with the adoption of rigorous diagnostic guidelines administered by interdisciplinary teams.[2,3,15,23,26-28,34,35,37,39] It is now time to focus research on FASD intervention.[40]

Conclusions

The FASD 4-Digit Diagnostic Code offers an intuitively logical, numeric approach to reporting outcomes and exposure that reflects the true diversity and continuum of disability associated with prenatal alcohol exposure. It also offers substantially greater precision, accuracy and validity than the gestalt method of diagnosis, through the use of quantitative measurement scales, specific case-definitions and an interdisciplinary team approach.

Implications for Parents, Services and Policy

Parents (830 over 13 years) have expressed high satisfaction with the FASDPN interdisciplinary approach to diagnosis using the 4-Digit Code.[26] They report the method was easy to understand and provided them with information they were unable to obtain elsewhere (99% would recommend the clinic to others). The FASDPN model has also earned the respect of service providers statewide. The diagnostic reports provide the detail and direction providers need to qualify children for services. Parents of children with FAS/PFAS, SE/AE and ND/AE confirm being able to access and benefit from recommended interventions.[26] The interdisciplinary model and 4-

Digit Code have been adopted worldwide, often initiated and supported through legislative policy.[26,41-44]

CANADIAN PALPEBRAL FISSURE LENGTH GROWTH CHARTS REFLECT A GOOD FIT FOR TWO SCHOOL AND FASD CLINIC-BASED U.S. POPULATIONS

Susan J Astley
Departments of Epidemiology and Pediatrics, University of Washington, Seattle, WA, U.S.A

ABSTRACT

Background
Short palpebral fissure lengths (PFL) are one of three facial features that define the unique facial phenotype of fetal alcohol syndrome (FAS). Published PFL growth charts vary greatly in both rate and magnitude of growth, placing their accuracy and validity in question. New PFL growth charts were recently published to reflect a racial/ethnic cross section of Canadian girls and boys 6-16 years of age. PFLs were measured from digital facial photographs using the FAS Facial Photographic Analysis Software.

Objectives
Assess the goodness of fit of two U.S. populations (healthy children and children with prenatal alcohol exposure) when plotted on the Canadian, Hall, and other published PFL charts.

Methods
The PFLs of 106 healthy children and 822 children with prenatal alcohol exposure from Washington State were measured from digital facial photographs using the FAS Facial Photographic Analysis Software. Goodness of fit was assessed graphically and by computation of the mean PFL z-score.

Results
Our predominantly Caucasian, healthy group of children scattered along the mean growth curve on the Canadian charts (mean PFL z-score +0.2), and fell 1.6 SDs below the mean on the Hall chart (mean PFL z-score -1.6). The mean PFL z-score for the children with FAS was 2.4 SDs below the mean on the Canadian charts and 3.9 SDs below the mean on the Hall chart. African Americans were not a good fit.

Conclusion
The Canadian PFL charts were a good fit for our predominantly Caucasian populations of healthy U.S. school-aged children. Children with FAS continued to present with PFLs 2 or more SDs below the mean when plotted on the Canadian PFL charts, supporting the FAS PFL diagnostic criteria used by the FASD 4-Digit Diagnostic Code. Use of PFL charts normed for African Americans is recommended. Updated PFL charts for 0-6 years of age are vital to prevent an artificial over-estimation of short PFLs in this age group.

Key Words: *Fetal alcohol syndrome (FAS); fetal alcohol spectrum disorders (FASD); FASD 4-Digit Diagnostic Code; palpebral fissure length*

Short palpebral fissure length (PFL) is a minor physical anomaly noted in several syndromes including fetal alcohol syndrome (FAS) The PFL is the distance between the endocanthion and exocanthion landmarks (Figure 1). Published charts depicting normal growth of the PFL have been generated from a variety of populations (both healthy and clinical) using a variety of measurement techniques (tape measures, rulers, calipers, photos).[1-9] The size and rate of growth of the PFL vary tremendously across these charts (Figure 2). This has led some to question their accuracy/validity.[10-13] As long ago as 1966, an opthalmalogist named Fox[13] expressed the following concern "literature on the subject (palpebral fissure) is scarce; where it exists no two authorities seem to agree on the size, shape and proportions of the lid fissure".

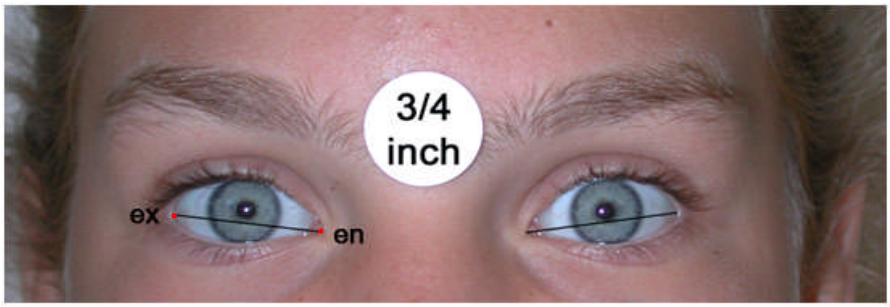

FIG. 1 The palpebral fissure length (PFL) is the distance from the inner corner of the eye (endocanthion landmark) to the outer corner of the eye (exocanthion landmark). The right and left PFLs were measured in this study using the FAS Facial Photographic Analysis Software.[21] A ¾ inch sticker (19.05 mm) is placed between the patient's eyebrows to serve as an internal measure of scale.

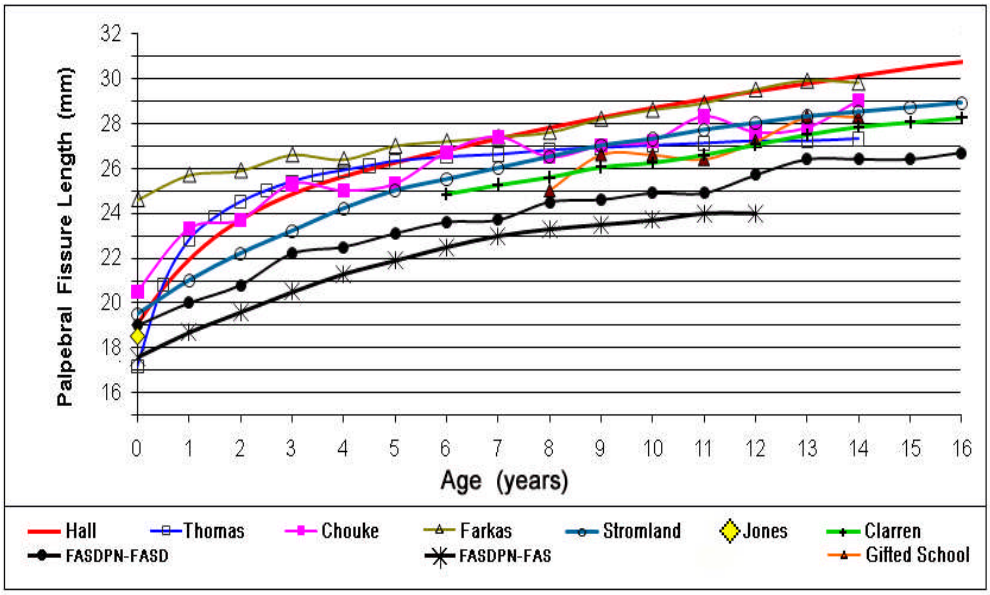

FIG. 2 Comparison of the mean PFL growth curve from published charts depicting normal growth (Hall et al.[5], Thomas et al.[9], Chouke[2], Farkas[3], Stromland et al.[8], Jones et al.[7], and Clarren et al[12]) and selected study samples from Washington State: (children attending a gifted school program (study population 1); and two populations of children diagnosed at the WA State FAS DPN: those with prenatal alcohol exposure (study population 4), and the subset with FAS (study population 3).

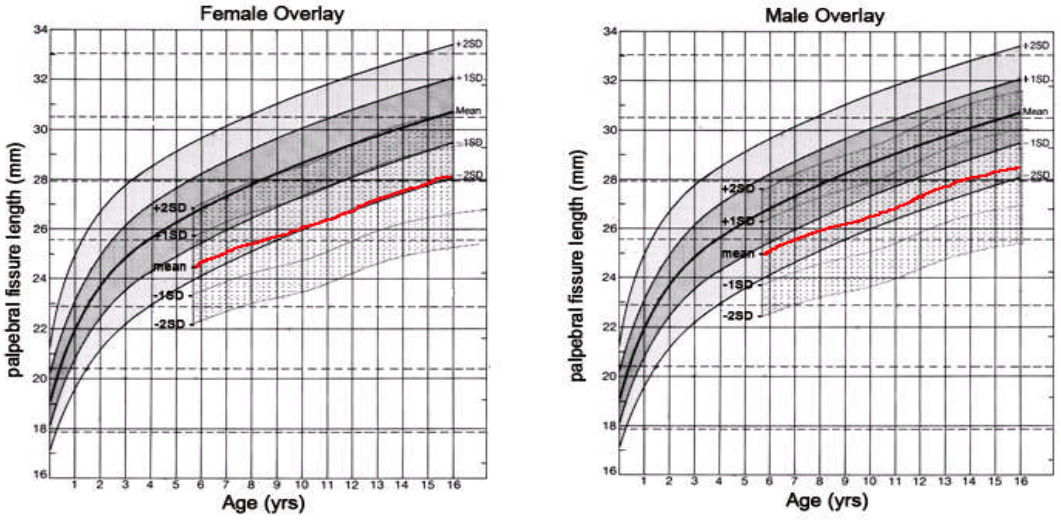
When the Washington State FAS Diagnostic & Prevention Network (FAS DPN) first opened in 1993, the Caucasian PFL growth chart constructed by Hall et al[5] was selected for use. The Hall chart is a composite of four previously published charts: Chouke[2]; Farkas[14], Laestadius[15], and Thomas.[9] Chouke[2] used a sliding caliper to measure the PFLs of 258 North American Caucasian patients and medical students, aged 1 week to 35 years of age, from St. Louis Children's Hospital. It is important to note that the purpose of his study was to ascertain the cause of the epicanthal fold, thus all patients showed some degree of the "Mongolian Fold". Farkas[14] used a sliding caliper to measure

the PFLs of 2,326 healthy Caucasian males and females, aged newborn to 25 years of age, residing in Alberta, Ontario, and Quebec, Canada. Thomas[9] derived a mathematical model of PFL growth from 348 North American Caucasian children 29 weeks to 14 years old. The PFLs were obtained from Chouke[2] and Jones et al.[7] Jones et al[7] used a ruler to measure the PFLs of 200 North American Caucasian newborns (32 to 40 weeks gestation). Laestadius[15] measured the innercanthal distance (distance between the right and left endocanthions) and the outer orbital distance (distance between the outermost edges of the bony orbits) of 472 Caucasian individuals, premature to adult, from clinical and school populations. Laestadius did not measure PFL. If one subtracted the innercanthal distance from the outer orbital distance and divided the outcome by two, one could compute the mean distance from the endocanthion to the outer orbital ridge. The distance from the endocanthion to the outer orbital ridge, by definition, is not the PFL. This measure would exceed the PFL by 4 to 5 mm, as depicted in Figure 1 published by Clarren et al[12] Ten years after the publication of the Hall PFL charts, Stromland et al[8] published PFL charts for white, Scandinavian, healthy males (n=291) and females (n-322), 1 month to 18 years of age, using photogammetry. And most recently, in 2010, Clarren et al[12] published PFL charts for a racial/ethnic cross section of Canadian girls (n=1,194) and boys (n=903), 6-16 years of age. PFLs were measured from digital facial photographs using the FAS Facial Photographic Analysis Software.

Over the years, it became apparent that the PFLs of Caucasian patients evaluated in the WA FAS DPN were frequently 2 or more standard deviations (SD) below the mean depicted on the Hall PFL chart. One plausible explanation for this observation could be that the PFL is especially vulnerable to the adverse impact of prenatal alcohol exposure. To test this theory, Dr. Astley measured a small, convenient sample of volunteers (the FAS DPN clinical staff, including herself) to see where they fell on the Hall PFL charts. Surprisingly, most fell two or more SDs below the mean. The individual with the largest PFLs fell 1 SD below the mean. This outcome suggested the Hall PFL chart over-estimated the normal size of a PFL. To further assess the accuracy of the Hall chart, the PFLs of 90 healthy children attending a Washington State elementary school for gifted children were measured with Human Subjects Review Board approval and parental consent in 1999. A gifted school program was selected to minimize risk of adverse outcomes from prenatal alcohol exposure. The average PFL of the 90 predominantly Caucasian children from 6.0 to 16.0 years of age was 1.6 SDs below the mean when plotted on the Hall PFL chart (Figure 3, Table 1). Once again, the Hall PFL charts appeared to over-estimate the normal size of a PFL. This outcome was not unique to the Hall PFL chart. Based on Figure 2, all published PFL charts[2,3,5,.8,.9] appeared to over-estimate the size of the PFL observed in our samples by 1-3 mm (or 4-12%). The magnitude of this over-estimate is clinically concerning, since 1.5 mm is roughly equivalent to 1 SD. Until new, more accurate PFL charts became available, the FAS DPN chose to continue using the Hall PFL chart because even though it appeared to over-estimate the length of a normal palpebral fissure, the rate of growth (slope) depicted in the chart best matched the rate of growth observed across the lifespan in both our clinic and normal populations (Figure 2). Use of a PFL growth chart that matched our rate of growth assured that the PFL would be over-estimated equally across the lifespan, preventing age-dependent diagnostic misclassification. Although the best error is no error at all, the next best option is to select a chart that produces a consistent error, rather than an inconsistent error. If one uses a PFL chart that over-estimates the length of a normal palpebral fissure, the chart will over-estimate the prevalence of short palpebral fissures. This, in turn could lead to a risk of over-diagnosis of FAS. We were aware of this risk, but observed that when a patient presented with all of the features of FAS as defined by the 4-Digit Code (growth deficiency, all three FAS facial features, CNS abnormalities, and alcohol exposure), their PFLs were not just 2 SDs below the mean (as required by the diagnostic guidelines), but were always 3-4 SDs below the mean. It appeared the Hall PFL charts were not leading to an over-diagnosis of FAS in our clinics. It was always our belief that the Hall PFL charts over-estimated the PFL by 1-2 mm. With the creation of the Canadian PFL charts[12], we now have an opportunity to test this hypothesis.

Canadian palpebral fissure length growth charts reflect a good fit for two school and FASD clinic-based U.S. populations



3A **3B**

FIG. 3 Illustration of the contrast between the Canadian[12] and Hall[5] PFL growth charts. The Canadian female (A) and male (B) PFL growth charts (speckled backgrounds), for children 6 to 16 years of age, are overlaid on the Hall PFL growth chart for both genders, 0-16 years of age. The red lines on the overlays reflect the mean PFL growth curve. The mean PFL growth curve (red line Fig. 3A) for Canadian females aligns with the -2.0 SD growth curve on the Hall PFL chart. The mean PFL growth curve (red line Fig. 3B) for Canadian males aligns with the -1.5 SD growth curve on the Hall PFL chart.

TABLE 1 Mean PFL z-scores* for the four study populations when plotted on the Hall[5] and Canadian[12] PFL charts.

Study Population	N	Hall[5] PFL z-score mean (SD)	Canadian[12] PFL z-score mean (SD)	Age range years
1. Healthy School-based				
Both genders	90	-1.59 (0.90)	+0.17 (0.82)	6.0 - 16.0
Girls	42	-1.80 (0.83)	+0.17 (0.87)	6.0 – 16.0
Boys	48	-1.40 (0.93)	+0.18 (0.82)	6.0 – 16.0
2. Healthy MRI Controls				
Both genders	16	-1.66 (0.69)	+0.19 (0.67)	8.3 – 15.8
Girls	8	-1.76 (0.49)	+0.16 (0.84)	8.3 – 14.4
Boys	8	-1.55 (0.87)	+0.22 (0.51)	8.4 – 15.8
3. FAS DPN: FAS				
Both genders	22	-3.86 (0.82)	-2.36 (0.97)	6.2 – 13.8
Girls	11	-4.18 (1.02)	-2.51 (1.22)	6.6 – 13.8
Boys	11	-3.55 (0.40)	-2.21 (0.65)	6.2 – 12.6
4. FAS DPN: prenatal alcohol exposed				
Both genders	822	-2.61 (1.45)	-1.05 (1.46)	6.0 – 16.9
Girls	320	-2.74 (1.52)	-1.04 (1.61)	6.0 – 16.9
Boys	502	-2.54 (1.41)	-1.06 (1.36)	6.0 – 16.9

* A z-score reflects how many standard deviations a data point is from the normal population mean. The mean PFL for a healthy population would be expected to have a mean z-score close to 0.0. The mean PFL for a population with FAS should have a mean z-score at or below -2.0.

METHODS

Primary Objectives

The primary objectives of this study were to:

1. Compare the Canadian[12] and Hall[5] PFL normal growth charts.
   a. Graphically overlay digital images of the two charts to compare the positions of the mean, ±1SD, and ±2SD growth curves.
2. Determine the goodness of fit of a healthy U.S. population on the Canadian[12] and Hall[5] PFL normal growth charts:
   a. Plot the PFLs of 106 healthy U.S. children on the Canadian and Hall PFL normal growth charts to visually assess goodness of fit. A good fit would be depicted by U.S. PFLs scattering along the mean PFL growth curves on the two charts.
   b. Compute PFL z-scores for the 106 healthy U.S. children (using on the population mean and 1-SD levels depicted in the Canadian and Hall PFL normal growth charts) to quantitatively assess goodness of fit. A good fit would be depicted by a mean PFL z-score near zero.
3. Determine how far below the mean a U.S. population of patients with FASD fall on the Canadian[12] and Hall5 normal PFL charts.
   a. Compute the mean PFL z-scores for 1) 822 patients with prenatal alcohol exposure and 2) the subset of 22 with full FAS, using the population mean and 1-SD levels depicted in the Canadian and Hall PFL normal growth. One would expect the mean PFL z-scores for the alcohol exposed group to fall between zero and -2.0. The mean PFL z-score for FAS should be at or below -2.0.
   b. Plot the mean PFL growth curve for the 822 patients with prenatal alcohol exposure and the subset of 22 with full FAS on a composite graph of published mean PFL growth curves to visually compare and contrast.
4. Compare the mean PFL growth curves across several published PFL normal charts.
   a. Plot the mean PFL growth curves for the following published PFL charts[2,3,5,7,8,9,12] and the healthy and FASD populations from our U.S. healthy and alcohol-exposed study samples.
5. Assess the impact of race (specifically: Caucasian versus African American) on PFL.
   a. Compare the mean PFL between Caucasian and African American among the WA FAS DPN populations.

Study Populations

PFLs from four existing U.S. (Washington State) study populations were used in this study. The populations were restricted to those individuals from 6.0 to 16.9 years of age to match the age range portrayed in the Canadian PFL charts. All datasets were collected with Human Subject Review Board approval.

1. Healthy School Population (1999): 90 healthy children (6.0-16.0 years of age) from a Washington State elementary school for gifted children. (47% female, 89% Caucasian, 1% African American). A gifted program was selected to minimize the risk of prenatal alcohol exposure.
2. Healthy MRI Control Study Population (2003): 16 healthy children (8.3-15.8 years of age) enrolled as controls in a University of Washington FASD magnetic resonance study.[16-19] (50% female, 81% Caucasian, 6% African American). Prenatal alcohol exposure was confirmed absent.
3. FAS Clinical Population (1993-2005): 22 individuals (6.2-13.8 years of age) with a 4-Digit Diagnosis of FAS (Diagnostic categories A and B) from the WA State FAS DPN clinical database[20] (50% female, 73% Caucasian, 5% African American).
4. Alcohol-Exposed Clinical Population (1993-2005): All 822 individuals (6.0-16.9 yrs of age) receiving a FASD diagnostic evaluation at the WA State FAS DPN[20] (39% female, 49% Caucasian, 7% African American, 10% FAS/Partial FAS, 33% Static Encephalopathy/Alcohol Exposed, 52% Neurodevelopmental Disorder/Alcohol Exposed). All had confirmed prenatal alcohol exposures.

Acquisition and measurement of digital facial photographs.

All PFLs were measured by one individual (SJA) from digital facial photographs taken by one photographer (SJA) using the FAS Facial Photographic Analysis Software.[21] Briefly, over

the past two decades, standardized digital frontal facial photographs were obtained for the subjects in the four clinical, research, and school-based populations described above. For study population 1 (the school population) only the eyes were photographed to maintain confidentiality. Photographic standardization included no left-to-right rotation of the head, camera lens aligned in the subject's Frankfort horizontal plane (see video animation posted on FAS DPN website), and eyes fully open so the endocanthion and exocanthion landmarks were clearly visible (Figure 1). A ¾ inch (19.05 mm) paper sticker was placed on the forehead between the eyebrows as an internal measure of scale. To measure the PFLs, the digital photos are opened into the FAS Facial Photographic Analysis Software. The User enters the subject's gender, birth date, photo date, and the size of the internal measure of scale (3/4 inch sticker on forehead). The User measures the width of the paper sticker and the lengths of the right and left palpebral fissures in the photos using mouse-controlled distance measuring tools provided in the software. A video demonstration of the FAS Facial Photographic Analysis Software is posted on the FAS DPN website. The software computes the subject's age in years, computes the right and left PFLs in mm, and computes the PFL z-score based on which normal PFL growth charts the User selected (Caucasian[5], or African American[6]).

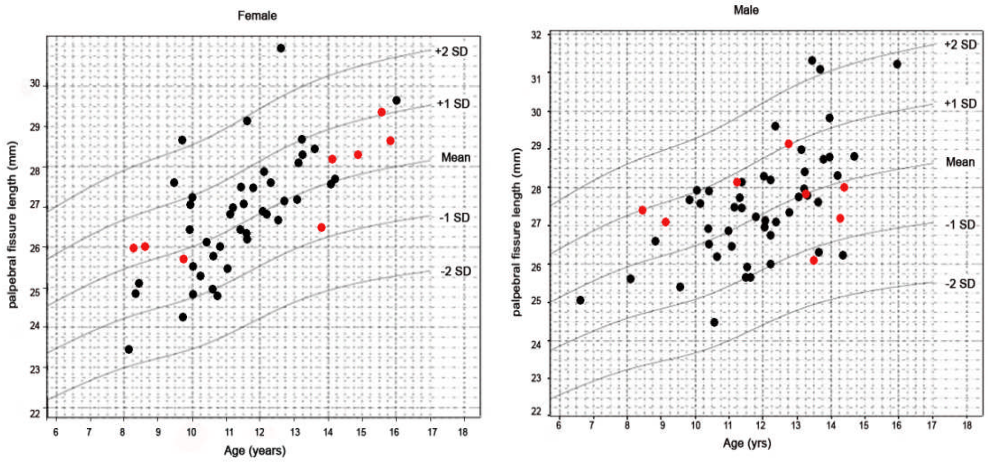
Plotting PFLs of healthy U.S. populations on the Canadian and Hall PFL growth charts.
The PFLs of the two healthy U.S. study populations (study populations 1 and 2) were plotted on the male and female Canadian[12] PFL charts and the Hall[5] PFL chart to visually assess how well the U.S. populations clustered around the mean growth curves (Figures 4 a, b, and c).

Computation of PFL z-scores:
PFL z-scores were computed for each subject based on the means and SDs depicted in the Canadian[12] and Hall[5] PFL charts. A z-score reflects the number of standard deviations (SD) a PFL is above or below the population mean depicted on the normal growth chart for that individual's age. Z-scores provide a quantitative measure of where the four study populations fell on the Canadian and Hall PFL charts. The formula for the PFL z-score is as follows: PFL z-score = ((population mean PFL in mm) – (subject's PFL in mm)) / ((population mean PFL in mm) – (population 1 SD PFL in mm)). For example, if a 10 year old girl had a PFL = 24.0 mm, her PFL z-score calculated based on the Canadian PFL chart for girls would be ((26.03 – 24.0)/(26.03-24.76)) = -1.6. In other words, the girl's PFL is 1.6 SDs below the mean for a 10 year old girl as depicted on the Canadian PFL chart.

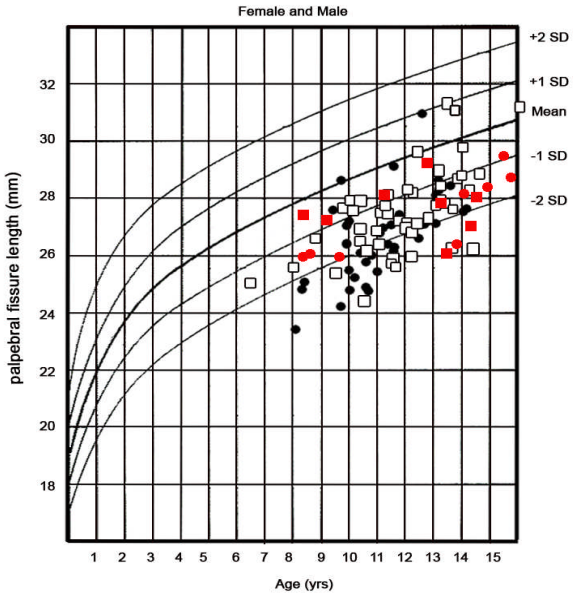
PFL z-scores were computed for each subject based on the population means and SDs depicted in both the Canadian[12] and Hall[5] normal PFL growth charts. To generate the z-scores, the mean and 1 SD lines for the Canadian and Hall PFL charts were digitally traced to generate x,y coordinates along the full length of the growth curves. These x,y coordinates were then used to generate 6th order polynomial best-fit formulas of each line. The formula's predicted the lines with R-squares greater than 0.9999999 (reflecting a perfect fit). These formulas were also used to create a PFL z-score calculator for the Canadian and Hall PFL growth charts posted on the FAS DPN website.

Overlay of Canadian and Hall PFL charts.
Adobe Photoshop CS2[22] was used to overlay captured digital images of the Canadian and Hall PFL charts (Figure 3). This provided a visual comparison of the contrasts in the mean, $\pm$1 SD, and $\pm$2 SD growth curves for individuals 6-16 years of age.

Statistical Analyses
SPSS 14.0[23] was used for all statistical analyses. Chi-square tests and t-tests were used to compare proportions and mean between two groups, respectively. Two-tailed p-values < 0.05 were interpreted as statistically significant.



4A **4B**



4C

FIG. 4 Scatter plots illustrating the goodness of fit of our two healthy U.S. study populations (study populations 1 and 2) on the Canadian[12] and Hall[5] PFL charts. **A**) Canadian female PFL growth chart with the females from the healthy school population (black circles) and healthy MRI control group (red circles) plotted. **B**) Canadian male PFL growth chart with the males from the healthy school population (black circles) and healthy MRI control group (red circles) plotted. **C**) Hall PFL chart for males and females combined with the healthy school population (females: black circles, males black outlined squares) and the healthy MRI control group (females: red circles, males red squares) plotted. Plots A and B reflect a good fit (mean PFL z-scores range from +0.17 to +0.19). Plot C reflects a poor fit (mean PFL z-score = -1.6). These healthy groups of children are depicted on the Hall PFL chart as having PFLs on average 1.6 SDs below the mean (reflecting a poor fit). These same children are depicted as having PFLs on average 0.2 SDs above the mean when plotted on the Canadian PFL charts (reflecting a good fit).

RESULTS

Objective 1. Graphic comparison of Canadian and Hall PFL normal growth charts.
When the Canadian PFL charts are overlaid on the Hall PFL chart, the mean PFL growth curves for Canadian males and females fall 1.5 and 2.0 SDs below the mean, respectively on the Hall PFL growth chart (Figure 3).

Objective 2. Goodness of fit of the healthy U.S. groups on the Canadian and Hall PFL normal growth charts.
The mean PFL of the 106 predominantly Caucasian, healthy U.S. children (90 school-based children and 16 healthy children enrolled as unexposed controls in a MRI study) scatter along the mean PFL growth curve on the Canadian PFL charts (Figures 4A and B). The mean PFL z-scores for the school and MRI study groups were +0.17 and +0.19 respectively (Table 1). Both the scatter plots and mean z-scores are reflective of a very good fit with the Canadian PFL charts. In contrast, these same children scatter, on average, 1.6 SDs below the mean PFL growth curve on the Hall PFL chart (Figure 4C, Table 1) demonstrating a poor fit. The Canadian PFL charts identify these children as having normal PFLs. The Hall PFL charts identify these children as having PFLs that are, on average, 1.6 standard deviations below normal.

Objective 3. Goodness of fit of the U.S. group with FASD on the Canadian and Hall PFL normal growth charts.
The mean PFL z-score for the 22 children diagnosed with full FAS from the WA FAS DPN clinics was 2.4 SDs below the mean on the Canadian PFL charts and 3.9 SDs below the mean on the Hall PFL charts (Table 1, Figure 2). These outcomes document the PFL for a child with FAS continues to fall 2 or more SDs below the mean when the Canadian PFL charts are used. The mean PFL z-score for the larger population of children with prenatal alcohol exposure was 1.1 SDs below the mean on the Canadian PFL charts and 2.6 SDs below the mean on the Hall PFL charts (Table 1, Figure 2). As hypothesized above, when the clinical population is expanded to include all children with prenatal alcohol exposure (not just the subset with FAS), the mean PFL z-score would still fall below the population mean, but not as far below the mean as the subgroup with full FAS. Twenty-five percent of the children with prenatal alcohol exposure had PFLs two or more SDs below the mean on the Canadian PFL charts. Sixty-eight percent of these children had PFLs two or more SDs below the mean on the Hall PFL chart.

Objective 4. Graphic comparison of the mean PFL growth curves across published PFL normal growth charts.
The mean PFL growth curves vary considerably in magnitude and slope across the published PFL normal growth charts[2,3,5,9,8,12] (Figure 2). All present with mean PFLs 0.5 to 2.0 mm greater than that depicted in the Canadian PFL charts. The mean PFL growth curves for the WA State FAS DPN patient population (all FASD and the subset with FAS) have the same rate of growth depicted in the Canadian PFL growth curve, but fall 1 and 2 SDs below the mean Canadian PFL growth curve respectively, as expected.

The greatest variability across the mean PFL growth curves occurs among children under 6 years of age. The rate of growth in the Thomas[9], Hall[5], and Chouke[2] charts, from birth to 4 years of age, is substantially faster than that depicted in the Farkas[3] and Stromland[8] charts. It is important to note that the Hall[5] chart is a composite of Thomas[9], Chouke[2], Farkas[15], and Jones.[7] This rate of growth is not observed in the FAS DPN clinical sample.

Objective 5. Assess the impact of race (specifically Caucasian versus African American) on PFL.
Of the 822 patients with prenatal alcohol exposure from the FAS DPN clinic between 6.0-16.9 years of age, 400 were Caucasian and 54 were African American. These two groups did not differ significantly in mean age, gender, or FASD diagnostic classification. The mean PFL for the African Americans (26.5 mm, 2.0 SD) was 1.5 mm longer than the mean PFL of the Caucasians (25.0 mm, 2.1 SD) ($t = 5.0$, $p < 0.001$) (Figure 5). A 1.5 mm difference is equivalent to 1 SD on the Canadian PFL chart. In other words, if these two racial groups were plotted on the Canadian male and female PFL charts, the mean PFL z-score for the African American group (-0.1, 1.3 SD) would be 1 SD larger than the mean PFL z-score for the Caucasian group (-1.2, 1.4 SD) ($t = 6.0$, $p < 0.001$). Not only is the African American group 1 SD higher on the Canadian PFL chart, but they fall along the mean PFL growth curve

(reflecting normal growth). One would expect an alcohol-exposed group to fall below the mean (like the Caucasian alcohol-exposed group does). There were not a sufficient number of African Americans in our two healthy study populations (populations 1 and 2) to accurately compare PFLs between healthy, unexposed African Americans and Caucasians. There were, however, 105 Caucasian children and 7 African American children evaluated in the FAS DPN clinics whose suspected prenatal alcohol exposures could not be confirmed. The mean PFL for these 7 African Americans (26.2 mm, 1.9 SD) was also 1.6 mm longer than the mean PFL of the 105 Caucasians (24.6 mm, 2.2 SD) ($t = 1.9$, $p = 0.05$).

DISCUSSION

The Canadian PFLs charts[12] provide a much needed update in normal PFL growth from 6.0 to 16.9 years of age across a large, healthy, school-based, racially diverse sample. The current study demonstrates the Canadian PFL norms are a good fit for the PFLs we observed in two predominantly Caucasian, healthy, U.S. (Washington State) school and population-based samples of children. As a result, we have posted a free PFL z-score calculator on our FAS DPN website that will allow clinics to compute a patient's PFL z-score (based on the means and SDs depicted in the Canadian PFL charts) by entering the patient's age, gender, and PFL. We will also include the Canadian PFL charts as one of several PFL growth charts Users may select to use in the next version of the FAS Facial Photographic Analysis Software. The Canadian PFL norms also performed as we would have anticipated for our large, racially diverse, alcohol-exposed population evaluated in the WA State FASD diagnostic clinics. Children with FAS continued to present with PFLs 2 or more SDs below the mean when plotted on the Canadian PFL charts, supporting the FAS PFL diagnostic criteria (PFL 2 or more SDs below the mean) used by the FASD 4-Digit Diagnostic Code.[10] When the clinical population was expanded to include all children with prenatal alcohol exposure (not just the subset with FAS), the mean PFL z-score (-1.0) still fell below the population mean, but not as far below the mean as the subgroup with full FAS. The only subgroup that did not appear to be a good fit was our African American group.

It is well established in the published literature that African American's have significantly longer PFLs than Caucasians.[1,3,4] African Americans in our FASD clinical population had PFLs that were on average 1.5 mm longer (or 1 SD higher on the Canadian PFL growth charts) than Caucasians, across the lifespan (Figure 5). This magnitude of difference was both clinically and statistically significant, and consistent with the magnitude of difference reported for healthy populations of African Americans and Caucasians.[1,3,4] Starting at birth, Fuchs et al[4] reported the PFL was 1.5 mm longer among African American term neonates (20.0 mm, 2.0 SD) compared to Caucasian neonates (18.5mm, 1.3 SD) (7). Among adults, Barretto et al[1] reported the mean PFLs for African American women and men were 31.5 mm and 32.3 mm, respectively. These measures are on average 2.4 mm longer than PFLs for Caucasian women (29.4 mm) and men (29.5 mm). Farkas[3] reported the mean PFLs for African American adult women and men were 32.3 mm and 32.9 mm, respectively. These measures were on average 1.7 mm longer than the mean PFLs for Caucasian women (30.7 mm) and men (31.3 mm). Although the Canadian PFL charts are based on a racially diverse sample, the proportion of African Americans (2.5%) would not be sufficient to overcome this magnitude of difference in PFL between Caucasians and African Americans. It is well understood that norms based on multiracial groups will marginally over or under estimate the growth of individuals who are indigenously at the upper and lower boundaries of the physical spectrum. Clarren et al[12] created separate male and female PFL charts because of their 0.5 mm difference in PFL. The magnitude of difference between African American and Caucasian PFLs is 1.5 to 2.4 mm. This magnitude of difference warrants the use of PFL charts normed to African Americans. African American PFL normal growth charts exist[1,3,4,6], but they too would undoubtedly benefit from an update. The FAS DPN uses the Iosub et al[6] African American PFL charts for African American patients because they provide norms for children. A 10 year old African American boy with a PFL of 26.5 mm would fall directly on the mean using the Canadian multiracial chart for boys (PFL z-score 0.0), 1.6 SDs below the mean on the Hall Caucasian PFL chart, and 2.1 SDs below the mean on the Iosub[6] African American PFL charts.

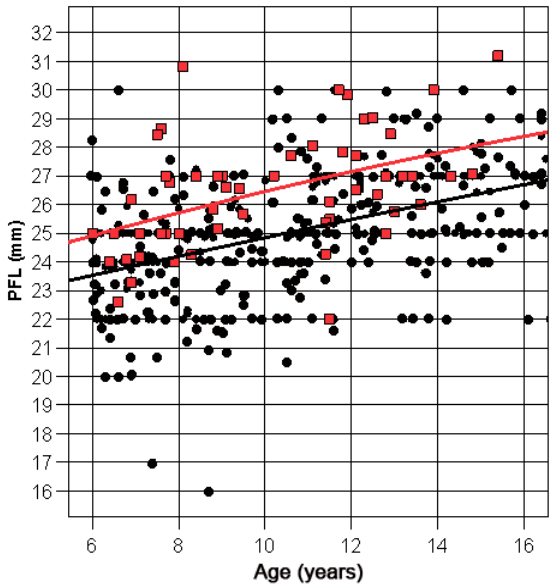


FIG. 5. Among the patients with prenatal alcohol exposure (study population 4), African Americans (red squares, red best linear-fit line) had significantly larger PFLs (mean = 26.5 mm, 2.0 mm SD) than the Caucasians (black circles, black best linear-fit line) (mean = 25.0mm, 2.1 mm SD). Age, gender, and FASD diagnostic classification were comparable between the two groups.

The Canadian PFL charts are a valuable clinical resource for use with patients 6 years of age and older. The absence of updated PFL charts for children under six years of age, however, poses quite a dilemma, especially in FASD diagnostic clinics where accurate interpretation of the PFL is critical to the accurate diagnosis of FAS. If a clinic uses the Canadian PFL charts for children 6 years of age and older, they will have to use one of the other currently published PFL charts for children under 6 years of age.

This will result in an abrupt increase in PFL as one transitions from the Canadian charts for older children to other published PFL charts for younger children (Figure 5). This, in turn, will create what appears to be a higher prevalence of short PFLs among children under age 6 versus over age 6. To illustrate this-the mean PFL for a 6-year-old boy is 25 mm on the Canadian[12] chart. The mean PFL for a 5.9-year-old boy leaps to 26.5 mm to 27.2 mm on the Thomas et al[9], Hall et al[5], and Farkas[3] charts. To further illustrate-a PFL of 25 mm reflects the mean PFL for a 6-year-old boy on the Canadian[12] charts. This same PFL reflects the mean PFL for a 5-year-old on the Stromland et al[8] chart, a 4-year-old on the Chouke[2] chart, a 3-year-old on the Hall et al[5] chart, a 2.3-year-old on the Thomas et al[9] chart, and a 6-month-old on the Farkas[3] chart. Updated PFL growth charts for children birth to 6 years of age are needed immediately. The U.S. National Children's Study[24] could serve as an excellent source of data to generate these norms. The National Children's Study is a prospective longitudinal observational study that will examine the effects of the environment and genetics on the growth, development, and health of thousands of children across a representative U.S. sample, following them from before birth until age 21 years.

CHAPTER 1

Diagnosing Fetal Alcohol Spectrum Disorders (FASD)

While we try to teach our children about life, our children teach us what life is all about

Angela Schwindt

Abstract: Fetal Alcohol Syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. Almost four decades have passed since the term FAS was first coined. The condition is now recognized as a spectrum of disorders: Fetal Alcohol Spectrum Disorders (FASD). Substantial progress has been made in developing specific criteria for delineating diagnoses under the umbrella of FASD. In the 14 years since the publication of the seminal report on FAS by the Institute of Medicine in 1996, clear consensus has been reached on two fundamental issues: 1) an FASD diagnostic evaluation is best conducted by a team of professionals from multiple disciplines (medicine, psychology, speech-language, occupational therapy) and 2) the team should use rigorously case-defined and validated FASD diagnostic guidelines. This chapter will provide a brief overview of the discovery of FASD, diagnostic challenges, how diagnostic guidelines and clinical models have evolved over time to address these challenges, and how new technology may influence the future of FASD diagnosis.

INTRODUCTION

What is FASD?

Fetal Alcohol Syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The definition of FAS has changed little since the 1970's when the condition was first described and refined [1-5]. The condition has been broadly characterized by prenatal and/or postnatal growth deficiency, a unique cluster of minor facial anomalies, and central nervous system (CNS) abnormalities. FAS is the leading known preventable cause of intellectual disabilities in the Western World [6]. The prevalence of FAS is estimated to be 1 to 3 per 1,000 live births [1] in the general population, but has been documented to be as high as 10 to 15 per 1,000 in some higher-risk populations such as children residing in foster care [7,8].

The physical, cognitive, and behavioral deficits observed among individuals with prenatal alcohol exposure are not dichotomous, that is either normal or clearly abnormal. Rather, the outcomes, and the prenatal alcohol exposure, all range along separate continua from normal to clearly abnormal and distinctive [9-12]. This full range of outcomes observed among individuals with prenatal alcohol exposure has come to be called Fetal Alcohol Spectrum Disorders (FASD). Diagnoses like FAS, Partial FAS (PFAS), and Alcohol-Related Neurodevelopmental Disorder (ARND) fall under the umbrella of FASD.

The Diagnostic Challenge

FASD can present a daunting, but not insurmountable challenge for diagnosis. Individuals with prenatal alcohol exposure present with a wide range of outcomes, most of which are not specific to prenatal alcohol exposure and often manifest differently across the lifespan. Professionals from multiple disciplines (medicine, psychology, speech-language pathology, occupational therapy, etc.) are needed to assess and interpret accurately the broad array of outcomes that define the diagnoses. The pattern and severity of outcomes are dependent on the timing, frequency, and quantity of alcohol exposure (which is rarely known with any level of accuracy), and is frequently confounded by other adverse prenatal and postnatal exposures and events.

In the absence of objective, accurate, and reproducible methods for measuring and recording the severity of exposures and outcomes in individual patients, diagnoses have varied widely from clinic to clinic [1,13-16]. From a clinical perspective, diagnostic misclassification leads to inappropriate patient care, increased risk for secondary

Susan Adubato and Deborah Cohen (Eds)

disabilities [17], and missed opportunities for primary prevention [18]. From a public health perspective, diagnostic misclassification leads to inaccurate estimates of incidence and prevalence [1,14,16,19]. Inaccurate estimates thwart efforts to allocate sufficient social, educational, and health care services to this high-risk population, and preclude accurate assessment of primary prevention intervention efforts. From a clinical research perspective, diagnostic misclassification reduces the power to identify clinically meaningful contrasts between FAS and control groups and between FASD clinical subgroups like FAS and ARND [9,14,20]. Non-standardized diagnostic methods also thwart valid efforts to compare outcomes between research studies [9,10, 21].

DISCOVERY OF FETAL ALCOHOL SYNDROME

Reference to the harmful effects of maternal drinking on infant outcome date back to biblical times (Behold, thou shalt conceive, and bear a son; and now drink no wine or strong drink…Judges 13:7) [22], with several remarkably comprehensive descriptions by physician groups in the 1700s and 1800s [23-25]. But several hundred years would go by before another entry would be made to the medical literature. In 1968 Lemoine and colleagues from France published an article describing 147 patients [26]. In 1970, unaware of the Lemoine publication, Ulleland and colleagues from Seattle, Washington published similar observations describing a small group of alcohol-exposed infants admitted to several high-risk maternal-child health clinics at the University of Washington [27,28]. Dr. Ulleland's findings were accepted for presentation at the American Pediatric Society-Society for Pediatric Research meeting, held in Atlantic City New Jersey in 1970 [27]. Through a presentation to the University of Washington pediatric faculty, David Smith, M.D., a dysmorphologist, became interested in Dr. Ulleland's research. This would eventually lead to a collaborative publication in 1973 describing the pattern of outcome associated with prenatal alcohol exposure [29] and the publication that coined the term FAS [2].

Initial FAS Diagnostic Guidelines (1973-89)

Progress in refining the FAS diagnosis can be traced by reviewing Clarren and Smith [4], who summarized the available clinical reports from 1973 to 1976, and the reports from the fetal alcohol workshops of the Research Society of Alcoholism in 1980 and 1989 [3,5].

IOM FAS Diagnostic Guidelines (1996)

In recognition of the seriousness of FAS for the individual and society, the U.S. Congress mandated (in Section 705 of Public Law 102-321, the ADAMHA Reorganization Act) the Institute of Medicine (IOM) of the National Academy of Sciences to conduct a study of FAS and related birth defects. A seminal report was published in 1996 covering the full spectrum of issues from prevalence, diagnosis, prevention, to treatment [1]. A chapter entitled "Diagnosis and Clinical Evaluation of FAS" was included. The committee was charged with evaluating existing diagnostic criteria and formulating the best possible diagnostic guidelines reflective of current knowledge. The IOM diagnostic guidelines for FASD are presented in their entirety across Tables 1-4, as they represent an important baseline from which current guidelines evolved. The IOM committee recognized the following issues as central to delineating FASD:

1. Should a documented history of exposure to alcohol be required for a diagnosis of FAS?
2. Which physical features should be used to define the disorder?
3. Can behavioral or cognitive features be used to define the disorder?
4. Is there a role for ancillary measures (e.g., magnetic resonance imaging [MRI] in making the diagnosis?
5. Can criteria be designed to be used across the lifespan?
6. What is the relationship of so-called fetal alcohol effects to fetal alcohol syndrome?

These issues will be discussed later in this chapter as they relate to both the IOM guidelines and current guidelines.

While the IOM guidelines reflected an important advancement in FASD diagnosis: 1) the IOM committee felt "a medical diagnosis of FAS remained the purview of dysmorphologists and clinical geneticists" (page 79), and 2) the guidelines remained intentionally broad and conceptual (e.g., gestalt) rather than specific and operational (e.g., case-defined) [1].

Table 1. FAS diagnostic criteria: Comparison across the five most current FAS/D diagnostic guidelines.

	4-Digit Code (2004)[38]	CDC (2004) [36]	Canadian (2005) [37]	Hoyme (2005)[19]	IOM (1996)[1]
Growth	Prenatal and/or postnatal height or weight ≤ 10th percentile (Growth Ranks 2-4)	Prenatal and/or postnatal height or weight ≤ 10th percentile (Growth Ranks 2-4)	At least 1 of the following: • Prenatal and/or postnatal height or weight ≤ 10th percentile • Weight-to-height ratio (≤10th percentile) (Growth Ranks 2-4)	Prenatal and/or postnatal height or weight ≤ 10th percentile (Growth Ranks 2-4)	At least 1 of the following: • Low birth weight • Low weight for height • Decelerating weight (Growth Ranks 1-4)
Face	All 3 of the following at any age: • PFL ≤ 3rd percentile • Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5 (Face Rank 4)	All 3 of the following: • PFL ≤ 10th percentile • Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5 (Face Ranks 3-4)	All 3 of the following at any age: • PFL ≤ 3rd percentile • Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5 (Face Rank 4)	2 or more of the following: • PFL ≤ 10th percentile • Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5 (Face Ranks 2-4)	Characteristic pattern that includes features such as short PFL, flat upper lip, flattened philtrum, and flat midface. (Face Ranks 1-4)
CNS	At least 1 of the following: • Structural/Neurological: (e.g., OFC ≤ 3rd percentile, abnormal structure, seizure disorder, hard signs) • Severe Dysfunction: (3 or more domains[a] of function with impairment 2 or more SDs below the mean) (CNS Rank 3 and/or 4)	At least 1 of the following: • Structural/Neurological: (e.g., OFC ≤ 10th percentile, abnormal structure, seizure disorder, hard/soft signs) • Dysfunction[b]: ○ 3 or more domains of function with impairment 1 or more SDs below the mean ○ Global deficit (2 or more SDs below the mean) (CNS Ranks 2-4)	At least 3 of the following Structure/Neurological/ Functional domains with impairment[c]: • Hard/soft signs, structure, cognition, communication, academic achievement, memory, executive functioning, abstract reasoning, ADD, adaptive behavior, social skills, or communication (CNS Ranks 3 and/or 4)	At least 1 of the following: • Structural ○ OFC ≤ 10th percentile ○ Abnormal structure (CNS Rank 1 or 4)	At least 1 of the following: • Structural/Neurological: ○ Decreased cranial size at birth ○ Abnormal structure (e.g., microcephaly, partial/complete agenesis of the corpus callosum, cerebellar hypoplasia) ○ Neurological hard/soft signs (CNS Rank 4?)
Alcohol	Confirmed or Unknown (Alcohol Ranks 2,3 or 4)	Confirmed or Unknown (Alcohol Ranks 2,3 or 4)	Confirmed or Unknown (Alcohol Ranks 2,3 or 4)	Confirmed-excessive or Unknown (Alcohol Ranks 2 or 4)	Confirmed-excessive or Unknown (Alcohol Ranks 2 or 4)

a. 4-Digit Code: Domains may include, but are not limited to: executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention, or activity level.

b. CDC: Performance substantially below that expected for an individual's age, schooling, or circumstances, as evidenced by: 1. Global cognitive or intellectual deficits representing multiple domains of deficit (or significant developmental delay in younger children) with performance below the 3rd percentile (2 standard deviations below the mean for standardized testing) or 2. Functional deficits below the 16th percentile (1 standard deviation below the mean for standardized testing) in at least three of the following domains: a) cognitive or developmental deficits or discrepancies b) executive functioning deficits c) motor functioning delays d) problems with attention or hyperactivity e) social skills f) other, such as sensory problems, pragmatic language problems, memory deficits, etc.

c. Canadian: Impairment indicates scores ≥ 2 SDs below the mean, discrepancies of 1.5-2 SDs among subtests, or ≥ 1 SD discrepancy between subdomains.

The equivalent 4-Digit Ranks for Growth, Face, CNS and Alcohol are inserted in red font to facilitate comparison across the guidelines.

FASD diagnosis has now advanced beyond the 1996 IOM FASD diagnostic guidelines. While areas of debate still exist, the field has reached consensus on two fundamental issues: 1) an FASD diagnostic evaluation is best conducted by an interdisciplinary team of professionals, and 2) the team should use rigorously case-defined and validated FASD diagnostic guidelines.

Interdisciplinary Diagnostic Approach

The University of Washington FAS Diagnostic & Prevention Network (FAS DPN) first introduced an interdisciplinary approach to FASD diagnosis through a CDC-sponsored FAS prevention project conducted in 1992-97 [18,30-32]. Because of the complexity and broad array of outcomes observed in individuals with prenatal alcohol exposure, an interdisciplinary team is essential for an accurate and comprehensive diagnosis and treatment plan. An interdisciplinary FASD diagnostic team typically includes a medical doctor, psychologist, speech language pathologist, occupational therapist, social worker, and family advocate. Other members of the interdisciplinary team may include, but are not limited to, psychiatrists, neuropsychologists, geneticists, public health nurses, and mental health specialists.

Interdisciplinary models will necessarily vary to accommodate site-specific factors like funding, location (rural versus urban), access to services, target population, etc. The model used by the University of Washington FAS DPN diagnostic clinic targets both a general population and a high-risk foster care population. Individuals from the general population (birth to adult) are referred to the clinic by a broad array of community professionals (medical, educational, social-service, justice). In addition, all children who screen positive for the full FAS facial phenotype from the FAS DPN-Foster Care Passport Program FAS screening program [7,8] are also referred to the clinic.

The patient population served by the FAS DPN has expressed strong preference for an evaluation that can be completed in a single visit. Thus, two patients are evaluated per day, one in the morning and one in the afternoon. The interdisciplinary team includes a pediatrician, two psychologists, a speech-language pathologist, an occupational therapist, a social worker, and a family advocate. Prior to an evaluation, previous medical, school, and social records are collected by the clinic coordinator and reviewed by the lead psychologist. On the day of the evaluation, the lead psychologist presents the case to the team. The child is then assessed by the second psychologist, speech language pathologist, and occupational therapist while the caregivers are interviewed by the pediatrician and lead psychologist. Upon completion of the interview, the pediatrician conducts a physical exam of the patient. The team reconvenes to derive the FASD 4-Digit Code and compose an intervention plan. The team shares the diagnostic results and intervention plan with the family at the end of the 4-hour appointment. A single comprehensive report documenting the diagnostic outcome, all data used to derive the diagnostic outcome, and intervention recommendations are submitted to the patient's medical record.

A more detailed description of the interdisciplinary diagnostic approach used by the University of Washington FAS DPN is presented in Clarren et al., [32]. A short video of an interdisciplinary diagnostic team conducting an FASD diagnostic evaluation can be viewed by clicking on http://depts.washington.edu/fasdpn/htmls/diagteamvideo.htm (Fig. 1)

Figure. 1: This video segment portrays an interdisciplinary team conducting an FASD diagnostic evaluation using the FASD 4-Digit Code. The video is a live recording of an actual FASD diagnostic evaluation. The patient is an adolescent adopted from Russia. The interdisciplinary team includes a pediatrician, two psychologists, a speech-language pathologist, an occupational therapist, a social worker, a family advocate, and a public health professional. The child will receive a 4-Digit Code of 4442 (FAS / Alcohol Exposure Unknown). The team conducted a 2-hour interview with the adoptive parents and a 2-hour evaluation of the child. The team has already derived the first two digits of the 4-Digit Code (the Growth and Face Ranks). This segment portrays the team's derivation of the last two digits of the 4-Digit Code (the CNS and Alcohol Ranks). The team will also document all other prenatal and postnatal risk factors that may have contributed to the child's outcomes. This video segment is one of several presented in the FASD 4-Digit Diagnostic Code Online Course offered at the FAS DPN at the University of Washington.[33] Copyright: Susan Astley, University of Washington, Seattle, WA

Current FAS/D Guidelines (1997 2005)

Four FAS/D diagnostic guidelines have been published since the IOM Guidelines in 1996 [1]: the FASD 4-Digit Code in March 1997 [34,35]; the CDC FAS guidelines in July 2004 [36]; the Hoyme FASD guidelines in January 2005 [19], and the Canadian FASD guidelines in March 2005 [37]. The 4-Digit Code was subsequently updated in January, 1999 [34] and November 2004 [38]. All four guidelines are in current use. This is not to imply the 1996

IOM guidelines are not in use. But each of the four new guidelines purports to have been created to replace or augment the 1996 IOM guidelines.

Table 2: Partial FAS diagnostic criteria. Comparison across the five most current FAS/D diagnostic guidelines.

	4-Digit Code (1997-2004)[38]	CDC[a] (2004) [36]	Canadian (2005)[37]	Hoyme (2005)[19]	IOM (1996)[1]
Growth	Prenatal or postnatal height or weight ≤ 10th percentile (Growth Ranks 1-4)	--	No growth deficiency (Growth Rank 1)	Prenatal and/or postnatal height or weight ≤ 10th percentile (Growth Ranks 2-4)	At least 1 of the following: • Low birth weight • Low weight for height • Decelerating weight (Growth Ranks 1-4)
Face	All 3 of the following at any age: • PFL ≤ 3rd percentile • Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5 (Face Ranks 3 or 4)*	--	2 of the following at any age: • PFL ≤ 3rd percentile • Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5 (Face Ranks 2 or 3)	2 or more of the following: • PFL ≤ 10th percentile • Smooth philtrum Rank 4 or 5 • Thin upper lip Rank 4 or 5 (Face Ranks 2-4)	Some components of the pattern of FAS characteristic facial anomalies. (Face Ranks 1-4)
CNS	At least 1 of the following: • Structural/Neurological: (e.g., OFC ≤ 3rd percentile, abnormal structure, seizure disorder, hard signs) • Severe Dysfunction: (3 or more domains[b] of function with impairment 2 or more SDs below the mean) (CNS Rank 3 and/or 4)	--	At least 3 of the following Structure/Neurological/Functional domains with significant impairment[c]: • Hard/soft signs, structure, cognition, communication, academic achievement, memory, executive functioning, abstract reasoning, ADD, adaptive behavior, social skills, or communication (CNS Rank 3 and/or 4)	At least 1 of the following: • Structural ○ OFC ≤ 10th percentile ○ Abnormal structure • Dysfunction ○ Complex pattern[d] of behavior / cognitive abnormalities (CNS Ranks 1-4)	At least 1 of the following: • Structural/Neurological : ○ Decreased cranial size at birth ○ Abnormal structure ○ Hard/soft signs • Dysfunction ○ Complex pattern[e] of behavior / cognitive abnormalities (CNS Ranks 2-4)
Additional Criteria	PFAS requires the CNS and Alcohol criteria to be met and allows the Growth and/or the Face criteria to be relaxed just slightly. • *One facial feature may be relaxed as follows: (PFL ≤ 1 SD, or Philtrum Rank 3, or Lip Rank 3) or • Growth can be relaxed to normal.	--	None	PFAS requires the Face and Alcohol criteria to be met and only one of the following additional criteria : • Growth • CNS Structural • CNS dysfunction	PFAS requires the Face and Alcohol criteria to be met and only one of the following additional criteria : • Growth • CNS Structural / Neurological • CNS dysfunction
Alcohol	Confirmed (Alcohol Ranks 3 or 4)	--	Confirmed (Alcohol Ranks 3 or 4)	Confirmed-excessive or Unknown (Alcohol Ranks 2 or 4)	Confirmed-excessive (Alcohol Rank 4)

a. The CDC Guidelines only address FAS.

b. 4-Digit Code: Domains may include, but are not limited to: executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention, or activity level.

c. Canadian: Impairment indicates scores ≥ 2 SDs below the mean, discrepancies of 1.5-2 SDs among subtests, or ≥ 1 SD discrepancy between subdomains.

d. Hoyme: Marked impairment in the performance of complex tasks (complex problem solving, planning, judgment, abstraction, metacognition, and arithmetic tasks); higher-level receptive and expressive language deficits; and disordered behavior (difficulties in personal manner, emotional lability, motor dysfunction, poor academic performance, and deficient social interaction).

e. IOM: Complex pattern of behavior or cognitive abnormalities that are inconsistent with developmental level and cannot be explained by familial background or environment alone: e.g., learning difficulties; deficits in school performance; poor impulse control; problems in social perception; deficits in higher level receptive and expressive language; poor capacity for abstraction or metacognition; specific deficits in mathematical skills; or problems in memory, attention or judgment.

The equivalent 4-Digit Ranks for Growth, Face, CNS and Alcohol are inserted in red font to facilitate comparison across the guidelines.

Why are there four separate guidelines? Their existence reflects the ongoing debate on how best to approach FASD diagnosis. All present with strengths and limitations. Each was developed under different circumstances that influenced their outcome. The 4-Digit Code was investigator initiated in a statewide clinical/research arena using a clinical sample of 1,014 individuals of all races and ages (birth to 51 years of age) [14]. Empirical methods were used both to develop [20,39] and validate the performance of the 4-Digit Code [7-9,14,20,39]. The CDC [36] and Canadian [37] guidelines were federally mandated and commanded a more consensus-driven process. These guidelines were not empirically validated prior to publication. The Hoyme [19] guidelines were also investigator initiated in a clinical/research arena, using a clinical sample of 164 Native American and South African children to augment an existing set of guidelines: the IOM Guidelines.

Table 3. ARND (or its equivalent: Static Encephalopathy/Alcohol Exposed or Neurobehavioral Disorder/Alcohol Exposed) diagnostic criteria. Comparison across the five most current FAS/D diagnostic guidelines.

	4-Digit Code (1997-2004)[38]	CDC[a] (2004)[36]	Canadian (2005)[37]	Hoyme (2005)[19]	IOM (1996)[1]
Growth	Normal to deficient (Growth Ranks 1-4)	--	No growth deficiency (Growth Rank 1)	No growth deficiency (Growth Rank 1)	No growth deficiency (Growth Rank 1)
Face	No more than 1 of the following: • PFL ≤ 3rd percentile • Philtrum Rank 4 or 5 • Lip Rank 4 or 5 (Face Ranks 1-2)	--	No FAS facial phenotype (Face Rank 1)	No FAS facial phenotype (Face Rank 1)	Presumably no components of the pattern of FAS characteristic facial anomalies. (Face Rank 1)
CNS	Criteria for "Static Encephalopathy" At least 1 of the following: • Structural/Neurological: (e.g., OFC ≤ 3rd percentile, abnormal structure, seizure disorder, hard signs) • Severe Dysfunction: (3 or more domains[b] of function with impairment 2 or more SDs below the mean) (CNS Rank 3 and/or 4) Criteria for "Neurobehavioral Disorder"[c] • No Structural/Neurological abnormalities. • Moderate Dysfunction: (1-2 domains[b] of function with impairment ≥ 1.5 SDs below the mean) (CNS Rank 2)	--	At least 3 of the following Structure/Neurological/ Functional domains with significant impairment[c]: • Hard/soft signs, structure, cognition, communication, academic achievement, memory, executive functioning, abstract reasoning, ADD, adaptive behavior, social skills, or communication (CNS Ranks 3-4)	At least 1 of the following: • Structural ○ OFC ≤ 10th percentile ○ Abnormal structure • Dysfunction ○ Complex pattern[d] of behavior / cognitive abnormalities (CNS Ranks 1-4)	At least 1 of the following: • Structural/Neurological: ○ Decreased cranial size at birth ○ Abnormal structure ○ Hard/soft signs • Dysfunction ○ Complex pattern[e] of behavior / cognitive abnormalities (CNS Ranks 2-4)
Additional Criteria	The term ARND is not used. The following terms are used in lieu of ARND: Static Encephalopathy (Severe dysfunction) Neurobehavioral Disorder (Moderate dysfunction)	--	--	--	--
Alcohol	Confirmed (Alcohol Ranks 3 or 4)	--	Confirmed (Alcohol Ranks 3 or 4)	Confirmed-excessive (Alcohol Rank 4)	Confirmed-excessive (Alcohol Rank 4)

a. The CDC Guidelines only address FAS.

b. 4-Digit Code: Domains may include, but are not limited to: executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention, or activity level. MRI research confirms Neurobehavioral Disorder/Alcohol Exposed is a distinct, clinically meaningful subclassification under the umbrella of FASD [9]

c. Canadian: Impairment indicates scores ≥ 2 SDs below the mean, discrepancies of 1.5-2 SDs among subtests, or ≥ 1 SD discrepancy between subdomains.

d. Hoyme: Marked impairment in the performance of complex tasks (complex problem solving, planning, judgment, abstraction, metacognition, and arithmetic tasks); higher-level receptive and expressive language deficits; and disordered behavior (difficulties in personal manner, emotional lability, motor dysfunction, poor academic performance, and deficient social interaction)

e. IOM: Complex pattern of behavior or cognitive abnormalities that are inconsistent with developmental level and cannot be explained by familial background or environment alone: e.g., learning difficulties; deficits in school performance; poor impulse control; problems in social perception; deficits in higher level receptive and expressive language; poor capacity for abstraction or metacognition; specific deficits in mathematical skills; or problems in memory, attention or judgment.

The equivalent 4-Digit Ranks for Growth, Face, CNS and Alcohol are inserted in red font to facilitate comparison across the guidelines.

Each guideline is introduced below. Since the circumstances that surrounded the development of each guideline influenced its outcome, it seemed most appropriate to let each guideline introduce itself (the published abstract or executive summary of each is presented below, with permission).

Table 4. ARBD diagnostic criteria. Comparison across the five most current FAS/D diagnostic guidelines.

	4-Digit Code[a] (1997-2004) [38]	CDC[b] (2004) [36]	Canadian[a] (2005) [37]	Hoyme (2005) [19]	IOM (1996) [1]
Growth	--	--	--	Not specified (Growth Rank ?)	Not specified (Growth Rank ?)
Face	--	--	--	2 or more of the following: • PFL ≤ 10th percentile • Philtrum Rank 4 or 5 • Lip Rank 4 or 5 (Face Ranks 2-4)	Not specified (Face Rank ?)
CNS	--	--	--	Not specified (CNS Rank ?)	Not specified (CNS Rank ?)
Congenital Defects	--	--	--	1 or more of the following: • Cardiac: Atrial septal defects, Ventricular septal defects, Aberrant great vessels, Tetralogy of Fallot. • Skeletal: Hypoplastic nails, Shortened fifth digits, Radioulnar synostosis, Flexion contractures, Camptodactyly, Clinodactyly, Pectus excavatum and carinatum, Klippel-Feil syndrome, Hemivertebrae, Scoliosis. • Renal: Aplastic/dysplastic/hypoplastic kidneys, Horseshoe kidneys, Ureteral duplications, Hydronephrosis. • Ocular: Strabismus, Retinal vascular anomalies, Refractive problems secondary to small globes. • Auditory: Conductive hearing loss, Neurosensory hearing loss. • Other: Virtually every malformation has been described in some patient with FAS. The etiologic specificity of most of these anomalies to alcohol teratogenesis remains uncertain.	Congenital structural defects in 1 of the following categories, including malformations and dysplasias (if the patient displays minor anomalies only, 2 must be present): • Cardiac: Atrial septal defects, Ventricular septal defects, Aberrant great vessels, conotruncal heart defects. • Skeletal: Radioulnar synostosis, Vertebral segmentation defects, Large joint contractures, Scoliosis. • Renal: Aplastic/dysplastic/hypoplastic kidneys, "Horseshoe" kidney/ureteral duplications. • Eyes: Strabismus, Ptosis, Retinal vascular anomalies, Optic nerve hypoplasia. • Ears: Conductive hearing loss, Neurosensory hearing loss. • Minor Anomalies: Hypoplastic nails, Short fifth digits, Clinodactyly of fifth fingers, Pectus carinatum / excavatum, Camptodactyly, "Hockey stick" palmar creases, Refractive errors, "Railroad track" ears.
Alcohol	--	--	--	Confirmed-excessive (Alcohol Rank 4)	Confirmed-excessive (Alcohol Rank 4)

a. The 4-Digit Code and Canadian Guidelines do not recognize ARBD as a FASD diagnostic classification.

b. The CDC Guidelines only address FAS.

The equivalent 4-Digit Ranks for Growth, Face, CNS and Alcohol are inserted in red font to facilitate comparison across the guidelines.

To facilitate comparisons across the five guidelines, the FAS criteria used by the 4-Digit Code [38], CDC [36], Canadian [37], Hoyme [19], and IOM [1] guidelines are presented in Table 1. The same format is used to present the criteria for PFAS, ARND, and ARBD (Tables 2-4 respectively).

It is important to note that for the purposes of this chapter, the 4-Digit Code has been translated, as best as possible, into a text, rather than numeric, format across Tables 1-4. This was done to facilitate comparison to the other guidelines that publish their diagnostic criteria in text format. Diagnostic teams should not use the textual translations of the 4-Digit Code presented in Tables 1-4 to derive a 4-Digit Code. Diagnostic teams should use the numeric format presented in the 2004 Diagnostic Guide [38].

FASD 4-Digit Code (1997, 1999, Nov 2004) [34,35,38]

Rationale for the FASD 4-Digit Code

One year after the release of the 1996 IOM guidelines [1], the FASD 4-Digit Diagnostic Code was created [14,34,35,38] to address the following limitations in the extant gestalt approach to FASD diagnosis.

1. *There have been no standardized operational definitions for FAS or for any of the other diagnoses that fall under the umbrella of FASD. Rather, there have been diagnostic guidelines that physicians have been encouraged to follow, but the guidelines have not been sufficiently specific to assure diagnostic accuracy or precision.*

For example, according to the diagnostic guidelines published by Sokol and Clarren [5], which were a minor modification of the 1980 definition of FAS by the Fetal Alcohol Study Group of the Research Society for Alcoholism [3], which, in turn, were derived from the work of Clarren and Smith [4]: "The diagnosis of FAS can only be made when the patient has signs of abnormality in each of the three categories: 1) Prenatal and/or postnatal growth retardation [weight and/or length below the 10th percentile when corrected for gestational age], 2) central nervous system involvement (including neurological abnormality, developmental delay, behavioral dysfunction or deficit, intellectual impairment, and/or structural abnormalities, such as microcephaly [head circumference below the 3rd percentile or brain malformations found on imaging studies or autopsy] and 3) a characteristic face, currently qualitatively described as including short palpebral fissures, an elongated midface, a long and flattened philtrum, thin upper lip, and flattened maxilla."

The 1996 guidelines for the diagnosis of FAS proposed by the IOM [1] took a similar approach. The diagnosis of FAS can be made when the patient presents with: "1) Evidence of growth retardation, as in at least one of the following: a) low birth weight for gestational age; b) decelerating weight over time not due to nutrition; or c) disproportional low weight to height; 2) Evidence of a characteristic pattern of facial anomalies that includes features such as short palpebral fissures and abnormalities in the premaxillary zone (e.g., flat upper lip, flattened philtrum, and flat midface); and 3) Evidence of CNS neurodevelopmental abnormalities, as in at least one of the following: a) decreased cranial size at birth; b) structural brain abnormalities (e.g., microcephaly, partial or complete agenesis of the corpus callosum, cerebellar hypoplasia);c) neurological hard or soft signs (as age appropriate), such as impaired fine motor skills, neurosensory hearing loss, poor tandem gait, poor eye-hand coordination."

Although these descriptions do provide guidance, they are not sufficiently specific to assure diagnostic accuracy and precision. They reflect a gestalt approach to diagnosis. The guidelines for CNS abnormalities do not address how many areas of deficit must be present, how severe the deficits must be, or what level of documentation must exist to substantiate the presence of the deficit. The guidelines for the facial phenotype are equally nonspecific. How many facial features must be present, how severe must the features be, and what scale of measurement should be used to judge the severity? One need only read the clinical literature or review medical records, birth certificates, birth defect registries or ICD-9 codes to see how variably these criteria are interpreted, applied and reported [1,40-43].

2. *There has been a lack of objective, quantitative scales to measure and report the magnitude of expression of key diagnostic features*

For example, although a thin upper lip and smooth philtrum are key diagnostic features [1,2,4,39,44], quantitative measurement scales were never used to measure thinness or smoothness, and guidelines had never been established for how thin or smooth the features must be. Objective quantitative scales not only improve accuracy and precision, but also establish a common numeric language for communicating outcomes in medical records and in the medical literature.

3. *The term fetal alcohol effects (FAE) was broadly used and poorly defined.*

The term 'suspected fetal alcohol effects' was first introduced into the medical literature in 1978 and was defined as 'less complete partial expressions' of FAS in individuals with prenatal alcohol exposure [4]. Based on this definition, an individual whose mother drank a few glasses of wine intermittently throughout pregnancy and presented with attention deficit hyperactivity disorder would meet the criteria for FAE. So would an individual whose mother drank a fifth of vodka daily throughout pregnancy and presented with microcephaly, severe mental retardation, growth deficiency and no facial anomalies. The broad use of this term and the reluctance to abandon it points to the clear need to develop diagnostic terms for individuals with prenatal alcohol exposure who present with physical anomalies and/or cognitive/behavioral disabilities, but do not meet the criteria for FAS. New diagnostic terms that more finely differentiate the variable exposures and outcomes of individual patients, without implying alcohol as the sole causal agent, were needed.

4. *Clinical terms like FAE [4,5], alcohol-related birth defects (ARBD) [1] and alcohol-related neurodevelopmental disorder (ARND) [1] imply a causal link between alcohol exposure and outcome*

in a given individual that cannot be medically confirmed. Leading dysmorphologists in the field of FAS diagnosis have formally requested that the term FAE no longer be used for this reason[13].

With the likely exception of the full facial phenotype, no other physical anomalies or cognitive/behavioral disabilities observed in an individual with prenatal alcohol exposure are necessarily specific to (caused only by) their prenatal alcohol exposure [1]. Features such as microcephaly, neurological abnormalities, attention deficit, mental retardation, and growth deficiency frequently occur in individuals with prenatal alcohol exposure, and frequently occur in individuals with no prenatal alcohol exposure. The diagnostic terms ARBD and ARND introduce the same limitation as does FAE, namely, implying alcohol exposure caused the birth defect or neurobehavioral disorder in an individual patient.

5. *Too often diagnoses depicting FASD are reported in the medical records and scientific literature with no documentation of the method used to derive the diagnosis and little or no documentation of the data used to render/support the diagnosis.*

Failure to report this information can limit the patient's ability to qualify for and receive appropriate intervention services from subsequent health care, social service, and educational providers. For example, simply reporting that an individual has FAS does little to convey the individual's strengths and disabilities. Some individuals with FAS have low IQs, some have IQs in the normal range, some have attention deficits, some do not, some have problems with memory, while others have language deficits. From a public health perspective, failure to report these data also prevents surveillance efforts from accurately tracking the prevalence of FASD diagnoses in the population. The supportive data are needed to validate the diagnoses. Accurate surveillance is vital for setting public health policy and assessing the effectiveness of primary prevention efforts. The 4-Digit Code requires that data be collected not just to support the diagnosis, but to derive the diagnosis. The 4-Digit Code provides a comprehensive FASD Diagnostic Form for recording all supportive data and provides a numeric classification scheme that is readily incorporated into clinical, research, and surveillance databases.

6. *FAS is a medical diagnosis and thus has historically been diagnosed by a medical doctor (e.g., dysmorphologist, geneticist). There is now clear consensus that an interdisciplinary team approach is superior [32,35-37].*

Each of the above limitations was largely overcome with the development of the FASD 4-Digit Diagnostic Code in 1997[35]. Briefly, the 4 digits of the FASD 4-Digit Code reflect the magnitude of expression of the 4 key diagnostic features of FASD, in the following order: (1) growth deficiency, (2) FAS facial phenotype, (3) CNS structural/functional abnormalities, and (4) prenatal alcohol exposure (Figs. 2 and 3). The magnitude of expression of each feature is ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong "classic" presence of the FASD feature. Each Likert rank is specifically case defined. For example if a patient received the following Ranks: Growth = 3, Face = 4, CNS = 4, Alcohol = 4; the resulting 4-Digit Code would be 3444. Code 3444 is one of twelve 4-Digit Codes that meet the criteria for FAS/Alcohol Exposed (Fig. 2). An interactive, electronic FASD 4-Digit Code Short Form [45] is provided (Fig. 4) to demonstrate the simple, numeric approach used by the 4-Digit Code to define and derive a diagnosis. There are 256 possible 4-digit diagnostic codes, ranging from 1111 (reflecting complete absence of growth deficiency, FAS facial features, CNS abnormalities, and alcohol exposure) to 4444 (reflecting the most severe presentation of FAS: severe growth deficiency, the full FAS facial phenotype, significant CNS abnormalities, and high exposure to alcohol). Each 4-Digit diagnostic code falls into 1 of 22 unique clinical diagnostic categories (labeled A through V). Seven of the 22 diagnostic categories (4-Digit Categories A–C and E–H) fall broadly under the umbrella of FASD (A. FAS/Alcohol Exposed B. FAS/Alcohol Exposure Unknown, C. Partial FAS/Alcohol Exposed, E-F. Static Encephalopathy/Alcohol Exposed, and G-H. Neurobehavioral Disorder/Alcohol Exposed) (Fig. 2).

The FASD 4-Digit Diagnostic Code was developed from the clinical records of 1,014 patients of all races and ages evaluated by the FAS DPN interdisciplinary team at the University of Washington. The purpose was not to redefine, but rather, more specifically case-define the key diagnostic components of FAS as presented across several previously published FAS diagnostic guidelines [1,3-5]. The performance of the 4-Digit Code was validated prior to

Figure 2: The 4-Digit Code is derived by ranking the severity of growth deficiency, FAS facial features, CNS abnormality, and alcohol exposure on 4-point Likert scales. Each rank is specifically case-defined [38]. The 4-Digit Code 3444 is one of twelve 4-Digit Codes that meet the diagnostic criteria for FAS / Alcohol Exposed.

its release [14]. Its performance was compared to the standard gestalt method of diagnosis on the first 454 patients who had received a gestalt diagnosis of FAS, PFAS or possible fetal alcohol effect (PFAE) prior to the development of the 4-Digit Code.

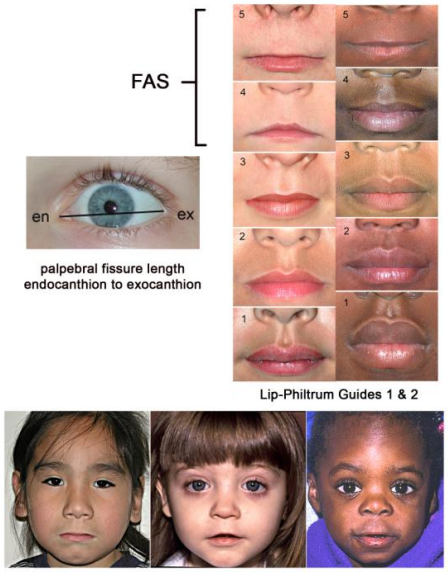

Figure 3: FASD 4-Digit Code FAS facial phenotype. The Rank 4 FAS facial phenotype determined with the 4-Digit Diagnostic Code requires the presence of all 3 of the following anomalies: (1) palpebral fissure length 2 or more standard deviations below the norm; (2) smooth philtrum (Rank 4 or 5 on the Lip-Philtrum Guide), and (3) thin upper lip (Rank 4 or 5 on the Lip-Philtrum Guide). Examples of the Rank 4 FAS facial phenotype for Native American, Caucasian, and African American children are shown. Copyright: Susan Astley, University of Washington, Seattle, WA.

The FASD 4-Digit Diagnostic Code:

1. Greatly increased diagnostic precision and accuracy through the development of objective, quantitative measurement scales (e.g., Lip-Philtrum Guides), facial analysis software, and specific case definitions.
2. Diagnosed the full spectrum of outcomes across the lifespan.
3. Offered an intuitively logical numeric approach to reporting outcomes and exposure that reflects the true diversity and continuum of disability observed in individuals with prenatal alcohol exposure.
4. Established a method for case-defining the highly variable, nonspecific CNS dysfunction that typifies FASD, by quantifying the breadth and magnitude of dysfunction (number of domains of function 2 or more SDs below the mean) without unduly constraining which domains must be impaired.
5. Established diagnostic subclassifications that captured the full spectrum of FASD without inferring alcohol is the sole causal agent.
6. Documents all other prenatal and postnatal adverse exposures and events that can also impact outcome.
7. Provides a quantitative measurement and reporting system (the 4-Digit Code) that can be used independent of the diagnostic nomenclature.
8. Has received extensive assessment/validation of its performance.
9. Was designed for use by an interdisciplinary FASD diagnostic team.
10. Is readily taught to a wide array of health care and social service providers (e.g., FASD 4-Digit Code Online Course[46]), thus greatly expanding the availability of diagnostic services.

Figure 4: FASD 4-Digit Diagnostic Code Short Form. In lieu of the more comprehensive 7-page FASD Diagnostic Form, some clinics may prefer to use the **1-page FASD 4-Digit Short Form**. The Short Form allows a clinician to record the minimum amount of data required to derive/support the 4-Digit Code. Diagnostic teams who do not have the time/capacity to complete the more comprehensive form will find this electronic, interactive, Short Form helpful.

The 4-Digit Code has served as the cornerstone of a fully integrated and highly successful screening, diagnostic, intervention, prevention, and surveillance program in Washington State for the past 17 years [7,8,18,1,47-49]. A comprehensive profile of all patients receiving an interdisciplinary FASD diagnostic evaluation using the 4-Digit Code at the Washington State FAS Diagnostic and Prevention network (WA FAS DPN) clinic in the first 12 years of operation is presented in the Astley paper [50]. Hundreds of FASD diagnostic teams have been trained worldwide to use this interdisciplinary FASD diagnostic system [46].

CDC FAS Guidelines, July 2004 [36]

In 2004 the CDC published the following Executive Summary to introduce the CDC FAS guidelines (p. vii-ix, with permission) [36]:

"As part of the fiscal year 2002 appropriations funding legislation, the U.S. Congress mandated that the Centers for Disease Control and Prevention (CDC), acting through the National Center on Birth Defects and Developmental Disabilities (NCBDDD) Fetal Alcohol Syndrome (FAS) Prevention Team and in coordination with the National Task Force on Fetal Alcohol Syndrome and Fetal Alcohol Effect (NTFFAS/FAE), other federally funded FAS programs, and appropriate nongovernmental organizations, would:

Develop guidelines for the diagnosis of FAS and other negative birth outcomes resulting from prenatal exposure to alcohol,

Incorporate these guidelines into curricula for medical and allied health students and practitioners, and seek to have them fully recognized by professional organizations and accrediting boards, and

Disseminate curricula to and provide training for medical and allied health students and practitioners regarding these guidelines.

Through the coordinated efforts of CDC, the NTFFAS/FAE, and a scientific working group (SWG) of experts in FAS research, diagnosis, and treatment, the diagnostic criteria were developed over a 2-year period.

A primary goal of these guidelines is to provide standard diagnostic criteria for FAS so that consistency in the diagnosis can be established for clinicians, scientists, and service providers. The guidelines are based on state-of-the-art scientific research, clinical expertise, and family input regarding the physical and neuropsychological features of FAS. The SWG sought to harmonize these guidelines with other diagnostic systems currently in use in this country and others (e.g., Canada). The SWG strove to provide a balance between conservative and overly inclusive diagnostic systems. Differential diagnosis from other genetic, teratological, and behavioral disorders was emphasized.

These guidelines are not intended to be an endpoint in the discussion of diagnosing FAS. There is a great need to acquire science-based information that will facilitate diagnostic criteria for additional related disorders, such as Alcohol Related Neurodevelopmental Disorder (ARND). These guidelines conclude with a call for further research and continuous refinement of the diagnostic criteria for FAS and related conditions so that affected individuals and their families can receive important services that enable them to achieve healthy lives and reach their full potential."

Hoyme FASD Guidelines, January 2005 [19]

In 2005, Hoyme et al [19] published the following abstract (p. 39, with permission) to introduce their FASD guidelines:

"The adverse effects of alcohol on the developing human represent a spectrum of structural anomalies and behavioral and neurocognitive disabilities, most accurately termed fetal alcohol spectrum disorders (FASD). The first descriptions in the modern medical literature of a distinctly recognizable pattern of malformations associated with maternal alcohol abuse were reported in 1968 and 1973. Since that time, substantial progress has been made in developing specific criteria for defining and diagnosing this condition. Two sets of diagnostic criteria are now used most widely for evaluation of children with potential diagnoses in the FASD continuum, ie, the 1996 IOM [1] criteria and the Washington criteria. Although both approaches have improved the clinical delineation of FASD, both suffer from significant drawbacks in their practical application in pediatric practice. Objective. The purpose of this report is to present specific clarifications of the 1996 IOM criteria [1] for the diagnosis of FASD, to facilitate their practical application in clinical pediatric practice. A large cohort of children who were prenatally exposed to alcohol were identified, through active case-ascertainment methods, in 6 Native American communities in the United States and 1 community in the Western Cape Province of South Africa. The children and their families underwent standardized multidisciplinary evaluations, including a dysmorphology examination, developmental and neuropsychologic testing,

and a structured maternal interview, which gathered data about prenatal drinking practices and other demographic and family information. Data for these subjects were analyzed, and revisions and clarifications of the existing IOM FASD diagnostic categories were formulated on the basis of the results. The revised IOM method defined accurately and completely the spectrum of disabilities among the children in our study. On the basis of this experience, we propose specific diagnostic criteria for fetal alcohol syndrome and partial fetal alcohol syndrome. We also define alcohol-related birth defects and alcohol-related neurodevelopmental disorder from a practical standpoint. The 1996 IOM criteria [1] remain the most appropriate diagnostic approach for children prenatally exposed to alcohol. The proposed revisions presented here make these criteria applicable in clinical pediatric practice. "

Canadian FASD Guidelines, March 2005 [37]

In 2005 Chudley et al [37] published the following abstract (p. s1) to introduce the Canadian FASD guidelines:

"A subcommittee of the Public Health Agency of Canada's National Advisory Committee on Fetal Alcohol Spectrum Disorder reviewed, analyzed and integrated current approaches to diagnosis to reach agreement on a standard in Canada. The purpose of this paper is to review and clarify the use of current diagnostic systems and make recommendations on their application for diagnosis of FASD-related disabilities in people of all ages. The guidelines are based on widespread consultation of expert practitioners and partners in the field. The guidelines have been organized into 7 categories: screening and referral; the physical examination and differential diagnosis; the neurobehavioural assessment; and treatment and follow-up; maternal alcohol history in pregnancy; diagnostic criteria for fetal alcohol syndrome (FAS), partial FAS and alcohol-related neurodevelopmental disorder; and harmonization of Institute of Medicine and 4-Digit Diagnostic Code approaches. The diagnosis requires a comprehensive history and physical and neurobehavioural assessments; a multidisciplinary approach is necessary. These are the first Canadian guidelines for the diagnosis of FAS and its related disabilities, developed by broad-based consultation among experts in diagnosis."

Comparison of Current Guidelines

An interdisciplinary approach to FASD diagnosis using more rigorously case-defined guidelines, as originally proposed by the WA FAS DPN [14,32,35] was adopted in principal in all subsequent guidelines. Key contrasts do exist, however (Tables 1-4). Of the guidelines currently in use, the FASD 4-Digit Code[38] and Canadian FASD guidelines [37] are most similar. Both systems cover the full spectrum of diagnostic outcomes, use FAS facial criteria with confirmed high specificity to prenatal alcohol exposure, and adhere to strict criteria that use the standard medical/statistical definition of "abnormal" (2 or more SDs below the mean or its equivalent $\leq 2.5^{th}$ percentile) [51]. In contrast to the 4-Digit Code and Canadian guidelines, the CDC guidelines [36] address only FAS; have more relaxed facial criteria (with unknown specificity); and have more relaxed CNS criteria (using diagnostic cutoff values for "abnormal" of 1 SD below the mean or $\leq 10^{th}$ percentile). The Hoyme guidelines [19], while addressing the full spectrum of outcomes, diverge considerably from the 4-Digit Code, CDC, and Canadian guidelines, but are closely aligned with the IOM guidelines [1] from which they were derived. For the diagnosis of FAS, the Hoyme guidelines further relax the facial criteria requiring only 2 of the 3 diagnostic features be present while allowing the palpebral fissure length (PFL) to move further into the normal range ($\leq 10^{th}$ percentile). This results in facial criteria that are no longer specific to prenatal alcohol exposure [16]. The Hoyme guidelines for FAS also restrict the CNS criteria to structural abnormalities only; and relax the criterion for small head circumference from the medical definition of microcephaly ($\leq 2.5^{th}$ percentile) [52] to $\leq 10^{th}$ percentile. All 4 sets of guidelines require prenatal alcohol exposure to be documented, but allow a diagnosis of FAS to be rendered if prenatal alcohol exposure is unknown. The Hoyme guidelines, like the IOM guidelines, go further by requiring that the confirmed exposure be "excessive" (e.g., characterized by substantial regular intake or heavy episodic drinking). Features unique to each guideline are: 1) The 4-Digit Code does not use the term ARND and is the only guideline that measures all four features of FAS (growth, face, CNS, and alcohol exposure) on continuous scales; 2) The Canadian guidelines require severe CNS dysfunction be present for a diagnosis of FAS; and 3) The Hoyme guidelines use only physical features to define FAS.

Diagnostic Nomenclature

A number of terms have been established over the years to label the diagnostic subclassifications under the umbrella of FASD. These include FAS, PFAS ARND, Static Encephalopathy/Alcohol Exposed (SE/AE),

Neurodevelopmental Disorder/Alcohol Exposed (ND/AE), Alcohol Related Birth Defects (ARBD), and Fetal Alcohol Effects (FAE). Table 5 presents each term, the clinical features that delineate each term, and which guidelines use the terms.

Table 5: FASD diagnostic terms, the clinical features that define each term, and which FAS/D guidelines use each term.

FASD Diagnostic Terms	Clinical Features Present					Guidelines That Use the Term				
	Growth Deficiency	FAS Facial Phenotype	CNS Abnormality	Prenatal Alcohol Exposure	Other Congenital Defects	4-Digit[38]	CDC[a][36]	Canadian[37]	Hoyme[19]	IOM[1]
FAS	Yes	Yes	Yes	Yes or Unknown		■	■	■	■	■
PFAS	Yes or No	Yes (Full or Partial)	Yes or No[b]	Yes or Unknown[c]		■	-	■	■	■
ARND			Yes	Yes			-	■	■	■
SE/AE			Yes, Severe	Yes		■	-			
ND/AE			Yes, Moderate	Yes		■	-			
ARBD		Yes and No[d]		Yes	Yes		-		■	■
FAE[e]			Yes	Yes			-			

a. (-) CDC guidelines currently address only FAS.
b. The Hoyme and IOM guidelines allow PFAS to be diagnosed in the absence of CNS abnormality.
c. Only the Hoyme guidelines allow an unknown alcohol exposure for PFAS.
d. The Hoyme guidelines require the FAS facial phenotype be present for ARBD. The IOM guidelines do not.
e. Used in the Sokol & Clarren FASD guidelines [5]

Issues to Consider

The following issues are important to consider as one assesses the strengths/limitations of the current FAS/D diagnostic guidelines.

Why are the criteria used to define the FAS facial phenotype so important to the medical validity of a FAS diagnosis? When one makes a diagnosis of FAS, one is stating implicitly that the individual has a syndrome caused by prenatal alcohol exposure[16]. One is also stating implicitly that the biological mother drank alcohol during pregnancy and, as a result, harmed her child. These are bold conclusions to draw and are not without medical and ethical consequences. How confident can one be when one infers a causal link between an individual's prenatal alcohol exposure and his or her syndromic features, especially when 2 of the 3 diagnostic features of this syndrome (growth deficiency and CNS damage/dysfunction) are not specific to (caused only by) prenatal alcohol exposure. The validity of the diagnosis rests solely on the specificity of the facial phenotype to the exposure (alcohol) and to the outcome (FAS). If a cluster of facial features is truly unique to prenatal alcohol exposure (e.g., alcohol is the only agent that can cause this facial phenotype) and is unique to the diagnosis of FAS (e.g., this exact phenotype is not present in any other medical condition), then one would expect to observe the following: (1) the face would be highly sensitive to FAS (e.g., individuals with FAS would have the FAS facial phenotype), (2) the face would be highly specific to FAS (e.g., individuals without FAS would not have the FAS facial phenotype), and (3) the face would be highly specific to prenatal alcohol exposure (e.g., individuals without prenatal alcohol exposure would not have the FAS facial phenotype). The rank 4 FAS facial phenotype, as defined by the 4-Digit Code, demonstrates all three of these qualities [7,9,16,20,39].

A highly specific FAS facial phenotype validates the FAS diagnosis, because the presence of the face confirms that an individual was affected, at least in part, by their prenatal alcohol exposure. The face also confirms the individual was exposed to alcohol. The latter is used to render a diagnosis of FAS in the absence of confirmed prenatal alcohol exposure. If the face is truly specific to alcohol, then individuals cannot have the face if they were not exposed to alcohol. This is why all diagnostic guidelines allow FAS to be diagnosed, even when prenatal alcohol exposure is

unknown. When the face is confirmed to be highly specific to alcohol exposure, it can serve as a valid proxy measure for exposure. This is also why diagnostic guidelines cannot and do not allow ARND (or its equivalent) to be diagnosed when alcohol exposure is unknown. Since the FAS facial phenotype is not present in ARND, it cannot serve as a proxy measure for alcohol exposure. In the absence of a highly specific facial phenotype, the validity of the diagnostic process breaks down precipitously; an individual's outcome cannot be linked to their prenatal alcohol exposure, FAS becomes indistinguishable from ARND, and valid diagnoses cannot be made when alcohol exposure is unknown.

Considering the quintessential role the FAS facial phenotype plays in FAS diagnosis, its specificity cannot be assumed, it must be confirmed through properly designed empirical studies. The FAS facial criteria (Rank 4) used by the 4-Digit Code and Canadian Guidelines have confirmed, high sensitivity and specificity (> 95%) [39]. The CDC and Hoyme guidelines have not reported the sensitivity and specificity of their relaxed facial criteria. When the Hoyme criteria were applied to a sample of normal to high functioning children with confirmed absence of prenatal alcohol exposure, 4 of the 16 met the Hoyme criteria for the full FAS facial phenotype [16]. This demonstrates the facial criteria have been relaxed too far.

Should an 'excessive' alcohol exposure be required for diagnoses under the umbrella of FASD? There remains no clear scientific consensus on what quantity, frequency, and duration of exposure is toxic to the fetus. There are a multitude of reasons for this. 1.) As our tools for measuring outcome become more sensitive, our ability to identify adverse outcomes at lower exposures increases [53]. 2.) Risk from alcohol exposure varies between fetuses, even between fraternal twins with ostensibly identical exposure [54, 55]. It is not uncommon for one fraternal twin to have full FAS, while the other appears unaffected. Identical twins are typically identically affected. 3.) From a public health perspective, requiring excessive exposure implies lower levels of exposure are 'safe'. Safe for whom? 4.) From a research perspective, artificially linking outcome to a threshold level of high exposure prevents assessing the true relationship between exposure and outcome. 5.) Finally, from a clinical perspective, if an "excessive" exposure is required, it would be difficult to rationalize why an individual with all the features of FAS would receive a diagnosis of FAS if their exposure was unknown, but would fail to receive a diagnosis of FAS if their exposure was confirmed, but reportedly not excessive. This implies that practitioners have the ability to confirm the accuracy of exposure histories. They do not. "Excessive" alcohol exposures should not be required for FASD diagnoses.

FAE and ARND: The field continues to struggle with what to label the condition characterized by prenatal alcohol exposure and CNS abnormalities when the FAS facial phenotype is absent. The problem with the diagnostic terms used to date (Fetal Alcohol Effects (FAE) and Alcohol-Related Neurodevelopmental Disorder (ARND) is they imply that the patient's outcomes are *alcohol effects* or *alcohol-related* outcomes. They imply alcohol caused the patient's outcomes. But this presumption in an *individual* patient is medically invalid because CNS abnormalities are not specific to (caused only by) prenatal alcohol exposure. There are many other known or unknown risk factors that may be partly or even fully responsible for the patient's outcome. In the absence of the FAS facial phenotype, current medical technology has no ability to confirm or rule-out the etiologic role of alcohol in an *individual* patient.

The term FAE (or more accurately, possible FAE) was first introduced by Clarren and Smith in 1978 [4]. In 1995, Aase, Jones, and Clarren argued effectively that clinical use of the term FAE, with its implications of causation, should be abandoned [13]. In 1996, the IOM [1] acknowledged the concerns expressed by Aase and colleagues [13] and introduced ARND (and ARBD) to replace FAE. But ARND (and ARBD) presented with all the same limitations as FAE. In 1997, the 4-Digit Code introduced Static Encephalopathy/Alcohol Exposed (SE/AE)) and Neurobehavioral Disorder/Alcohol Exposed (NDAE) to replace ARND [35]. These new clinical classifications divided ARND into two subgroups; 1) individuals with severe dysfunction (CNS Rank 3) and 2) individuals with moderate dysfunction (CNS Rank 2). A recent MRI study confirmed SE/AE and ND/AE are distinct clinical subclassifications with clear evidence of CNS structural abnormality detectable by MRI volumetric analyses [9]. Importantly, the terms neither confirm nor rule-out the causal role of alcohol. In 2005, the Hoyme [19] and Canadian [37] guidelines also acknowledged the concern expressed by Aase and colleagues [13], but chose to continue the use of the term ARND. The Hoyme guidelines expressed the following reservations about the SE/AE and ND/AE terms introduced by the 4-Digit Code. They raised a number of important issues that warrant discussion.

"The Washington criteria place much emphasis on the encephalopathy and neurobehavioral disorder present among affected children. These 2 findings are not specifically defined and, as general terms, they are not unique to the prenatal effects of alcohol on fetal development. In addition, the family and genetic background of the child is not adequately integrated into the criteria. Because this highly structured system seems all-encompassing, there is the potential for over-diagnosis of alcohol-related disabilities; any child with a disability who has been exposed to

alcohol prenatally can be assigned a diagnostic classification easily, even if the cause of the disability is genetic" (p. 41) [19].

To clarify, the 4-Digit Code cannot over-diagnose "alcohol-related" disabilities because the only "alcohol-related" diagnoses the 4-Digit Code generates are FAS and Partial FAS. The potential to over-diagnosis alcohol-related disabilities occurs with the use of the term Alcohol-Related Neurodevelopmental Disorder. The 4-Digit Code is the only FASD guideline that does not use this term. The 4-Digit Code does assign a diagnostic classification to all individuals who present with a disability. The classification reflects their disability; their *outcome* per se (e.g., FAS, PFAS, Static Encephalopathy, Neurobehavioral Disorder, etc). For example, if the individual presented with moderate impairment in memory and executive function, their disability would be classified as Neurodevelopmental Disorder. All children with or without a disability also have their prenatal alcohol exposure status reported. Their exposure is reported separate from their disability using the following naming convention: "disability/exposure" (eg., FAS / Alcohol Exposed, FAS / Alcohol Exposure Unknown, Neurobehavioral Disorder/ Confirmed Absence of Alcohol Exposure; No Sentinel Physical Findings or CNS Abnormalities Detected/Alcohol Exposed, etc). This naming convention neither implies nor rules-out a causal association between the outcome and the exposure in an individual patient. Hoyme and colleagues are correct in stating that static encephalopathy and neurobehavioral disorder are not unique to the prenatal effects of alcohol on fetal development. The same holds true for the neurodevelopmental disorder referenced in ARND. This is why it is so important that the nomenclature not assert the outcomes are unique (related to) the alcohol exposure. The use of a nomenclature that reports outcome separate from exposure is perhaps one of the most important features and strengths of the 4-Digit Code that distinguishes it from all other FASD diagnostic guidelines.

The 4-Digit Code was developed under the premise that a diagnosis should be based on verifiable facts, not supposition. The diagnostic nomenclature used by the 4-Digit Code reflects this. Growth deficiency and CNS damage/dysfunction are not specific to (caused only by) prenatal alcohol exposure. When an individual presents with prenatal alcohol exposure and CNS damage/ dysfunction, but does not have the FAS facial phenotype, the damage/dysfunction may be entirely attributable to the prenatal alcohol exposure, partially attributable to the prenatal alcohol exposure, or unrelated to the prenatal alcohol exposure. It is important to remember that even when a diagnosis of full FAS is rendered, one cannot necessarily attribute ALL of the individual's disabilities to their alcohol exposure. To the extent that other adverse risk factors are present, they too can, and likely will, contribute to the overall constellation of outcomes.

Current medical technology has no ability to confirm or rule-out the etiologic role of alcohol in an *individual* patient. This does not prevent one from effectively moving forward. An accurate diagnosis and effective intervention can proceed without confirming alcohol caused the person's disability. Access to services should be based on a person's disability, not on what caused their disability. Prevention can also proceed without linking outcome to exposure in an individual patient. In fact, on an empirical level, valid identification of causal associations requires exposures and outcomes to be documented separately.

When an individual presents with CNS damage/dysfunction and prenatal alcohol exposure, the 4-Digit Code calls it what it is; Static Encephalopathy/Alcohol Exposed if the CNS damage/dysfunction is severe or Neurobehavioral Disorder/Alcohol Exposed if the CSN dysfunction is moderate. The medical definition of static encephalopathy is *"any significant abnormal condition of the structure or function of brain tissue that is neither progressing nor regressing*" [56]. Including the phrase "Alcohol Exposed" in the diagnostic name serves to alert clinical providers that the individual was exposed to a teratogen and therefore is at risk for underlying brain damage. Knowledge of this risk is important, because the presence of underlying brain damage should influence a clinician's approach to ongoing care and intervention.

Aase and colleagues [13] urged "*simple recording of the verifiable conclusions. . . . If prenatal alcohol exposure has taken place, but FAS cannot be substantiated, the exposure still should be indicated, and any nonspecific abnormalities or problems noted*." (p. 49) This is the approach taken by the 4-Digit Code. The clinical summary templates for SE/AE and ND/AE include the following statement: "The diagnosis of Static Encephalopathy/Alcohol Exposed (or Neurobehavioral Disorder/Alcohol Exposed) does not mean that alcohol is the cause of the problem. A number of other factors could be contributing to the present issues, such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth" [14, 38]. The 4-Digit Code also devotes a chapter and 4-Digit ranking system to documentation of other prenatal (including genetic) and postnatal exposures and events that frequently occur with prenatal alcohol exposure and likely contribute to the outcomes observed for individuals [38]. In fact, the vast majority of the 1,400 patients with prenatal alcohol exposure

diagnosed in the WA FAS DPN between 1993-2005 presented with multiple risk factors (93% were exposed to tobacco or illicit drugs in utero, 31% had no prenatal care, 36% had confirmed physical and/or sexual abuse, and 70% were in foster/ adoptive care) [50]. The impact of prenatal alcohol exposure is rarely if ever assessed in isolation from other risk factors.

The Hoyme guidelines [19] state, "FASD must always be a diagnosis of exclusion. Many genetic and malformation syndromes have some of the other clinical characteristics of FAS. If there is no indication of another genetic or malformation syndrome, then the revised IOM criteria can be applied to categorize a diagnosis within the FASD continuum" (quotes from pp. 45-46). Overlap between individual symptoms/anomalies is common throughout medicine. An astute clinician would not mistake FAS for William's syndrome simply because the two have some, but not all features in common. It is the constellation of features that distinguish the two syndromes. FAS is not a diagnosis of exclusion. Alcohol is a teratogen to all developing fetuses, including those with other genetic disorders or syndromes. It is worth noting that one child diagnosed with FAS in the WA FAS DPN also had Down syndrome. The child presented with growth deficiency below the 2nd percentile on a growth chart for children with Down syndrome. The child presented with the facial features of Down syndrome and FAS. The facial features of Down syndrome are distinct from the facial features of FAS. The two phenotypes were readily apparent and easily distinguished. The child presented with microcephaly (3 SDs below the mean for children with normal development, 1 SD below the mean for children with Down syndrome). The child presented with Bayley[57] Motor and Mental Index scores below 50; a level of developmental delay that can be observed in both Down syndrome and FAS. The birth mother was reported to have consumed alcohol daily throughout pregnancy. A FASD diagnostic team should consider alternative or co-occurring syndromic diagnoses and medical conditions at all times. The prevalence of other syndromes among 1,400 patients with prenatal alcohol exposure receiving a FASD diagnostic evaluation in a WA FAS DPN clinic is 1.8% [50]

Hoyme and colleagues [19] expressed concern that SE/AE and ND/AE are not specifically defined. The growth, face, CNS, and alcohol criteria are specifically defined for SE/AE and ND/AE (Table 3). The CNS functional criteria specify which functional domains may be impaired, how many must be impaired, and how severely (in SDs) each must be impaired. Most of the current guidelines (4-Digit Code [38], CDC [36], and Canadian [37] now provide this enhanced level of detail when defining the CNS functional criteria for their FAS, PFAS and ARND classifications.

ARBD: The term Alcohol-Related Birth Defects (ARBD) was introduced by the IOM [1] with the caveat that "*virtually every malformation has been described in some patient with FAS. The etiologic specificity of most of the anomalies to alcohol teratogenesis remains uncertain*". This statement remains true today. For this reason, the 4-Digit Code[38] and Canadian [37] Guidelines do not include ARBD as a diagnostic classification. The 4-Digit Code and Canadian guidelines require the reporting of all birth defects; they simply do not support labeling them as ARBD. The Hoyme [19] guidelines do include ARBD as a diagnostic classification, but require the FAS facial phenotype to be present. Inclusion of the FAS facial phenotype may help increase the chance that the birth defect may be related to the alcohol exposure, but only if the etiologic specificity of the guideline's FAS facial criteria is confirmed to be high.

Are Lip-Philtrum Guides Needed for each Race? All guidelines published subsequent to the 4-Digit Code have adopted the use of the University of Washington Lip-Philtrum Guides for measuring philtrum smoothness and upper lip thinness (Fig. 3). There are currently two Lip-Philtrum Guides; one normalized to Caucasians and one normalized to African Americans (Fig. 3). The Guides are purposely labeled Guide 1 and Guide 2, respectively, for they were created for use on more than just Caucasian and African American individuals. Guide 1 is intended for use on all races (or racial combinations) that indigenously have lips similar in thickness to Caucasians. Guide 2 is intended for use on all races (or racial combinations) that indigenously have lips similar in thickness to African Americans. The Guide that best matches the indigenous phenotype of the patient's race(s) should be used. It is essential that the patient's medical record document which Guide was used for their diagnostic evaluation.

While it may seem obligatory to create a Lip-Philtrum Guide for every race, there are two fundamental reasons why this is neither feasible nor clinically necessary. First, racial categories are more a social-political construct than scientific or anthropological classifications. Racial categories are not sufficiently case-defined to classify individuals accurately into discrete groups and a large portion of the population is multiracial. Finally, race rarely translates into one homogeneous phenotype. For example, there is tremendous phenotypic variability between American Indian tribes, thus creation of an "American Indian" Lip-Philtrum Guide would be clinically invalid. Second, the magnitude of difference that would differentiate lips of the same rank across more than two "racially-normed" guides would become imperceptibly small. The magnitude of difference would become clinically irrelevant and below the level of

accurate detection. To demonstrate this, look at how little difference there is between the Rank 5 lips on Guides 1 and 2 (Fig. 3). Now imagine the Rank 5 lip on a Lip-Philtrum Guide for a race that falls between Guides 1 and 2.

Can an accurate diagnosis be rendered at any age? The answer depends on the diagnosis and the guidelines. If a diagnostic classification requires standardized psychometric evidence of *higher level* dysfunction across multiple domains like language, memory, executive function, and/or cognition, then a patient must be old enough to engage in this higher level assessment (generally > 7 years old) to confirm or rule-out dysfunction. This is not to say a diagnostic evaluation should be postponed until after age 7. There is tremendous benefit to early diagnosis and intervention [17,48,58]. The 4-Digit Code explicitly states that a diagnosis rendered at an early age could change (upgrade to a more severe classification) as the child ages and higher level cognitive impairments emerge. As an example, if a 10 year old child presented with the following features (growth deficiency, the FAS facial phenotype, a normal head size, severe dysfunction in memory, executive function, and attention, and prenatal alcohol exposure), she would receive a diagnosis of FAS (4-Digit Code 4434). If she had received a diagnostic evaluation at 1 year of age, her severe functional impairments would not yet be apparent. They may only manifest as moderate developmental delays on a Bayley Scales of Infant Development [57], resulting in a 4-Digit Code of 4424 (sentinel physical findings, neurobehavioral disorder, alcohol exposed). Her true diagnosis would be FAS, but at 1 year of age, she would not be old enough to reveal the true magnitude of her CNS dysfunction. She benefits nonetheless from her early diagnosis in two ways: 1) she receives early intervention, and 2) her high risk status is documented in her medical record with recommendations to monitor her closely over time. If and when she presents with more severe CNS dysfunction, she would receive a FASD diagnostic re-evaluation to upgrade her diagnostic classification appropriately.

Can an accurate diagnosis be rendered in an adult? Yes. Adults often present with more complex life histories and competing risks (traumatic head injury, their own alcohol and drug abuse, and mental health problems). Confirmation of exposure can also be more challenging. But the same diagnostic criteria and interdisciplinary approach are utilized. The interdisciplinary team will need expertise in adult psychological assessment and knowledge of community services available to adults. While adults will not have benefited from early intervention, an accurate diagnosis will lead to a better understanding of their disability and improved access to disability assistance and services.

Before leaving this topic, one additional question regarding age and diagnosis is often asked: **Does the face of FAS change with age?** Literature from the 80's and 90's [59-61] would lead one to believe that infants and adults are less likely to present with the full FAS facial phenotype than school-aged children. But the data were largely anecdotal and focused on facial features that are no longer regarded as diagnostic of the FAS facial phenotype [20]. Data from 1,400 patients evaluated for FASD in the WA FAS DPN document just the opposite. The proportion of subjects who presented with the full FAS facial phenotype (Rank 4) by age group was as follows: birth to 3.9 yrs (14%), 4 to 16.9 years (7.7%), and 17 to 53 years (9.5%). The age group with the highest prevalence of the FAS facial phenotype was infants under one year of age (23%) [50]. It is certainly possible for the facial features to change with age. Although, in our experience, when change occurs it has always been quite subtle. In the event that facial features do change over time, most diagnostic guidelines address this by stating that the features may be present at *any* age. For example, if an adult presents with some, but not all of the FAS facial features, but childhood photos document the full FAS facial phenotype, then the adult would meet the full FAS facial criteria based on their childhood photos.

Overall, diagnostic evaluations for FASD can be conducted across the lifespan (newborn to adult). The diagnostic criteria do not change with age. The most accurate diagnosis can be rendered in childhood when the child is old enough to engage in all levels of assessment, but a diagnostic evaluation should not be postponed for this reason. Infants may require re-assessment. Adults present with unique challenges, but benefit nonetheless.

Validation of FASD Guidelines. It is imperative that the performance (reliability, accuracy, specificity, and validity) of diagnostic guidelines be confirmed through properly designed empirical studies [1]. A number of empirical studies have been published confirming the performance of the measurement tools, case-definitions, and diagnostic subclassifications used by the 4-Digit Code [7,9,10,14,16,20,21,39,50,62]. A recently completed MRI/fMRI/MRS study of children with FASD identified significant differences in neuropsychological outcomes [10], neurostructural outcomes [9], neuroactivation levels [21], and neurometabolite levels [63] between the FAS/PFAS, SE/AE and ND/AE clinical subgroups. Significant correlations were observed between size of brain regions and level of prenatal alcohol exposure, magnitude of FAS facial phenotype, and level of CNS dysfunction (Fig. 5). These findings confirm the 4-Digit Code produces three clinically distinct and increasingly more affected diagnostic subclassifications (FAS/PFAS, SE/AE, and ND/AE) under the umbrella of FASD.

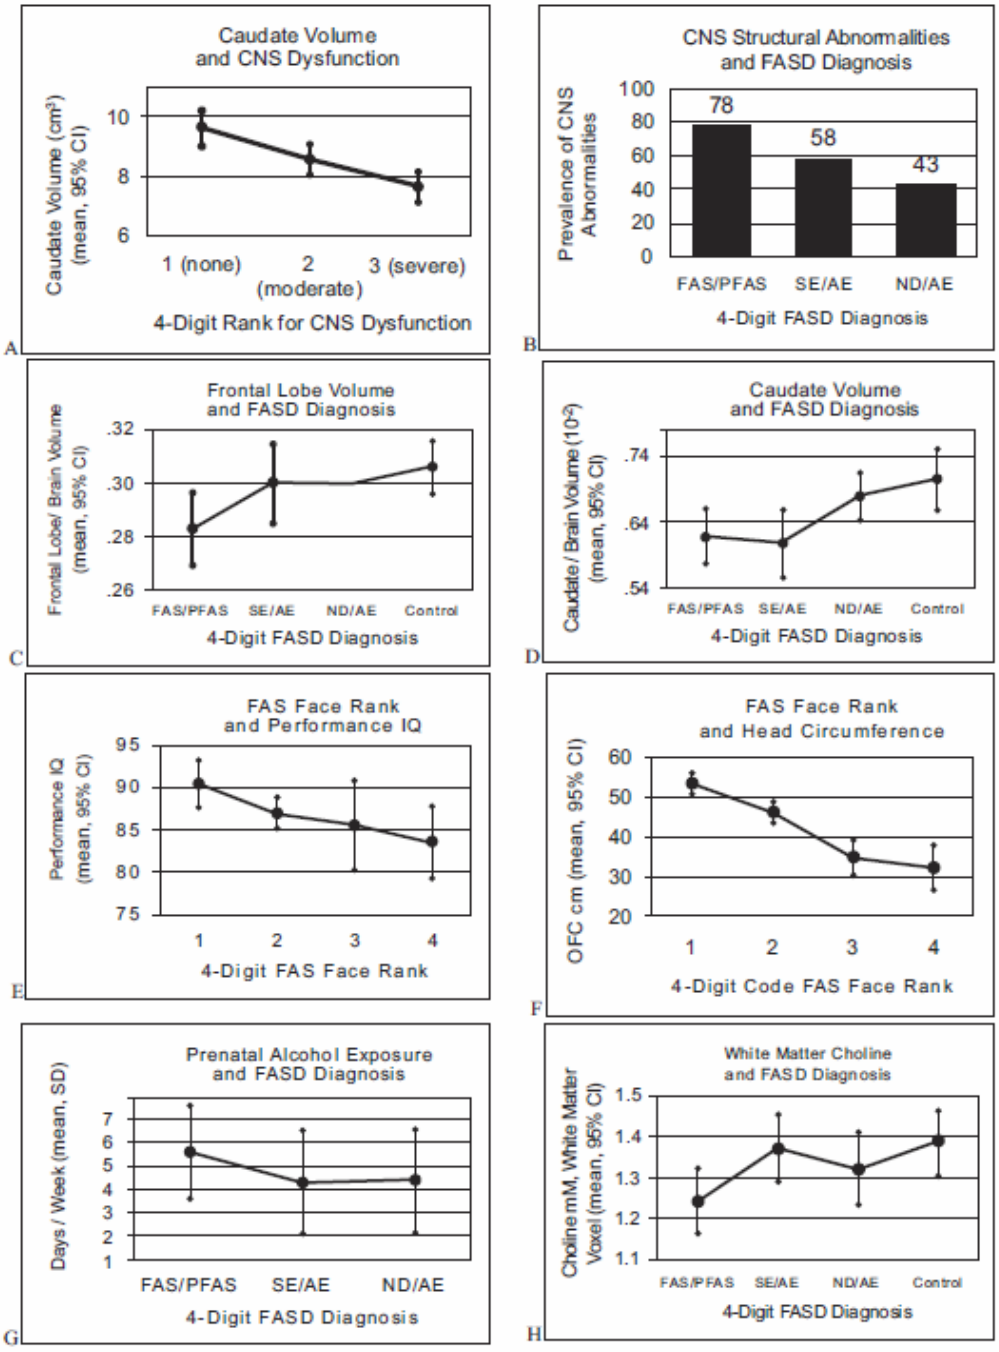

Figure 5: Examples of some of the many significant, empirical findings that serve to validate the performance of the FASD 4-Digit Diagnostic Code [9.10.50.63].

Patient Examples that Exemplify Key Contrasts between the Guidelines.

One practical method to assess the performance of the guidelines is to compare/contrast how they classify cases across the spectrum. Below are four hypothetical patient examples and the diagnostic classifications each would receive from the five most current FAS/D diagnostic guidelines [IOM [1], 4-Digit Code[38], Canadian[37], CDC[36], and Hoyme[19]]. These examples were selected to exemplify key contrasts between the guidelines. There are certainly many other examples that would result in identical diagnostic classifications across all five guidelines.

PATIENT EXAMPLE 1 (10 years old):

Growth: Hgt 10th percentile, wgt 95th percentile
Face: PFL 10th percentile;
Somewhat smooth philtrum, Rank 4;
Thick upper lip, Rank 1
CNS: OFC 10th percentile, FSIQ 120, No evidence of dysfunction.
Alcohol: Unknown

Diagnostic Classifications:

IOM: Unable to definitively classify. The IOM criteria are not sufficiently case-defined.
4-Digit Code: No sentinel physical findings or CNS abnormalities detected / Alcohol Unknown (4-Digit Code = 2212), Not FASD
Canadian: Not FASD
CDC: Not FAS
Hoyme: FAS / Alcohol Unknown

PATIENT EXAMPLE 2 (10 years old)

Growth: Hgt 2nd percentile, wgt 2nd percentile
Face: Small PFL, 2nd percentile,
Smooth philtrum, Rank 5,
Thin upper lip, Rank 5
CNS: OFC 30th percentile, No CNS structural/neurological abnormalities, FSIQ 50 (1st percentile). Severe dysfunction across all domains.
Alcohol: Intoxicated weekly throughout pregnancy

Diagnostic Classifications

IOM: Partial FAS? (This diagnostic classification is in question because the IOM growth deficiency criteria are not strictly met)
4-Digit Code: FAS/Alcohol Exposed (Code = 4434)
Canadian: FAS/Alcohol Exposed
CDC: FAS/Alcohol Exposed
Hoyme: Partial FAS/Alcohol Exposed

PATIENT EXAMPLE 3 (10 years old)

Growth: Hgt 50th percentile, wgt 50th percentile
Face: Normal PFL 50th percentile,
Normal philtrum Rank 2,
Normal upper lip Rank 2
CNS: OFC 50th percentile, No CNS structural/neurological abnormalities. ADHD, Significant memory impairment, All other domains of function within normal range.
Alcohol: One glass of wine nightly throughout pregnancy. No reports of binge drinking, intoxication, or problems with alcohol use.

Diagnostic Classifications:

IOM: Not FASD
4-Digit Code: Neurobehavioral Disorder / Alcohol Exposed (Code = 1123)
Canadian: Not FASD
CDC: Not FAS.
Hoyme: Not FASD

PATIENT EXAMPLE 4: (2 years old)

Growth: Hgt 1st percentile, wgt 1st percentile
Face: Small PFL 1st percentile,
Smooth philtrum, Rank 5,
Thin upper lip, Rank 5
CNS: OFC 1st percentile, Bayley Scales of Infant Development outcomes within low-normal range.
Alcohol: Intoxicated weekly throughout pregnancy

Diagnostic Classifications:
IOM: Partial FAS? (This diagnosis is in question because the IOM growth deficiency criteria are not strictly met)
4-Digit Code: FAS/Alcohol Exposed (Code = 4444)
Canadian: Not FASD
CDC: FAS/Alcohol Exposed
Hoyme: FAS/Alcohol Exposed

FUTURE DIRECTIONS

Without doubt, the one emerging arena that will have the greatest impact on the future of FASD diagnosis is brain imaging. All diagnostic guidelines include "evidence of abnormal brain structure (e.g., abnormal MRI, microcephaly)" as a key diagnostic criteria for FAS, PFAS, and ARND (or its equivalent). Detection of abnormal structure currently relies on radiologist review (visual inspection) of brain images. But MRI technology can now produce accurate measures of size/shape/and tissue composition of brain regions that provide far more sensitive measures of structural abnormality [9, 64-66]. For example, in a recently completed FASD MRI study, none of the 23 children with ND/AE were identified as having an abnormal MRI by radiologist review, yet 43% of the subjects had one or more brain regions, two or more standard deviations below the mean size observed in the healthy Control group using MRI volumetric analysis [9]. Does this mean 43% of these children now meet the diagnostic criteria for having an "abnormal MRI"? Not necessarily. Norms for the size of brain regions, by gender and age, must be established using large, representative, population-based samples, rather than small, convenient research control samples. The National Institutes of Health MRI Study of Normal Brain Development [67, 68] is a landmark study that is documenting structural brain development and behavior longitudinally from birth to young adulthood in a large population-based sample of healthy children targeted to the United States 2000 census distribution. Thus, we will soon have "normal growth charts" for the size of brain regions, much like we have normal growth charts for height, weight, and head circumference. If microcephaly meets the FASD criteria for a structural brain abnormality, should a significantly small frontal lobe or caudate volume meet the criteria? The answer will likely depend, in part, on how size correlates with function. Decreasing head circumference is correlated with increasing severity of dysfunction [9, 69]. A rapidly growing literature documents similar correlations exist between regional brain volumes and function [9, 65,70] (Fig. 5A). If brain imaging technology is adopted into the FASD diagnostic evaluation process, the prevalence of FAS/D will increase, simply by virtue of increased sensitivity to detect structural brain abnormality.

SUMMARY REMARKS

1. An FASD diagnostic evaluation is most accurately conducted by an interdisciplinary team.

2. The field should strive to adopt a single set of diagnostic guidelines for FASD.

3. Guidelines should undergo rigorous assessment of their accuracy, reliability, specificity, and validity to confirm their high performance, preferably before their release.

4. Use of the terms ARND and ARBD, like FAE, should be discontinued. They should be replaced by terminology that does not imply or rule-out a causal association between outcome and exposure in an individual patient.

5. Exposure and outcome should be assessed and reported separately.

6. The FAS facial phenotype must by highly specific to prenatal alcohol exposure and FAS to render a valid diagnosis of FAS, especially in the absence of a confirmed prenatal alcohol exposure. Specificity must be confirmed through properly designed empirical studies.

7. Diagnostic criteria should not require 'excessive' levels of alcohol exposure because a safe level of exposure has not been confirmed for all individuals and the accuracy of an exposure history can never be verified.

8. The report summarizing the outcome of an FASD diagnostic evaluation should report the FASD diagnostic classification, which diagnostic guidelines were used, all data required to confirm the diagnostic criteria were met and all recommendations documented.

9. Access to intervention services should be based on a patient's disability, not on what caused their disability.

CONCLUSIONS

Accurate, reliable, diagnoses across the full continuum of FASD have been available to families and clinicians for over a decade. As medical technology and our understanding of FASD advance, so must our diagnostic methods and tools. It is imperative that advancements in diagnostic methods be guided by an evidence base of rigorously designed, implemented, and peer-reviewed research. When a diagnosis under the umbrella of FASD is made, two individuals are affected directly; the child and the birth mother. The consequences of an incorrect diagnosis for both mother and child must be considered carefully. Diagnostic guidelines should guide professionals in rendering an accurate medical diagnosis. A diagnosis reflects the condition of a patient; however, because a diagnosis serves many purposes (eg, treatment, prevention, communication among specialists, and qualification for services), the process of rendering a diagnosis can sometimes be influenced by those different purposes. The only diagnosis that serves all purposes most effectively is a correct diagnosis. Access to services should be based on an individual's disabilities and not on what caused their disabilities. Therefore, services should be available for individuals across the full continuum of FASD and not just those with FAS.

Another perspective on 'The effect of different alcohol drinking patterns in early to mid pregnancy on the child's intelligence, attention, and executive function'

Sir,

It has been suggested in a series of papers published on 20 June 2012 in *BJOG*[1–5] that low and moderate weekly alcohol consumption in early pregnancy is not associated with adverse neuropsychological effects in children aged 5 years. The authors of the papers state that it remains the most conservative advice for women to abstain from alcohol during pregnancy; however, small amounts may not present a serious concern.

The researchers studied 870 preschool children whose mothers reported drinking during pregnancy and compared them with 758 preschool children whose mothers reported not drinking during pregnancy. They measured the children's IQ and attention levels at the age of 5 years. Children exposed prenatally to 1–8 drinks per week had the same IQ and attention levels as children with no exposure to alcohol.

We contend that the reason the children in this study did not appear to be harmed by the alcohol is because the children were too young to measure the full impact alcohol may have had on their brains. At 5 years of age, the brain is still developing. A 5-year-old's brain is not developed sufficiently to perform complex tasks, such as remembering and following multiple instructions, writing a report, communicating abstract ideas effectively or exercising good judgment. Over 30 years of research on fetal alcohol syndrome (FAS) confirms that alcohol has its greatest impact on complex brain functions.[6] This is why children exposed to and damaged by prenatal alcohol exposure do deceptively well in their preschool years. The full impact of their alcohol exposure will not be evident until their adolescent years.

Please consider the following statistics based on 2600 children who received a diagnostic evaluation for FAS in the Washington State FAS Diagnostic & Prevention Network clinics over the past 18 years.

- One of every seven children diagnosed with FAS (the most severe outcome caused by prenatal alcohol exposure) had a reported exposure of 1–8 drinks per week. (The Danish studies did not conduct FAS diagnostic evaluations on the children.)
- One-half of the children with FAS had developmental scores in the normal range as preschoolers. However, all had severe brain dysfunction confirmed by the age of 10 years. (The Danish studies only assessed preschoolers.)
- Only 10% of the children with FAS had attention problems by the age of 5 years; 60% had attention problems by the age of 10 years. (The Danish studies only assessed attention at the age of 5 years.)
- Only 30% of the children with FAS had an IQ below normal. However, 100% had severe dysfunction in other areas, such as language, memory and activity level. (The Danish studies did not assess these areas.)

Although the science may be complicated and studies sometimes yield conflicting messages, the public health message is simple: to have the *healthiest baby possible*, women should not drink alcohol when trying to conceive and during pregnancy. When a pregnant woman drinks, her child is at risk. If she drinks heavily, her child is at higher risk. ■

Parenting Stress and Sensory Processing: Children With Fetal Alcohol Spectrum Disorders

Tracy Jirikowic, PhD, OTR/L; Heather Carmichael Olson, PhD; Susan Astley, PhD

key words: sensory processing, prenatal alcohol exposure, school-aged children

ABSTRACT

Sensory processing differences are reported in a high proportion of children with fetal alcohol spectrum disorders (FASD), but how these problems impact caregiver burden has not been investigated. Linear regression was used to examine the association between parenting stress and problems in sensory processing, along with other child and family characteristics, among 52 children aged 5 to 12 years with FASD. Participants also had clinically significant problem behaviors. Higher levels of child-related parenting stress were moderately correlated with more parent-reported sensory processing problems (r = *-.60). Regression findings revealed that parent-reported problems in children's behavior regulation, an aspect of executive function, and sensory processing deficits were the strongest predictors of child-related parenting stress, together accounting for 62% of variance. Children's sensory processing deficits and executive function impairments affect the parent–child system and should be central considerations when developing family-centered supports for children with FASD.*

Prenatal alcohol exposure can result in a continuum of neurodevelopmental disabilities known collectively as fetal alcohol spectrum disorders (FASD; Bertrand et al., 2004). Children with FASD demonstrate a range of neurobehavioral deficits often including sensory processing problems that can interfere with successful occupational performance and participation. Using validated caregiver report measures, high rates of sensory processing problems (80% to 88%) have been reported among clinical samples of children with FASD (Carr, Agnihotri, & Keightley, 2010; Franklin, Deitz, Jirikowic, & Astley, 2008; Jirikowic, Kartin, & Olson, 2008). Poor sensory processing has shown moderate associations with child characteristics including increased problem behaviors (Franklin et al., 2008) and poorer adaptive skills (Carr et al., 2010; Jirikowic et al., 2008) among school-aged children with FASD. However, the relationships between children's sensory processing difficulties and attitudes important to parenting success have not yet been examined in this clinical population, despite their importance for informing intervention.

It is well established that caregivers raising children with many types of neurodevelopmental disabilities report elevated levels of parenting stress (Estes et al., 2009; Hauser-Cram et al., 2001; Johnston et al., 2003; Webster, Majnemer, Platt, & Shevell, 2008). Over the long term, parenting stress may have

doi: 10.3928/15394492-20120203-01

deleterious effects on family relationships, maternal health and quality of life, and child behavioral outcomes in families raising children with developmental disabilities (Eisenhower, Baker, & Blacher, 2009; Hauser-Cram et al., 2001). Indeed, parenting stress is an overarching concern for caregivers raising children born prenatally exposed to alcohol and high rates of clinically elevated parenting stress have been found among caregivers raising school-aged children with FASD (Olson, Oti, Gelo, & Beck, 2009; Paley, O'Connor, Frankel, & Marquardt, 2006; Paley, O'Connor, Kogan, & Findlay, 2005).

In the effort to understand sources of parenting stress, common characteristics among children with developmental disabilities have been explored, such as intellectual level, magnitude of problem behaviors, and decrements in adaptive function. Important contributors differ across clinical populations. For example, among preschool children with autism spectrum disorders or developmental delays, the magnitude of child problem behaviors was the most significant predictor of parenting stress, whereas child intellectual level and adaptive function were not salient predictors (Estes et al., 2009). In contrast, lower child cognitive levels and poorer adaptive function were both associated with greater parenting stress among biologically vulnerable toddlers with varying developmental risk factors, including prenatal alcohol exposure, although problem behaviors were not considered (Secco et al., 2006).

Interestingly, sensory processing deficits have rarely been considered as a contributor to parenting stress in these populations. Yet, the behavioral sequelae that stem from sensory processing impairments (i.e., the need to avoid or seek sensation in ways that are different from children with typical development) may be stressful for parents. This is because associated behaviors can prolong or impede household routines, impact family participation in community activities or social events, and hinder the development of mutually positive and satisfying parent–child relationships (Dunn, 2007). To our knowledge only one study to date has systematically examined sensory processing and parenting stress. Epstein, Saltzman-Benaiah, O'Hare, Goll, and Tuck (2008) investigated the relationships between parenting stress and child characteristics in 39 children aged 5 to 12 years with Asperger syndrome. Findings revealed a significant, moderately high relationship between maternally reported sensory processing behaviors as measured by the Short Sensory Profile (SSP; Dunn, 1999) and higher levels of parenting stress (r = -.56; $p < .007$) on the Parenting Stress Index (PSI; Abidin, 1995) short form.

When challenging child characteristics co-occur with adverse parent and family factors, parenting stress can be compounded. Parent characteristics, family context, and life stress events have all been identified as important facets affecting the parent–child system (Abidin, 1995). Ecological factors that have been associated with parenting stress include the availability of parenting and social supports, income level and socioeconomic status, family structure, and maternal depression (Abidin, 1995; Guralnick, Hammond, Neville, & Connor, 2008; Johnston et al., 2003; Secco et al., 2006). The significance and relative contributions of each of these ecological factors vary widely among the populations studied. For families dealing with substance abuse issues, such as birth parents, these ecological risks may often be multiple and pervasive, which render factors such as family resources, social support, and overall life stress especially salient considerations for these families (Astley, Bailey, Talbot, & Clarren, 2000; Nair, Schuler, Black, Kettinger, & Harrington, 2003).

To date, two studies have examined the associations between parenting stress and maternal, family, and child factors among caregivers of children affected by prenatal alcohol exposure. Paley et al. (2005) used path analysis to explore the sources of stress among 42 high-risk mothers of preschool children with high levels of prenatal alcohol exposure. Child factors (e.g., externalizing behavior problems and intellectual level) and ecological factors (e.g., socioeconomic status, current maternal alcohol use, and available parent support resources) were analyzed. The model revealed that greater child externalizing behavior problems and fewer parent support resources best explained maternal stress above and beyond other child and family factors. Contributors to parenting stress were also examined among children with diagnoses across the fetal alcohol spectrum among a sample of 100 parent–child dyads (Paley et al., 2006). Greater child-related parenting stress, assessed using the PSI (Abidin, 1995), a standardized parenting stress questionnaire, was associated with parent reports of greater child externalizing and internalizing behavior problems, decreased adaptive function, and increased level of executive function impairment. Notably, child executive function impairment, measured by the overall General Executive Composite score on the Behavior Rating Inventory of Executive Function-Parent Form (BRIEF; Gioia, Isquith, Guy, & Kenworthy, 2000) was the strongest predictor of child-related parenting stress in this analysis.

Although it is clear that parents of children with FASD are highly stressed by characteristics of their children and face other psychosocial risks, this clinical population is not yet well understood and interventions are still in the early stages of development.

Given the high rates of sensory processing problems previously reported in this group of children with neurodevelopmental disabilities, this study aimed to determine whether poor sensory processing, in combination with other salient child and family characteristics, is a significant source of parenting stress among caregivers raising children with FASD.

Methods

Research Design

This was a descriptive study of 52 children, aged 5 to 12 years, with systematically diagnosed conditions falling under the umbrella term of FASD, all with clinical concerning behavior problems, who were enrolled in a two-group randomized control trial designed as an initial efficacy test of the Families Moving Forward (FMF) Program intervention model (see Bertrand & Interventions for Children With Fetal Alcohol Spectrum Disorders Research Consortium, 2009 [Study #5]; Olson et al., 2009). The FMF Program is a caregiver-focused behavioral consultation intervention that aimed to reduce challenging child behaviors and, ultimately, to enhance caregiving attitudes and parenting practices, meet family needs, promote caregiver self-care, and provide useful linkages to community services. The overall study was approved by the University of Washington Human Subjects Division. Data for the current descriptive study came from the baseline assessment, which took place prior to participant randomization or any intervention.

Participants

Children were recruited from the University of Washington Fetal Alcohol Syndrome Diagnostic and Prevention Network (FAS DPN) clinical database, which at the time of the study contained more than 1,500 patient records with patient consent and human subjects approval for research recruitment. Participants in the FAS DPN database represent a clinical population of individuals with confirmed prenatal alcohol exposure systematically diagnosed by an interdisciplinary team (Astley & Clarren, 2000; Clarren, Olson, Clarren, & Astley, 2000) using the FASD 4-Digit Diagnostic Code (Astley, 2004).

The 4-Digit Diagnostic Code has been demonstrated to be a sensitive and reliable method to diagnose fetal alcohol syndrome (FAS) and other conditions on the fetal alcohol spectrum (Astley, 2004, Astley et al., 2009a, 2009b). The four digits of the code reflect the magnitude of expression of the key diagnostic features of FASD: (1) growth deficiency; (2) characteristic facial phenotype; (3) central nervous system damage/dysfunction; and (4) maternal alcohol consumption during pregnancy. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with "1" reflecting complete absence of the FAS feature and "4" reflecting a strong "classic" presence of the FAS feature. The 4-Digit Codes that fall under the umbrella of FASD can be subclassified into one of four unique clinical diagnostic categories from more severe to less severe: (1) FAS, characterized by growth deficiency, facial anomalies, and severe central nervous system dysfunction, (2) partial FAS/alcohol-exposed (without growth deficiency), (3) static encephalopathy/alcohol-exposed (severe central nervous system dysfunction without the FAS facial features), and (4) neurobehavioral disorder/alcohol-exposed (mild to moderate central nervous system dysfunction without the FAS facial features) (Astley, 2004).

Procedures

Following enrollment and informed consent, all children received a comprehensive baseline neurodevelopmental assessment and primary caregivers were interviewed and asked to complete standardized questionnaires during a research laboratory visit. Caregiver interviews were conducted by trained psychometrists with an educational background in social or human services. Child assessments were completed by psychology graduate students with advanced training in child psychopathology and psychometric assessment. All testers were trained on the test administration and scoring via pilot testing, achieving acceptable interrater reliability at baseline and midway through the testing period. Testers were aware that the participants had a diagnosis on the fetal alcohol spectrum, but had no knowledge of prior or current test results. Testers were not involved in the intervention.

The child assessment profiled each child's neurodevelopmental function, including sensory processing, and evaluated child strengths, social skills, behavior problems, and cognitive/linguistic abilities including executive function. Caregiver needs and attitudes, including parenting stress, were assessed, as were parenting practices, family characteristics, child life experiences, and demographics. The assessments were typically done as one visit (4.5 hours) with several breaks and refreshment during the session. A few children, usually those who were younger, were seen for two sessions to minimize fatigue. Adaptive behavior data were gathered via a semi-structured interview during phone calls to the primary caregiver at a time convenient to the family following the baseline laboratory visit.

Instrumentation

PSI, Long Form (Abidin, 1995). This standardized questionnaire evaluates parenting stress for parents of

children from 1 month to 12 years of age. Scores in each domain at or above the 85th percentile suggest clinically elevated stress. The Child Domain (PSI Child) taps current child characteristics that may be major factors contributing to stress in the overall child–parent system. The Parent Domain (PSI Parent) taps current caregiver factors that may contribute to overall stress and dysfunction in the parent–child system. The Life Stress Domain provides an indicator of the amount of stress a caregiver has experienced during the past 12 months outside the parent–child system (e.g., divorce or changes in income). Internal consistency is reported for the Child Domain (α = .70 to.83) and Parent Domain (α = .70 to .84). Test–retest reliability coefficients across three different studies are reported for the Child Domain (r = .63 to .82) and Parent Domain (r =. 75 to .91). Construct and predictive validity are reported across child and parent populations.

SSP (Dunn, 1999). The SSP is a standardized parent questionnaire that examines sensory processing behaviors for children aged 3 through 10 years. The SSP measures the following domains of sensory processing: (1) Tactile Sensitivity; (2) Taste/Smell Sensitivity; (3) Movement Sensitivity; (4) Underresponsive/Seeks Sensation; (5) Auditory Filtering; (6) Low Energy/Weak; and (7) Visual/Auditory Sensitivity. A total score is generated from each domain and lower scores indicate that problem behaviors occur more frequently. Raw scores are also classified into categories of typical performance (scores > -1.0 standard deviation from the mean), probable difference (scores -1.0 to -2.0 below the mean), and definite difference (scores < -2.0 from the mean). The SSP has good internal reliability (α = .70 to .90). Behavioral outcomes on the SSP are consistent with physiological outcomes in children with and without sensory modulation disorders (i.e., children with lower scores on the SSP show abnormal electrodermal skin response to sensory stimuli), supporting the SSP construct validity (McIntosh, Miller, Shyu, & Hagerman, 1999).

BRIEF-Parent Form (Gioia et al., 2000). The BRIEF is a standardized caregiver report of executive functioning behaviors for children aged 5 to 18 years. The BRIEF has two indices, the Behavioral Regulation Index (BRIEF BRI) and the Metacognitive Index (BRIEF MCI), which combine to create the overall General Executive Composite score. The BRI and MCI were the variables of interest for this study, with higher T scores indicating more problematic behaviors. The BRIEF BRI and MCI have good test–retest reliability (r = .84; r = .88) and internal consistency (α = .96), respectively. The BRIEF has evidence of good convergent validity with other measures of inattention, learning, and impulsivity.

ASEBA Child Behavior Checklist (CBCL; Achenbach & Rescorla, 2000, 2001). Problem behaviors were measured using the age-appropriate version of the CBCL. These are standardized parent questionnaires used to assess behavioral/emotional problems that have occurred during the past 6 months. The Total Problem T score was the variable of interest for this study. Higher T scores reflect the presence of more problem behaviors. Test–retest reliabilities ranged from r = .82 to .94 and internal consistency reliabilities ranged from α = .82 to .97. For both age-level versions of the CBCL, evidence for content validity, criterion-related validity, and construct validity is provided.

Vineland Adaptive Behavior Scales, Interview Edition, Survey Form, First Edition (VABS; Sparrow, Balla, & Cicchetti, 1984). The VABS is a semi-structured interview that examines a caregiver's assessment of the child's adaptive function in four domains: (1) communication; (2) daily living skills; (3) socialization; and (4) motor skills (for children younger than 6 years). The Adaptive Behavior Composite (VABS ABC), the study variable of interest, is a standard score derived from the component domain standard scores. There is extensive data to support construct and concurrent validity, and the VABS ABC has excellent test–retest reliability (intraclass correlation coefficient = .99) and interrater reliability (intraclass correlation coefficient = .98).

Kaufman Brief Intelligence Test (KBIT; Kaufman & Kaufman, 1990). The KBIT provides an estimate of verbal and nonverbal intellectual status for individuals aged 4 to 90 years. Results yield three scores: Verbal IQ, Nonverbal IQ, and an overall composite IQ. The internal consistency reliability for the IQ composite for 4 to 19 year olds is α = .92. Test–retest reliability is r = .90. The Verbal IQ score was the variable of interest for this study because the composite IQ score could not be calculated for four children with significantly different scores between the verbal and nonverbal scales.

Data Analysis

Child and family characteristics were summarized using means, standard deviations, range of values, and proportions. The relationships between PSI outcomes and salient child and family characteristics were explored statistically prior to the regression analysis (e.g., chi-square for categorical variables and Pearson correlation coefficients for continuous variables). Child sociodemographic variables examined were age, gender, number of stressful life events, and diagnosis on the fetal alcohol spectrum. Child characteristics examined were sensory processing (SSP Total raw score), IQ (KBIT Verbal IQ standard

score), executive function (BRIEF MCI and BRIEF BRI T scores), problem behaviors (CBCL Total Problems T score), and adaptive function (VABS ABC standard score). Family characteristics considered were caregiver marital status, caregiver type, gross annual income, and number of children in the home. Variables that were statistically significant were then entered as independent variables into a stepwise linear regression to examine their relationship with the PSI. The stepwise F to enter in the regression analysis was set at a *p* value of less than .05 and F to remove was set at a *p* value of less than .10. Data were analyzed using Statistical Package for Social Sciences Version 18.0 software (SPSS, Inc., Chicago, IL).

Results

Sociodemographic data are presented in Table 1. This was a diverse sample of school-aged children with FASD and their caregivers from the standpoint of variables such as child ethnicity, gender, and socioeconomic status. The proportion of children in the care of their biological parent(s) in the study sample was small (11.5%); however, the proportion of children in the care of their biological parent(s) is also small (30%) in the FAS DPN clinical population from which they were drawn (Astley, 2010). The sample was representative of the larger clinical population in terms of gender and white/non-white participants, but this sample included a higher percentage (48%) of adoptive parents and caregivers reporting higher gross annual income levels.

Descriptive statistics for measures of parenting stress and child characteristics are presented in Table 2. A striking 92% of parents reported clinically elevated levels of stress (raw scores > 85th percentile) on the PSI Child Domain, compared to only 21% and 8% of the sample reporting clinically elevated stress on the Parent Domain and Life Stress Domain, respectively. Because most parents did not demonstrate clinically elevated levels of stress in the Parent Domain or Life Stress Domain, the regression analysis focused only on child-related parenting stress using the PSI Child as the dependent variable.

Regarding child characteristics, this sample of children with FASD displayed estimated intellectual level in the average range, coupled with well-below average adaptive function. A high proportion of the children had sensory processing difficulties. On the SSP, 83% of the children were categorized with "definite differences," 12% had "probable differences," and only 5% had typical performance. The children also showed high levels of clinically significant behavior problems and clinically concerning executive

function impairments in the domains of behavioral regulation and metacognition.

No significant correlations were found between the PSI Child Domain score and the child sociodemographic characteristics of age, gender, number of stressful life events, and diagnosis on the fetal alcohol spectrum or the family characteristics of caregiver marital status, caregiver type, gross annual income, and number of children in the home. Four measures of child neurobehavioral characteristics (BRIEF BRI, SSP, CBCL Total Problems, and VABS ABC) were significantly correlated with child-related parenting stress (PSI Child; see Table 3) and with each other. These four child neurobehavioral characteristics were entered into the regression equation as independent variables. Table 4 presents the regression analysis examining the relationship between these four child characteristics and the dependent variable of caregiver-reported parenting stress on the PSI Child Domain.

The overall model predicting child-related parenting stress was significant, at $F = 39.60$, $p < .001$. In this model, the BRIEF BRI and SSP Total score together explained 62% of variance in child-related parenting stress. The BRIEF BRI was the strongest predictor of parenting stress, whereas the SSP accounted for an additional R^2 change of .12.

Discussion

Child-related parenting stress occurred frequently and at high levels within the diverse group of caregivers raising children with FASD. To understand sources of stress in this clinical population, sensory processing behaviors were considered along with more commonly explored child and family characteristics associated with caregiving stress. Sensory processing differences together with the powerful variable of parent-reported problems in children's behavioral regulation (an aspect of executive function) were the strongest predictors of child-related stress in this sample of caregivers raising children with FASD. Assessment of differences in children's sensory processing captured variance beyond that explained by executive function impairments alone. Thus, for children with FASD with challenging behavior problems, difficulty modulating sensation, as perceived by their caregivers, had a significant and independent effect on daily parenting stress. This effect has important clinical implications because sensory processing knowledge can provide an additional and unique perspective to add to our understanding of parenting challenges reported by caregivers of children with FASD.

Consistent with previous findings among children with FASD (Paley et al., 2006), a strong association between child-related parenting stress and executive function impairment was seen. Results from the current study expand what is known about this common characteristic of children affected by prenatal alcohol exposure and its impact on caregivers (Kodituwakku, 2009; Vaurio, Riley & Mattson, 2008). The BRIEF BRI, assessing a child's inhibitory control and ability to shift cognitive set (e.g., make transitions, alternate

attention) and modulate emotions was clinically elevated and strongly and significantly correlated with parenting stress. In contrast, the BRIEF-MCI, which taps behaviors representing a child's ability to initiate, plan, and organize, and use working memory for problem-solving, was not significantly correlated with child-related parenting stress. Decrement in children's behavior regulation skills was the aspect of executive function that contributed most to child-related caregiver burden and stress.

Interestingly, measures of the children's level of adaptive function (VABS ABC) and behavior problems (CBCL Total Problems) did not explain additional variance in the regression model once executive function and sensory processing impairments were taken into account. This was most likely due to the strong intercorrelations between these four measures of child behavior (BRIEF-BRI, SSP, VABS-ABC, and CBCL Total Problems). It is also possible that with the moderate sample size of this study, the unique contributions of adaptive behavior and problem behavior to parenting stress were not detected in the model. Indeed, this sample of children demonstrated significant decrements in age-appropriate self-care, socialization, and communication skills and had clinically concerning problem behaviors. Previous studies of families raising children with prenatal alcohol exposure or FASD substantiate these adaptive skill and behavioral challenges (Jirikowic, Gelo, & Astley, 2010) and their relationship with more caregiver stress (Paley et al., 2005, 2006).

Conceptually, a neurodevelopmental viewpoint that interprets maladaptive behaviors as underlying "brain-based" difficulties offers insight into these strong interrelationships (Olson, Jirikowic, Kartin, & Astley, 2007; Olson & Montague, 2011). The relevant "brain-based" difficulties for children with FASD that stress parents appear to be challenges in both the child's sensory processing and executive function. Impairments in these neurodevelopmental domains may underlie many of the challenging, dysregulated behaviors that significantly compromise adaptive function in children with FASD and make parenting so difficult.

The pattern of caregiver stress reported in this study differs from earlier investigation of the sources of parenting stress among families raising children with FASD. The most significant issue for the current sample was child-related stress. This sample of relatively low-risk caregivers, even though a diverse group of birth, kinship, and foster and adoptive parents, did not on average report elevated levels of stress regarding the parenting role or overall life stress on the PSI. Demographics may explain why these findings differ from earlier studies of this issue. A high percentage of families in the current study were two-caregiver families, who were educated beyond high school graduation and reported low moderate to high income levels. Unlike the high-risk families examined earlier by Paley et al. (2006), where family resources were a significant predictor of stress in both parent and child domains, the environmental factors expected to be related to parenting stress (i.e., marital status, family type, and income) did not show significant associations. One exception was the number of children in the household, which was significantly associated with parenting role-related stress (-.30; $p < .05$). Thus, most families in the current study presumably had adequate family resources to meet basic needs and access social support.

Limitations

Although this study used a systematically diagnosed sample of children with FASD, the children in this sample were recruited for an intervention study

and selected because they presented with clinically concerning behavior problems. Thus, the sample may not be representative of all children affected by prenatal alcohol exposure and their caregivers. However, child problem behaviors are the primary reason families raising children with FASD seek clinical diagnosis and professional supports (Jirikowic et al., 2010), so this sample is likely to represent those who seek treatment and for whom treatment must be provided. Although caregivers of different types were represented in the study, which is common among this clinical population, a high proportion of caregivers in this study were adoptive parents. This limits the generalization of findings, particularly in regard to birth parents raising children with FASD. Further research is needed to understand the correlates of parenting stress among biological parents and whether types of stress differ by family structure, and these efforts are underway (Salmon, 2008).

Measurement limitations of the SSP are also noted, because 17% of participants in the study were 11 years of age, just outside the range of norms for the SSP (3 to 10 years). However, a post-hoc analysis did not find a significant relationship between age and SSP scores. Finally, the primary outcomes used in this regression analysis were based on parent questionnaires. Future research should validate parent report measures using performance-based child assessments, such as direct testing of executive function (e.g., classic executive function measures, ecologically valid assessments of executive dysfunction, and multi-tasking), and physiological reactivity to sensation. These methods may shed additional light on the strong interrelationships found between caregiver perceptions of sensory processing behaviors, the executive function of behavior regulation, and child problem behaviors.

Conclusion

Both the occupational therapy practice framework and standards for best practices for children with disabilities speak to the need for family-centered approaches and interventions that view the child within the context of the family and environment (American Occupational Therapy Association, 2008; Guralnick, 2001). Knowing the pivotal factors that place the parent–child system at risk in a specific clinical population can guide development of targeted family-centered interventions that support the co-occupation of parenting. For children with FASD, treatment approaches that educate parents about both their children's sensory needs and type of executive function impairment and use strategies for accommodating or remediating these impairments may be promising ways to empower parents with information and tools to help them solve day-to-day parenting challenges. Interventions that help parents raising children with FASD feel more efficacious, improve their cognitive appraisal of their children, and support positive parenting behaviors are being examined (Bertrand & Interventions for Children with Fetal Alcohol Spectrum Disorders Research Consotium, 2009; Olson et al., 2009) and warrant attention as a means to buffer child-related parenting stress and enhance child and family resiliency.

Acknowledgments

The authors thank the entire Families Moving Forward Program research team, without whom this study would not have been possible. Team members are listed in full at http://depts.washington.edu/fmffasd/team.php. This research was inspired and funded by the Centers on Disease Control and Prevention, Grant No. U01-12DD000038, awarded to Heather Carmichael Olson, PhD. The support of the Seattle Children's Research Institute and University of Washington School of Medicine, sites of research and manuscript preparation, and the University of Washington Center on Human Development and Disability, site of original participant recruitment, are also acknowledged with appreciation. Most importantly, the authors are deeply grateful to all of the families who participated. Their grace and courage are an inspiration to us all.

ABSTRACT

Background
Inefficient central processing and integration of visual, vestibular, and somatosensory information may contribute to poor balance and diminished postural control in children with fetal alcohol spectrum disorders (FASD).

Objectives
This pilot study examined sensorimotor performance and the sensory control of balance using a battery of clinical tests in combination with an experimental laboratory assessment that quantifies sensory subsystem use (i.e., sensory weighting) among a systematically diagnosed sample of children with FASD and children with typical development.

Methods
Using a case-control design, 10 children with FASD (8.0-15.9 years; 20% female) were compared to 10 age- and sex-matched controls on standardized clinical measures and on kinematic outcomes from the Multimodal Balance Entrainment Response system (MuMBER), a computerized laboratory assessment whereby visual, vestibular, and somatosensory input is manipulated at different frequencies during standing balance.

Results
Children with FASD showed poorer sensorimotor performance across clinical outcomes with significant group differences ($p < .05$) on parent-reported movement behaviors (Sensory Processing Measure and Movement Assessment Battery for Children-2 Checklist) and performance on the Dynamic Gait Index. Experimental kinematic outcomes yielded statistically significant group differences ($p < .10$) on a small proportion of somatosensory and vestibular sensory weighting fractions and postural sway velocity in response to the manipulation of sensory input.

Conclusions
Preliminary findings showed small group differences in sensorimotor and sensory weighting behaviors, specifically those that rely on the integration of vestibular sensation. Differences must be examined and replicated with a larger sample of children with FASD to understand the impact on balance control and functional sensorimotor behaviors.

Key Words: *Fetal alcohol spectrum disorder, prenatal alcohol exposure, postural control, balance, sensory weighting*

Alcohol is a well-established neurobehavioral teratogen. Prenatal alcohol exposure (PAE) can increase the risk for lifelong neurobehavioral problems, as well as developmental and

intellectual disabilities that fall under the umbrella term of fetal alcohol spectrum disorders (FASD). Balance deficits are a more frequent and persistent sensorimotor impairment reported among individuals with FASD.[1-5] Studies examining brain structures in association with PAE have identified cerebellar differences and deficits in cerebellar-dependent behaviors (e.g., gait, balance, and coordination) in both animal models[6,7] and in children.[8,9] Impairments on standardized clinical tests of balance and motor function have also been described among clinically affected children[1,2] and adults.[5] The nature of these balance deficits are not yet fully understood, and clinical assessment and intervention guidance remain limited.

Efficient balance and postural control provide the stability needed to support participation in many higher-level physical, play, and learning activities that promote function and healthy child development.[10,11] Children with impaired or inefficient balance and postural stability may have difficulty with simple tasks that rely on good postural control, such as sitting in a desk, maintaining attention, and learning and controlling complex movements. Poor balance and postural control may also underlie undesirable behaviors that may be misinterpreted as aggression or inattention and contribute to frustration, anxiety, and decreased self-esteem.[12,13,14] Accurately identifying and developing interventions for balance and postural control impairments has the potential to improve postural stability and adaptive motor function as a foundation for participation in childhood activities (e.g., playground activities, organized sports) that promote health and well-being (e.g., social interaction, self-esteem) among this high-risk and underserved clinical population.[15]

Postural control is a complex and dynamic perceptual-motor process that involves the integration of three sensory subsystems (visual, vestibular, and somatosensory), which cue the neuromuscular system to activate postural muscles in response to specific task or environmental conditions.[10,16] The inefficient use of, or adaptation to, sensory information has been explored as a potential mechanism for balance impairments in children with PAE; however, there has been limited replication or expansion of previous findings.[3,4] Roebuck et al[3] used computer posturography to evaluate postural sway while sensory information was manipulated both in accuracy and complexity during standing balance.

The children with PAE had significantly lower composite scores ($p < 0.01$) on the Sensory Organization Test than controls. Results indicated that the children with PAE had adequate postural stability when environmental conditions were stable (i.e., accurate visual and vestibular information), but had more postural sway when somatosensory information was inaccurate (i.e., they were less able to compensate with visual and vestibular information).

Roebuck et al[4] also examined whether the balance deficits among children with PAE were central or peripheral in nature. Twelve children with PAE were compared to 12 controls on postural and neuromuscular responses to movement perturbations using electromyographic (EMG) activity of the lower limbs. No significant group differences were found on short-latency and medium-latency EMG responses, suggesting intact peripheral responsiveness. However, the children with PAE demonstrated more delayed and variable long-latency responses, suggesting poor central processing of sensorimotor information during balance.

Taken together, these study results suggest that inefficient central processing and integration of visual, vestibular, and somatosensory information may play a role in balance and postural control impairments in children affected by PAE. While important, these findings do not precisely specify a child's ability to continually integrate the three sensory subsystems during balance, which is needed to adapt to changing environmental situations. For example, when standing on a moving surface (e.g., boat, escalator, bus) both the feet and the eyes may not give accurate orientation information, therefore, one needs to weight vestibular input to adequately maintain stability.

Recently, an experimental technique has been developed to examine how sensory subsystems integrate to permit successful stabilization for postural control.[16] This technique involves the manipulation of small, barely

perceptible oscillating sensory stimuli (visual field movement or tactile movement) provided at low frequencies in a standing position. The frequency and amplitude of an individual's body sway relative to a particular sensory stimulus frequency and amplitude are examined to determine how a person differentially weights each sensory subsystem for balance control (i.e., sensory weighting).[17,18]

Developmentally, children as young as 4 years have been shown to weight visual and tactile stimuli and shift their response between the two sensory stimuli when stimulus amplitude becomes too large.[19] This capacity to prioritize the reliance on a particular sensory input enhances postural stability in response to changing environmental conditions. In contrast, the inability to weight certain sensory inputs to activate the most efficient and effective postural motor adjustments has been implicated in individuals with postural control impairments and motor deficits.[20]

Sensory weighting between visual and tactile subsystems as a potential mechanism for balance and postural control impairments has not been examined in children with FASD. In addition, manipulations to discover vestibular weighting capabilities in both children with FASD and children with typical development (TD) have not been studied. A clearer understanding of balance impairments among children with FASD is needed in order to develop and evaluate the effects of sensory directed rehabilitation programs, especially in light of the potential for therapeutic motor training to ameliorate motor deficits described in alcohol-exposed animal models.[6,7]

This study had two primary objectives. The first objective was to describe clinical sensorimotor profiles, with an emphasis on the sensory control of balance, of a systematically diagnosed clinical sample of children with FASD compared to an age- and sex-matched control group of children with TD. The second objective was to examine visual, vestibular, and somatosensory weighting during standing balance between the two groups with an experimental laboratory test using kinematic outcome measures. We hypothesized that the children with FASD would show poorer performance on clinical sensorimotor outcomes compared to controls. On kinematic outcomes, we expected that compared to controls, children with FASD would demonstrate poorer postural control (higher velocity and greater area of postural body sway) and would show different sensory weighting fractions as compared to controls when the frequency of sensory input increased.

MATERIALS AND METHODS

This study was approved by the University of Washington Human Subjects Division Institutional Review Board. A sample of children with FASD was recruited from the University of Washington Fetal Alcohol Syndrome Diagnostic and Prevention Network (FAS DPN) clinical registry and database of over 2,500 patients. Participants in the database represent a clinical population of individuals with confirmed prenatal alcohol exposure systematically diagnosed by an interdisciplinary team[21] using the FASD 4-Digit Diagnostic Code.[22,23] The 4-Digit Diagnostic Code is a rigorously defined and extensively validated diagnostic system.[22,24,25] The four digits of the code reflect the magnitude of expression of the key diagnostic features of FASD: (a) growth deficiency, (b) facial features, (c) central nervous system (CNS) structural and/or functional abnormalities, and (d) maternal alcohol consumption during pregnancy. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale with 1 reflecting complete absence of the FAS feature and 4 reflecting a strong "classic" presence of the FAS feature. Each 4-Digit Diagnostic Code falls into unique clinical diagnostic categories, including the following that fall broadly under the designation of FASD: (a) fetal alcohol syndrome/alcohol-exposed (FAS/AE), (b) partial FAS/alcohol-exposed (PFAS/AE), (c) static encephalopathy/alcohol-exposed (SE/AE), and (d) neurobehavioral disorder/alcohol-exposed (ND/AE). See Astley[23] for a full explanation of the 4-Digit Diagnostic Code, diagnostic methods, and categories, and Astley[26] for a profile of the FAS DPN clinical population.

Participants

Ten children with FASD and 10 age- and sex-matched children with typical development (TD) participated in the study. Children in both groups were included in the study if they were ages 8-16 years, male or female, and of any race/ethnicity. Specific inclusion criteria for children with FASD were: confirmed prenatal alcohol exposure at any level, a diagnosis on the fetal alcohol spectrum of FAS, PFAS, SE/AE, or ND/AE, and a previously identified sensorimotor impairment based on clinical diagnostic assessment results. Exclusion criteria for the children with FASD included an IQ < 60 to assure children could adequately follow test directions. In addition, children with severe neuromotor conditions (e.g., cerebral palsy) that impaired ambulation or independent standing for less than 2 minutes, a history of serious head injury, seizures, a visual acuity impairment not corrected by glasses, or a lower limb or back injury within the previous six months were also excluded to control for severe neurological, visual, and orthopedic conditions. Children were recruited and enrolled in accordance with IRB guidelines established for the University of Washington FAS DPN.

Children with TD were recruited from a university research participant pool whose caregivers consented at the time of the child's birth to be contacted for university research studies, through flyers posted in the university community, and by word-of-mouth. Each child with TD was matched to a child in the FASD group by age (± 6 months) and sex. Children with TD were not eligible if, by parent report, they had a sensory or motor impairment, were enrolled in special education or occupational or physical therapy programs, reported any neurological illness/injury, seizure, genetic, metabolic, behavioral, cognitive disorders, or had a lower limb or back injury within the previous six months. Children in the comparison group were excluded from the study if during the enrollment screen caregivers reported prenatal alcohol exposure of ≥ 3 drinks (defined as ½ oz absolute alcohol = 12 oz beer = 5 oz wine= 1 oz of 100 proof spirit) prior to pregnancy recognition or during the pregnancy.

Procedures

Children were tested during a 2.5-hour laboratory visit. Assessments were administered in the same order by an occupational therapist or physical therapist trained in the assessment battery and who was masked to group status. Each parent completed three questionnaires.

Instrumentation

Measures to describe the participants were:

1. *Demographic Questionnaire:* Parent questionnaire to gather demographic, child health, and developmental information.
2. *Anthropometric Measures:* Child's height, weight, and foot size.
3. *Clinical Sensory Screen:*[27] Child's responses to light touch and light pressure on each foot and lower leg. A limb position test and limb movement test examined proprioception and kinesthesia. Responses were scored as pass or fail.
4. *Clinical Strength, Range of Motion, and Posture Screen:* Child's lower extremity range of motion and strength were examined, and standing posture for scoliosis, kyphosis, lordosis, leg length difference, and standing foot position were observed.
5. *Kaufman Brief Intelligence Test-2, Matrices Subtest (K-BIT-2):*[28] A measure of non-verbal intelligence for persons 4-90 years to estimate cognitive level. For children 4-18 years, good internal reliability (α = .86 - .92), test-retest reliability (r = .83 - 91), and construct validity have been reported. The Matrices Subtest standard score was the variable of interest with higher scores indicating better performance.

Standardized clinical measures of sensorimotor behaviors and adaptation during static and dynamic balance activities were:

1. *Movement Assessment Battery for Children-2nd edition (MABC-2):*[29] A measure of motor skills in children 3-16 years. Internal reliability (α = 0.90) and test-retest reliability for the total score are high (ICC = 0.97).[30] The Balance subtest scaled score is reported with higher scores indicating better performance.

2. *Sensory Processing Measure (SPM):*[31] A standardized parent questionnaire for children 5-12 years that examines child behavioral responses to touch, movement, visual, and auditory input. Internal reliability (α = .77-.95), inter-rater reliability (r > .94), and construct validity have been reported. Balance subsection and total score T scores are reported, with higher scores indicating more behaviors indicative of poor sensory processing.
3. *Pediatric Clinical Test of Sensory Interaction for Balance-2 (P-CTSIB-2):*[32] Static balance was assessed under six systematically altered sensory conditions. The conditions were: (1) eyes open standing on floor, (2) eyes closed standing on floor, (3) sway-referenced vision via wearing a dome with eyes open standing on floor, and (4-6) the three visual conditions repeated while standing on medium-density memory foam. Total ordinal score and vestibular (condition 5 + 6) sensory system scores are reported; higher scores indicate better performance. Test-retest reliability (ICC[2,1]=.67-.89), inter-rater reliability (ICC[2,1]=.49-.92), and validity are adequate.[33,34]
4. *Movement Assessment Battery for Children-2nd edition Checklist (MABC-2 Checklist):*[29] Parent questionnaire that examines child movement behaviors in everyday situations, including movement in static or predictable environments and in dynamic or unpredictable environments. Raw scores for each subtest are reported with lower scores indicating better performance.
5. *Dynamic Gait Index (DGI):*[35] Eight walking tasks test dynamic balance during vestibular challenges (e.g., walking 20' while turning head right and left, stepping over obstacles). Adequate test-retest reliability (ICC[2,1] = .71) and construct validity have been demonstrated in children.[36] The total raw score is reported with higher scores indicating better performance.

Laboratory measure of sensory weighting:

MultiModal Balance Entrainment Response (MuMBER) system: This computerized laboratory assessment system was developed based, in part, on the work of Jeka et al.[18] This experimental method measures sensory weighting across sensory subsystems by determining the fraction between body sway frequency and sensory stimulus frequency during standing balance under varying sensory conditions. The construct validity of the MuMBER system as sensitive measure of sensory system weighting has been demonstrated, as children with and without FASD showed changes in sensory weighting behaviors as sensory input was introduced and as sensory stimuli frequency was increased. Within session trial-to-trial reliability of sensory weighting is fair.

During the MuMBER protocol, participants stood on a piece of medium-density memory foam (5 cm thick) overlaid on a platform that tilts (vestibular stimulus), faced a visual screen that displayed a field of horizontally moving dots (visual stimulus), and rested the right index finger on a moveable touch pole (somatosensory stimulus) (Figure 1). The finger pressure on the touch pole was regulated to light touch indicated by a tone. If the child pressed too hard (>5N), the tone would stop and the examiner would assist the child to the correct touch pressure. A helmet (weighing 1.5 kg) restricted peripheral vision to the screen (approximately 110° horizontally and 45°vertically) and white noise was played through earphones during the trials to mask touch pole and platform noise. A safety harness was attached to an overhead trolley to prevent falls. Participants were instructed to stand with feet together, keep their finger resting on the touch pole, look at the screen, and then do whatever felt natural.

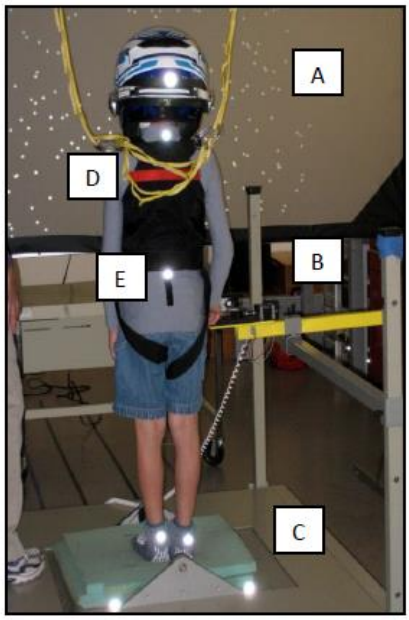

FIG. 1 MultiModal Balance Entrainment Response (MuMBER) system components:

A. Moveable visual screen dots (visual stimulus), **B**. touch pole for right index finger (somatosensory stimulus), **C**. moveable platform surface with foam overlay (vestibular stimulus). **D**. Safety harness for fall protection. **E**. Reflective markers for motion capture on heels, sacrum, spine, and head (helmet).

Sensory stimuli were provided in various combinations of Low (L), Medium (M), and High (H) frequencies for visual (dots on screen), somatosensory (touch pole), and vestibular (platform support surface) inputs, under fixed amplitudes (Table 1). For example, as the frequencies increased the dots, touch pole, and platform oscillated medially-laterally at a faster rate. Stimulus conditions were grouped in a sequence where the frequency of one sensory system increased from L, to M, to H while the other two were held at low frequency stimulation. Each stimulus was triggered to move in a medial-lateral direction at a specific frequency unique to each sensory stimulus and at consistent small amplitudes. Two trials of 60 seconds duration each, over seven test conditions, were applied (Table 1). A Qualysis Oqus 300 motion analysis system[37] captured body sway movements at 120 Hz through five cameras located posterior and lateral to the child. The system tracked five reflective markers located on the head (helmet), seventh cervical (C7) vertebra, sacrum between the posterior superior iliac crests, and Achilles tendons, approximately 5 cm above the inferior surface of each heel. Postural sway was tracked in response to the changing sensory stimulation, and kinematic data were used to determine the proportion that the child weighted each stimulus as the frequency of sensory movement was altered. The expectation was that children would decrease sensory weighting to high frequency stimuli due to the potential destabilizing effect on their balance.

TABLE 1 Multi Modal Balance Entrainment and Response (MuMBER) Protocol: Visual, Somatosensory and Vestibular Conditions

Condition[1, 2]	Acronym[3]	Visual Freq. [Hz] (V)	Somatosensory Freq. [Hz] (T)	Vestibular Freq. [Hz] (P)
All systems low	LLL	0.32	0.24	0.40
Medium V, low T, low P	MLL	0.57	0.24	0.40
High V, low T, low P	HLL	1.01	0.24	0.40
Low V, medium T, low P	LML	0.32	0.59	0.40
Low V, high T, low P	LHL	0.32	1.11	0.40
Low V, low T, medium P	LLM	0.32	0.24	0.52
Low V, low T, high P	LLH	0.32	0.24	0.86

[1]Amplitude range was kept constant as follows: visual dots (visual stimulus) = 9 mm medial-lateral; touch-pole (somatosensory stimulus) = 4 mm medial-lateral; platform tilt (vestibular stimulus) = 0.25º tilt; [2]V = Visual; T = Somatosensory; P = Vestibular; [3]L = low frequency movement; M = medium frequency movement; H = high frequency movement

Data Reduction

All kinematic data were examined frame by frame for missing data. If markers momentarily disappeared due to the child's body movements (e.g., if the child extended his head, the helmet could obscure the C7 marker; if the child's safety vest shifted it could obscure the C7 or sacral marker), those segments were interpolated. Any trials with a marker gap (>300 ms) were discarded. Each marker component was centered, by subtracting the mean, before further processing. Spectral analysis was conducted using custom LabVIEW software to derive the magnitude of the sacrum marker movement at the three sensory stimuli movement frequencies for the seven conditions tested. To derive the sensory weighting variables, we calculated the fraction, defined as the magnitude of (medial-lateral) body sway at each sensory frequency divided by all other peaks of body sway movement at other frequencies (Figure 2).

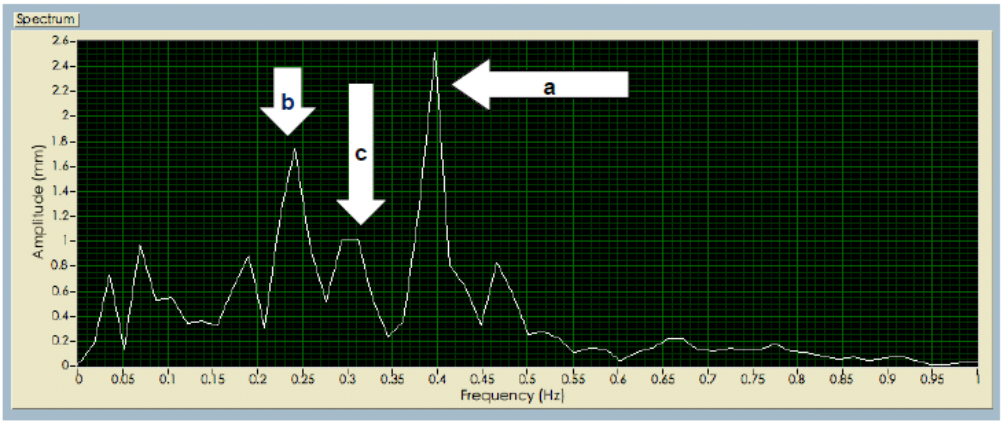

FIG. 2

Spectral analysis from the sacrum marker of one participant derived from Labview software for an LLL condition. a) Peak at the vestibular frequency 0.4Hz; b) Peak at the somatosensory frequency 0.24Hz; c) Peak at the visual frequency 0.32Hz.

The vestibular weighting fraction, somatosensory weighting fraction and visual weighting fraction are calculated as a/N, b/N and c/N, respectively, where N is the sum of all peaks observed. The methodology relies on stimulating the various balance subsystems, each with its own unique stimulus frequency, to reveal how much each subsystem contributes to the whole. The total response (i.e., marker motion) is broken down into frequency and amplitude components (i.e., spectral analysis), and the results across stimulus frequencies are compared. For each stimuli response the amplitude vs. frequency data form distinct amplitude peaks at specific frequencies (i.e., response peaks), which often, but not exclusively, correspond to the stimulus frequencies. For example, a response peak at the frequency of the somatosensory stimulus would suggest a large somatosensory subsystem contribution (weighting). The fraction of the somatosensory response peak to the total of all response peaks provides a relative weighting metric for the somatosensory subsystem. Two kinematic postural control variables were derived by sensory condition using MatLab software: (1) velocity of body sway movement (root mean square mm/sec), and (2) area of the ellipse of body sway (cm^2). The mean of two trials per sensory condition was used for all analyses. Outcomes from all body markers yielded similar trends, however, because the sacral marker is closer to the body center of mass and had fewer missing data points (as compared to the C7 marker where the helmet obscured more data points) only data from the sacral marker are reported for all analyses.[38]

Data Analysis

Descriptive statistics were used to summarize demographic, standardized sensorimotor clinical outcomes and sensory weighting/postural sway kinematic outcomes. Due to the small sample size, we used a non-parametric Wilcoxon signed-rank test for paired data to compare the performance of children with FASD to children with TD. Two-tailed significance levels were set at $\alpha = 0.05$ for clinical outcomes and $\alpha = 0.10$ for experimental outcomes (MuMBER). Since this is the first study to use MuMBER outcome variables, the study has an exploratory and preliminary nature, and corrections for multiple comparisons were not applied.

RESULTS

Sample Demographics

Personal characteristics for both groups are presented in Table 2. Matching during sampling produced comparable age and sex distributions. Only one child with FASD was in the care of a biological parent, whereas all 10 children with TD had a biological parent listed as primary caregiver. Groups were similar on parent level of education; however, all families of the TD group had income greater than $75K, compared to three families of the group with FASD. The mean intellectual estimate was lower for the children with FASD than children with TD. We refrained from doing hypothesis testing for group differences since the sample size was small, and due to self-selection (especially of the control group), the groups are not likely to be representative of the entire population of caregivers.

Clinical sensory, strength, range of motion, and posture screen measures were grossly intact and comparable between groups with one exception. A higher proportion of children with FASD (50%) than children with TD (10%) were unable to complete trunk force flexion testing for 30 seconds. A similar proportion of children in each group demonstrated minor postural or musculoskeletal differences that included postural lordosis (FASD 40%; TD 60%), hyper-pronated feet (FASD 50%; TD 40%), and borderline to mild signs of scoliosis (FASD 30%; TD 20%).

Standardized Clinical Measures of Sensorimotor Behaviors and Balance

Mean and median scores on child performance and caregiver-reported sensorimotor outcomes are reported by group in Table 3. The median scores for children with FASD suggested clinically poorer performance than the children with TD across all clinical sensorimotor measures. Statistically significant differences ($p < 0.05$) were seen on the MABC-2 checklist and SPM, indicating more parent-reported balance problems during functional movement for the children with FASD. The children with FASD also had significantly lower median scores on the DGI;

lower scores on the MABC-2 Balance and P-CTSIB-2 total ordinal and vestibular scores approached significance.

TABLE 2 Personal and Demographic Characteristics by Group

Characteristic	FASD (n= 10)	TD (n = 10)
Age in months		
Mean (SD)	142.2 (30.4)	144.5 (30.2)
Median (Min, Max)	130.5 (111, 186)	133.0 (113, 187)
Sex, % of females	20.0	20.0
Caregiver relationship to child, %		
Biological parent	10.0	100.0
Adoptive/legal guardian/other	90.0	0.0

Laboratory (kinematic) Measures

Table 4 and Figure 3 show the visual, somatosensory, and vestibular fractions across sensory conditions manipulated at low, medium, and high frequencies and group comparisons. Overall, both children with and without FASD systematically decreased sensory weighting as the stimulus frequency increased. *Visual median weighting fractions* were not statistically different between groups across the seven conditions tested. *Somatosensory median weighting fractions* were significantly different for two of the conditions tested: LLL ($p = 0.09$), with the children with FASD showing a lower median weighting fraction, and HLL ($p = 0.07$), with the children with FASD showing a slightly higher median weighting fraction. A statistically significant difference in one *Vestibular median weighting fraction* for the LLL condition ($p = 0.09$) was found. Clinical significance cannot yet

be determined as this is a new measure utilized only in the sample tested for this study. Postural control outcomes (median body sway area and velocity) were almost uniformly higher for the group of children with FASD; with a statistically significant group difference in sway velocity in the LLH condition (p = .07) (Table 5) suggesting poorer postural control in the children with FASD compared to children with TD.

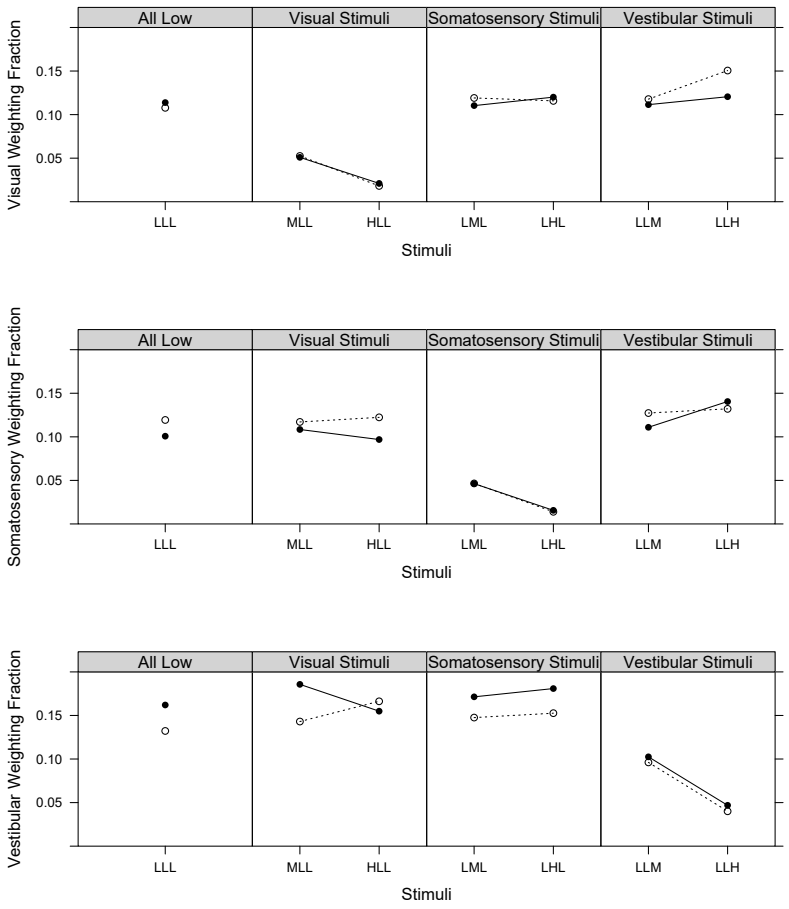
FIG. 3 Visual, somatosensory, and vestibular weighting fractions across conditions: Children with FASD are depicted in solid circles and children with TD are depicted in open circles.



DISCUSSION

This pilot study is the first to describe the sensory control of balance using an experimental assessment system that quantifies the sensory weighting of visual, somatosensory, and vestibular stimuli in combination with clinical sensorimotor tests among a systematically diagnosed sample of children with FASD and children with TD. Our overall results describe and replicate evidence of diminished functional sensorimotor performance on clinical measures for children with FASD compared to matched controls with TD. Our experimental outcome of sensory weighting yielded a small proportion of statistically significant group differences on somatosensory and vestibular sensory weighting fractions and postural sway velocity. Significant group contrasts were not found on other clinical and kinematic (postural control) measures that focused on the sensory control of balance. We interpret findings from our experimental measure

as evidence of possible differences in how efficiently children with FASD adapt to and use sensory subsystems, namely vestibular input, for balance control. These findings are small and preliminary given our limited sample size, and the clinical significance of our experimental sensory weighting outcomes needs further validation.

Clinical Measures

As expected, given the range of alcohol-related diagnoses of the children with FASD in this sample, standardized clinical measures yielded a heterogeneous descriptive profile of sensorimotor performance. As a group, the children with FASD generally had intact strength, musculoskeletal integrity, and peripheral responses to sensation. Mean and median scores on standardized clinical sensorimotor measures suggested poorer balance and functional sensorimotor performance for the children with FASD than their counterparts with TD. The children with FASD scored approximately 1 standard deviation lower than controls on the MABC-2 Balance subtest. Caregivers of the children with FASD almost uniformly reported difficulties with day-to-day movement behaviors on the SPM and MABC-2 checklist. This demonstrates the difficulties children with FASD have using motor and postural skills efficiently in the context of complex, dynamic tasks and environments.[2] While the results of the caregiver-reported measures (SPM and MABC-2 checklist) for participants older than age 12 (30%) should be interpreted with caution, as they were beyond the upper age limits of the normative sample, the latter findings are consistent with previous research.[2]

Mixed results were seen on clinical measures that examined the sensory control of balance under static and dynamic conditions. We found statistically significant group differences on the DGI, which measures gait quality during dynamic vestibular conditions. The lower score for the children with FASD on this measure suggests that the children with FASD demonstrated less efficient vestibular processing in response to dynamic vestibular challenges. However, the clinical significance of these subtle differences requires more investigation as the DGI has not been utilized extensively with children.

Group differences on the P-CTSIB-2, a clinical measure of the sensory control of balance, approached statistical significance for the total score and vestibular score. We consider the lower mean scores for the children with FASD as clinically significant and suggestive of decreased postural stability under complex sensory conditions (i.e., inaccurate or conflicting sensory information). We base this on previous testing of children with balance disorders with the P-CTSIB and P-CTSIB-2 in which most children ages 4-9 years receive the maximum total score.[39,40] Therefore, any deviation from a maximum total point score suggests a clinically significant difference, especially since the mean age of the children with FASD in our sample was 11.9 years. Poorer performance on the P-CTSIB-2 is aligned with previous research findings in children with PAE of similar age who showed less efficient vestibular processing during standing balance under altered sensory conditions.[3]

Sensory Weighting Measures

Using our novel laboratory MuMBER measurements, we have described and quantified how children in both groups weight visual, vestibular, and somatosensory information with the aim of examining how children differentially utilize each subsystem to control overall stability. Children in both groups showed similar decreases in sensory weighting for all subsystems as the frequency of the sensory stimuli increased. This suggests that all of the children could unweight from potentially destabilizing visual, somatosensory, and vestibular sensory stimuli. However, two interesting group differences in the sensory weighting outcomes were seen. First, the children with FASD showed consistently higher vestibular sensory weighting fractions than controls across most conditions. Second, the children with FASD showed consistently higher velocity of body sway (observed as "jerky" movements) to control standing balance as compared to controls across all of the sensory conditions.

These findings suggest that the children with FASD had less efficient postural stability specifically in response to the platform stimuli (±0.25 degree of medial-lateral tilt). We

hypothesize that the children with FASD were less able to actively synchronize their body sway to the subtle platform support surface movement. This, in turn, may have caused their body movement to be "dragged" by the platform movement, resulting in higher vestibular sensory weighting fractions in comparison to the children with TD. Children with TD appeared to react to the tilting by coordinating their movements opposite to the platform movement, resulting in smaller sway amplitudes and fractions. This hypothesis will need to be tested further with larger samples of children with FASD.

Taken together, our clinical and experimental findings are consistent with, and expand, previous research that suggests that children affected by PAE demonstrate poorer postural stability and static balance[2] and have more difficulty adapting when sensory (i.e., vestibular) information is inaccurate.[3] However, this study was preliminary and had a small sample size, and therefore, any statistically significant group differences need to be corroborated in larger studies powered to confirm findings. Results from our laboratory measurement system need replication in larger samples of children with and without FASD. Further, we observed that younger children (8-9 years) with and without FASD demonstrated poorer postural control during the computerized laboratory assessment compared to older controls. This agrees with other findings that suggest that sensory integration for postural control does not fully mature until adolescence.[41] We did not test enough children in either group to estimate the effect of developmental differences, but this warrants further study.

The overall severity of postural disability in the children with FASD was minimal to moderate, despite our effort to include children with FASD who had a history of sensorimotor dysfunction. In further exploration of the data utilizing only the seven matched pairs with children with FASD who had more "severe" diagnosis on the fetal alcohol spectrum (i.e., FAS or SE/AE) there were statistically significant differences between the groups on all clinical measures, but differences on the MuMBER sensory weighting fractions were unchanged. Examining larger samples of children with more moderate to severe postural control impairments is needed to better understand the clinical utility of the MuMBER system.

Despite study limitations, our results are congruent with other descriptive studies that report a range of sensorimotor abilities (from subtle to clinically significant impairments) in individuals clinically affected by PAE.[2,5] Our focus on the measurement of sensory weighting behaviors provides new and more precise information about how children with and without FASD integrate sensory information to control balance. Our comprehensive sensorimotor profile that included both clinical and kinematic outcomes was an attempt to more precisely test whether the inefficient central processing of sensation, in particular vestibular input, plays a role in diminished postural control and functional sensorimotor performance among children with FASD. Further investigation is warranted to more fully understand how children with FASD use and integrate visual, vestibular, and somatosensory information during balance under both experimental and naturalistic conditions and how this capacity affects functional movement behaviors.

VALIDATION OF THE FETAL ALCOHOL SPECTRUM DISORDER (FASD) 4-DIGIT DIAGNOSTIC CODE

Susan J Astley
Professor of Epidemiology and Pediatrics, University of Washington, Seattle WA

ABSTRACT

Background
The fetal alcohol spectrum disorder (FASD) 4-Digit Diagnostic Code has been used by interdisciplinary diagnostic teams worldwide for 17 years. It was created to improve the ease, accuracy, and reproducibility of diagnoses across the full spectrum of FASD. Over the years, a number of FAS/D diagnostic guidelines have been proposed. As the field of FASD moves forward, it will be important to adopt a single set of diagnostic guidelines worldwide. To achieve this, the performance (validity) of current diagnostic guidelines must be rigorously assessed and reported.

Objective
To summarize the body of evidence that has amassed over 20 years that validates the performance of the FASD 4-Digit Diagnostic Code.

Methods
The evidence validating the 4-Digit Code is documented across 35 studies published between 1992 and 2012, including new information presented in this report. These studies and data sources include the delineation of the FAS facial phenotype; creation of the 4-Digit Code (1997-2004); our 10-year, foster-care FAS screening program; our MRI/fMRI/MRS studies; analysis of 2,550 individuals evaluated for FASD over 20 years in the WA State FASDPN clinics, and analysis of 622 patient satisfaction/follow-up surveys; surveys of 10,000 professionals attending the University of Washington FASD diagnostic clinic trainings; and surveys of over 700 professionals worldwide who completed the 4-Digit Code Online Course.

Conclusion
The 4-Digit Code is a simple, comprehensive, evidence-based, validated diagnostic system. It has served as the cornerstone of a fully integrated FASD screening, diagnostic, intervention, prevention, and surveillance program in Washington State for the past 20 years.

Key Words: *Fetal alcohol spectrum disorders (FASD), fetal alcohol syndrome (FAS), diagnosis, validity, 4-Digit Diagnostic Code, FAS Diagnostic & Prevention Network (FASDPN)*

The fetal alcohol spectrum disorder (FASD) 4-Digit Diagnostic Code has been used by interdisciplinary diagnostic teams worldwide for 17 years (Figure 1).[1-3] It was created to improve the ease, accuracy, and reproducibility of diagnoses across the full spectrum of FASD.[4] Over the years, a number of FAS/D diagnostic guidelines have been proposed.[5-8] As the field of FASD moves forward, it will be important to adopt a single set of diagnostic guidelines worldwide.[9] To achieve this, the performance (validity) of current diagnostic guidelines must be empirically assessed and reported. The purpose of this report is to pull together the body of evidence that has amassed over 20 years that validates the performance of the FASD 4-Digit Diagnostic Code. This report highlights key evidence, directing readers to the source publications for more details.

What is FASD?

Fetal alcohol syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. The definition of FAS has changed little since the 1970's when the condition was first described and refined.[5,10-13] The condition has been broadly characterized by prenatal and/or postnatal growth deficiency, a unique cluster of minor facial anomalies, and central nervous system (CNS) abnormalities. FAS is the leading known and preventable cause of intellectual disabilities in the Western World.[14] The prevalence of FAS is estimated to be 1 to 3 per 1,000 live births[5] in the general U.S. population, but has been documented to be as high as 10 to 15 per 1,000 in some higher-risk populations such as children residing in foster care.[15]

The physical, cognitive, and behavioral deficits observed among individuals with prenatal alcohol exposure are not dichotomous, that is either normal or clearly abnormal. Rather, the outcomes, and the prenatal alcohol exposure, all range along separate continua from normal to clearly abnormal and distinctive.[16-19] This full range of outcomes observed among individuals with prenatal alcohol exposure has come to be called Fetal Alcohol Spectrum Disorders (FASD). Diagnoses like FAS, Partial FAS (PFAS), Static Encephalopathy / Alcohol Exposed (SE/AE), and Neurobehavioral Disorder / Alcohol Exposed (ND/AE) fall under the umbrella of FASD[4].

The Diagnostic Challenge

FASD can present a daunting, but not insurmountable challenge for diagnosis. Individuals with prenatal alcohol exposure present with a wide range of outcomes, most of which are not specific to prenatal alcohol exposure and often manifest differently across the lifespan. Professionals from multiple disciplines (medicine, psychology, speech-language pathology,

occupational therapy, etc.) are needed to assess and interpret accurately the broad array of outcomes that define the diagnoses.[20] The pattern and severity of outcomes are dependent on the timing, frequency, and quantity of alcohol exposure (which is rarely known with any level of accuracy), and is frequently confounded by other adverse prenatal and postnatal exposures, events, and conditions.

In the absence of objective, accurate, and reproducible methods for measuring and recording the severity of exposures and outcomes in individual patients, diagnoses use to vary widely from clinic to clinic.[4,5,21-23] From a clinical perspective, diagnostic misclassification leads to inappropriate patient care, increased risk for secondary disabilities, and missed opportunities for primary prevention.[4] From a public health perspective, diagnostic misclassification leads to inaccurate estimates of incidence and prevalence.[4,5,8,23] Inaccurate estimates thwart efforts to allocate sufficient social, educational, and health care services to this high-risk population, and preclude accurate assessment of primary prevention intervention efforts.[4,15,24] From a clinical research perspective, diagnostic misclassification reduces the power to identify clinically meaningful contrasts between FAS and control groups and between FASD clinical subgroups like FAS and ARND.[4,16,25,26] Non-standardized diagnostic methods also thwart valid efforts to compare outcomes between research studies.[16,17,27]

FASD Diagnostic Guidelines

FASD diagnostic guidelines have evolved over time since the term FAS was first coined in the medical literature in 1973.[9] Early guidelines were gestalt (purposely broad and conceptual) in nature and administered primarily by geneticists and dysmorphologists.[4,9] The Institute of Medicine (IOM) FASD guidelines[5] published in 1996 would be the last in this line of gestalt approaches to diagnosis. In 1997, the FASD 4-Digit Diagnostic Code was introduced to overcome the limitations of the gestalt approach to diagnosis.[1] It proposed an interdisciplinary approach to diagnosis guided by rigorously and empirically case-defined criteria.[20] In 2004-2005, three additional FAS/D diagnostic guidelines were published: the CDC FAS guidelines[6] in July 2004; the Revised IOM FASD guidelines[8] in January 2005, and the Canadian FASD guidelines[7] in March 2005. The 4-Digit Code was subsequently updated in January, 1999[2] and November 2004.[3] Why are there four separate guidelines? Their existence reflects the ongoing debate on how best to approach FASD diagnosis. All present with strengths and limitations.[9] Each was developed under different circumstances that influenced their outcome. The 4-Digit Code was investigator initiated in a statewide clinical/research arena using a large clinical sample of 1,014 individuals of all races and ages (birth to 51 years of age).[4] Empirical methods were used both to develop[28-30] and validate the performance of the 4-Digit Code.[4,9,15-17,23-26] The CDC[6] and Canadian[7] guidelines were federally mandated and commanded a more consensus-driven process. These guidelines were not empirically validated prior to publication. The Revised IOM[8] guidelines were also investigator initiated in a clinical/research arena, using a clinical sample of 164 Native American and South African children to augment an existing set of gestalt guidelines: the 1996 IOM Guidelines. All four of these guidelines have been compared/contrasted in detail by Astley in 2010.[9] In Astley's summary remarks, she reports "*The field should strive to adopt a single set of diagnostic guidelines for FASD*". This same conclusion was drawn at a recent meeting of FASD diagnostic guideline authors at the March 2013 International FASD conference in Vancouver British Columbia. It is important to note that the process of selection has long been underway by clinicians worldwide. It is clinicians who will ultimately decide which diagnostic guidelines best meet their needs and the needs of their patients and families. To guide this selection process, it will be essential for the authors of the various guidelines to validate (assess the performance) of their guidelines. Validity must be confirmed, not assumed, through properly designed empirical studies.[5]

Assessing a Diagnostic Tool's Performance (Validity)

Validity is the degree to which a tool (or diagnostic system) is measuring what it purports to measure.[31] Validity is not determined by a single statistic, but by a body of research that demonstrates the relationship between the diagnostic system and the condition it is intended to measure. There are three overarching forms of validity: **content validity, criterion validity, and construct validity**. **Content Validity** is a measure of how well the items in the diagnostic system represent the entire range of possible items the diagnostic system should cover. **Criterion validity** is a measure of a diagnostic tool's accuracy relative to a gold standard. **Construct validity** refers to the degree to which a test measures what it claims, or purports, to be measuring. It refers to the ability of a measurement tool to measure the physiological concept being assessed. Convergent and discriminant validity are two subtypes of construct validity. **Convergent validity** refers to the degree to which two measures of constructs that theoretically should be related are in fact related. In contrast, **discriminant validity** tests whether concepts or measurements that are supposed to be unrelated are in fact unrelated. An important aspect of clinical research is the inference that an association represents a cause-effect relationship. Features of associations that support causation include: the strength of the association; the consistency of observed evidence; specificity of the relationship; temporality of the relationship; the biological gradient of dose-response, biological plausibility; and experimental confirmation. **Predictive validity** refers to a tool's ability to predict something is should theoretically be able to predict. **Precision (Accuracy)** is the degree to which a measurement procedure produces the correct answer. **Reliability (Reproducibility)** is the degree to which a measurement procedure produces the same result each time. **Test-Retest Reliability** is the variation in measurements taken by a single person on the same item and under the same conditions**. Inter-rater Reliability** is used to assess the consistency of a test across two or more raters. **Intra-rater Reliability** is the degree of agreement among multiple repetitions of a diagnostic test performed by a single rater. Statistical measures used to assess these constructs include linear correlation coefficients, tests for trends, and Kappa statistics. Fundamental measures of diagnostic accuracy include sensitivity and specificity. The **sensitivity** of a test is the proportion of people with the condition who test positive for it (the true positive rate). The **specificity** of a test is the proportion of people who do not have the condition who test negative for it (the true-negative rate). **Positive Predictive Value (PPV)** is the probability that a patient with a positive test result really does have the condition. **Negative Predictive Value (NPV)** is the probability that a patient with a negative test result really does not have the condition. The body of research presented below that validates the performance of the FASD 4-Digit Code utilized all of these measures.

Introduction to the FASD 4-Digit Code

The FASD 4-Digit Code is described in full by Astley.[3] Briefly, the 4 digits of the FASD 4-Digit Code reflect the magnitude of expression of the 4 key diagnostic features of FASD, in the following order: 1) growth deficiency, 2) FAS facial phenotype, 3) CNS structural/functional abnormalities, and 4) prenatal alcohol exposure (Figure 2A). The magnitude of expression of each feature is ranked independently on a 4-point Likert scale, with 1 reflecting complete absence of the FASD feature and 4 reflecting a strong "classic" presence of the FASD feature. Each Likert rank is specifically case defined. There are a total of 102 4-Digit Codes that fall broadly under the umbrella of FASD (Table 2). These codes cluster under four clinically meaningful FASD diagnostic subcategories: fetal alcohol syndrome (FAS): Diagnostic Categories A and B; Partial FAS (PFAS): Diagnostic Category C; Static Encephalopathy/Alcohol-Exposed (SE/AE): Diagnostic Categories E and F; and Neurobehavioral Disorder/Alcohol-Exposed (ND/AE): Diagnostic Categories G and H (Figure 2B). The attributes of the 4-Digit Code are summarized in Table 3

A Validation Guide

As clinicians assess the performance of FAS/D Diagnostic Guidelines, they may find the list of questions presented in Table 1 a helpful guide.

TABLE 1: As clinicians assess the performance of FASD diagnostic guidelines, clinicians should ask the following questions. The answer to all of these questions is 'yes' for the FASD 4-Digit Diagnostic Code.

1. Have properly designed studies been published to confirm the case definition for the FAS facial phenotype is highly specific (>95%) to FAS and alcohol (e.g. observed only among individuals with prenatal alcohol exposure and FAS)?
2. Was data used to empirically derive the diagnostic guidelines? Was the data drawn from a large, representative, population-base?
3. Has the performance of the guidelines been empirically assessed (validated)?
4. Individuals are born with FAS/D. Can the diagnostic system identify FAS/D at birth and across the lifespan?
5. Growth deficiency, the FAS facial phenotype, CNS abnormalities, and alcohol exposure all present along clinically meaningful continuums. The FAS facial phenotype is not just present or absent. The brain is not just normal or abnormal. Do the Guidelines recognize/incorporate these important continuums?
6. Do the guidelines produce clinically distinct subgroups across the full spectrum (FAS, PFAS, SE/AE, ND/AE)?
   A. Do brain imaging studies identify statistically significant contrasts between the FASD subgroups?
   B. Individuals with FAS have more severe CNS dysfunction than individuals with "ARND". Do the Guidelines generate FAS and "ARND" groups that demonstrate this important contrast?
   C. Do individuals who meet the criteria for FAS actually have FAS?
7. Can the guidelines detect unique alcohol exposure patterns between the FASD subgroups?
8. Can the diagnostic system be effectively and efficiently taught to interdisciplinary teams?
9. Are the guidelines confirmed to be reproducible? If two clinics use the guidelines, do they render the same diagnoses?
10. Do families report high satisfaction/confidence with the diagnostic process/outcome?
11. Are the names of the diagnoses (FAS, PFAS, SE/AE, ND/AE) medically valid? Do they imply causality between alcohol and outcome that cannot be confirmed in the individual patient?
12. Do diagnoses under the umbrella of FASD qualify patients for intervention services that lead to improved outcomes?

J Popul Ther Clin Pharmacol Vol 20(3):e416-e467; November 15, 2013

FIG. 2 A. Abbreviated case-definitions of the FASD 4-Digit Code.[3] The 4-Digit Code 3434 is one of 12 Codes that fall under the diagnostic category FAS (Table 2). B. The 4-Digit Code produces four diagnostic subgroups under the umbrella of FASD: FAS, PFAS, SE/AE, and ND/AE.[16,26] The 4-Digit Code uses the terms SE/AE and ND/AE in place of the term ARND.

TABLE 3 Key Attributes of the FASD 4-Digit Diagnostic Code.[4]

1. Greatly increases diagnostic precision and accuracy through the development of objective, quantitative measurement scales (e.g., Lip-Philtrum Guides), facial analysis software, and specific, operational case definitions.
2. Diagnoses the full spectrum of outcomes across the lifespan.
3. Was developed empirically using a large, representative, population-base.
4. Offers an intuitively logical numeric approach to reporting outcomes and exposure that reflects the true diversity and continuum of disability observed in individuals with prenatal alcohol exposure.
5. Uses the universal language of numbers, thus facilitating ease of reporting worldwide. The numeric base also allows rapid and easy update of large datasets as diagnostic criteria are refined.
6. Establishes a method for case-defining the highly variable, nonspecific CNS dysfunction that typifies FASD, by quantifying the breadth and magnitude of dysfunction (number of domains of function 2 or more SDs below the mean) without unduly constraining which domains must be impaired.
7. Establishes diagnostic subclassifications that capture the full spectrum of FASD without inferring alcohol is the sole causal agent.
8. Documents all other prenatal and postnatal adverse exposures and events that can also impact outcome.
9. Provides a quantitative measurement and reporting system (the 4-Digit Code) that can be used independent of the diagnostic nomenclature.
10. Has received extensive assessment/validation of its performance.
11. Was designed for use by an interdisciplinary FASD diagnostic team.
12. Is readily taught to interdisciplinary teams through an Online Course, thus greatly expanding the availability of diagnostic services worldwide.
13. Qualifies patients for intervention services that produce improved outcomes.
14. Receives high satisfaction/confidence ratings from families and clinicians

Data sources used to assess/validate the FASD 4-Digit Diagnostic Code

The 4-Digit Code is a simple, comprehensive, evidence-based, validated diagnostic system (Figure 1).[9] The performance of the 4-Digit Code was assessed (validated) prior to its initial release in 1997 and extensively thereafter. The evidence supporting the validation of the 4-Digit Code is documented across over 35 studies published between 1992 and 2012, including new information presented in this report. These studies include the empirical delineation of the FAS facial phenotype (1992-2001)[25,28-30,32]; the creation and updates of the 4-Digit Code (1997-2004)[1-3]; a 10-year population-based FAS active screening/surveillance study of foster care using 2D facial photographs and the FAS Facial Photographic Analysis Software (1999-2009)[15,24,33]; WA State Pregnancy Risk Assessment Monitory System (PRAMS) public health surveillance data documenting annual maternal use of alcohol during pregnancy (1993-99)[34]; the MRI/fMRI/MRS studies (2002-2007)[16,17,27,35]; analysis of over 2,000 fields of data

on over 2,550 alcohol-exposed individuals evaluated for FASD over the course of 20 years in the seven WA State FASDPN clinics (1993-2013)[26], analysis of 577 patient satisfaction/follow-up surveys over 20 years[26]; surveys of over 10,000 professionals attending the UW FASD diagnostic clinic trainings (1993-2013); and surveys of over 700 professionals worldwide who completed the 4-Digit Code Online Course (2004-2013).

A synopsis of the published evidence validating the performance of the 4-Digit Code is presented in Table 4. Each entry in Table 4 is described in full in the body of this report, identified numerically to match the entry in Table 4.

TABLE 4 Synopsis of published evidence validating the performance of the FASD 4-Digit Code. Each entry in this Table is described in full in the body of this report.

1. The 4-Digit Code was created in 1997 to overcome the limitations of the gestalt approach to FASD diagnosis used from 1973-1996. Its advanced performance was empirically confirmed prior to its publication. The 4-Digit Code:
    - A. Produced more accurate, homogeneous diagnostic subgroups.
    - B. Detected clinically important correlations between growth, face, brain, and alcohol that the gestalt method failed to detect.
    - C. Demonstrated high inter- and intra-rater reliability.
    - D. Had a FAS facial phenotype with confirmed high sensitivity and specificity to FAS and prenatal alcohol exposure.
2. The Quintessential Role of the FAS Facial Phenotype
    - A. The full FAS Facial Phenotype (Rank 4):
        1. Is confirmed to be highly sensitive and specific (>95%) to FAS and alcohol and does not vary by race, gender or age.
        2. Serves as the most efficient/effective way to screen for FAS in population-based samples
        3. Is uniquely correlated with significantly and disproportionately smaller frontal lobe volumes which is consistent with midventral forebrain deficiencies associated with facial dysmorphia observed in animal studies of alcohol teratogenicity.
        4. Is quintessential to the validity of all diagnoses under the umbrella of FASD, not just FAS.
    - B. The FAS Facial Phenotype presents on a Continuum:
        1. Presents on a continuum that is significantly correlated with (predictive of) abnormal brain structure and function.
        2. Can be measured easily and accurately from a 2D photo using the FAS Facial Photographic Analysis Software.
3. The 4-Digit Code's method for case-defining the highly variable CNS dysfunction that typifies FASD demonstrates high construct validity.
    - A. The 4-Digit Code's method for classifying CNS dysfunction (CNS Ranks 1, 2, and 3) successfully predicts underlying CNS structural abnormality, as it was designed to do. For example, the more severe the CNS dysfunction (CNS Ranks 1,2 and 3), the smaller the caudate volume.
    - B. Microcephaly predicts severe CNS dysfunction among infants/toddlers who present with the full Rank 4 FAS facial phenotype.
4. The 4-Digit Code generates four distinct diagnostic subgroups (FAS, PFAS, SE/AE, and ND/AE), under the umbrella of FASD.

Validation of the fetal alcohol spectrum disorder (FASD) 4-Digit Diagnostic Code

A. The 4 diagnoses are clinically and statistically distinct and span the full continuum of FASD.
    1. Individuals with FAS have growth deficiency, those with PFAS do not.
    2. Only FAS/PFAS have the FAS face, small frontal lobe volumes, and reduced choline levels.
    3. Only FAS/PFAS and SE/AE have small caudate volumes.
    4. FAS/PFAS have more severe CNS dysfunction than SE/AE.
    5. SE/AE have more severe CNS structural/functional abnormalities than ND/AE.
    6. ND/AE have CNS structural abnormalities underlying their moderate CNS dysfunction.
    7. Even families detect/report clear distinctions between the diagnostic subgroups.
B. Extensive evidence validates the inclusion of individuals with moderate dysfunction (ND/AE) under the umbrella of FASD.
C. The term ARND (like Fetal Alcohol Effects) should be abandoned and replaced with medically valid terms like SE/AE and ND/AE that do not imply causation.

5. The 4-Digit Code's method of documenting prenatal alcohol exposure not only detects significant correlations between exposure and outcomes, but also detects exposure patterns that distinguish the diagnostic subgroups.
    A. The 1-page standardized form used to record prenatal alcohol exposure patterns effectively addresses the challenges of documenting exposure. Full information is rarely available. Despite this, the 4-Digit Code method can:
        1. Detect significant correlations between alcohol exposure and measures of growth, face, and CNS abnormalities.
        2. Identify exposure patterns among FAS/PFAS that are distinct from SE/AE and ND/AE.
    B. The prevalence of maternal alcohol use during pregnancy correlates with the prevalence of FAS as defined by the 4-Digit Code.
    C. An 'excessive' alcohol exposure history should not be required for a diagnosis under the umbrella of FASD for the following reasons:
        1. As tools become more sensitive, our ability to detect adverse outcomes improves.
        2. Risk varies among individuals, even between twins.
        3. Sends the wrong public health message "moderate exposure is safe?"
        4. Reliable histories on quantity/frequency/timing of exposure are rarely available.
        5. Only allowing high exposures to be associated with adverse outcomes prevents identifying the true dose-response relationship between alcohol and adverse outcomes.
6. The 4-Digit Code has been effectively and efficiently taught to interdisciplinary FASD diagnostic teams worldwide through an inexpensive Online Course.
7. The 4-Digit Code is reproducible across clinics. Of 677 patients diagnosed across 7 WA FASD Clinics, >93% received a diagnosis that matched the diagnosis rendered by the core clinic at the University of Washington.
8. Families report high satisfaction and confidence with the interdisciplinary approach to FASD diagnosis using the 4-Digit Code.
9. Patient follow-up surveys confirm all FASD diagnoses (FAS, PFAS, SE/AE, and ND/AE) provided equal access to intervention services that led to improved outcomes.

J Popul Ther Clin Pharmacol Vol 20(3):e416-e467; November 15, 2013

1 The 4-Digit Code was created in 1997 to overcome the limitations of the gestalt approach to FASD diagnosis. Its advanced performance relative to the gestalt approach was empirically confirmed prior to its publication.

When the University of Washington CDC-sponsored FASD diagnostic clinic first opened in January 1993, it was the first to propose/implement an interdisciplinary approach to diagnosis.[20,36-38] The interdisciplinary team (medical doctor, psychologist, speech language pathologist, occupational therapist, social worker, and family advocate) used the most current FASD diagnostic guidelines available at that time; the 1989 gestalt diagnostic criteria published by Sokol and Clarren.[13] In 1996, the IOM published an updated set of FASD diagnostic guidelines[5], but continued to propose a gestalt approach. The gestalt approach to diagnosis presented with many limitations as outlined in Astley & Clarren.[1,4] The 4-Digit Code was created in 1997 to overcome these limitations.[1] The medical/research records of the first 1,014 patients diagnosed at the Washington State FAS Diagnostic and Prevention Network of clinics were used to develop the 4-Digit Diagnostic Code.[4] Importantly, this was a representative statewide population of patients spanning all ages and races. To assess the performance of the 4-Digit Code, the subset of 454 patients who had received a gestalt diagnosis under the umbrella of FASD (FAS, atypical FAS, or possible fetal alcohol effect (PFAE)) were retroactively coded on the 4-Digit Code to empirically compare the FASD classification outcomes of the two diagnostic systems.[4] The superior performance of the 4-Digit Code relative to the gestalt approach to diagnosis is briefly summarized below.

1A The 4-Digit Code produced homogeneous FASD diagnostic subgroups. The gestalt method of diagnosis produced highly variable FASD diagnostic subgroups.

For example, of the first 454 patients who received a gestalt diagnosis under the umbrella of FASD, 69 were classified as FAS. In the absence of rigorous guidelines, this group was very heterogeneous.[4] Of the 69 subjects with a gestalt diagnosis of FAS: only 32 had growth deficiency ($\leq$10th percentile); only 27 had the Rank 4 FAS face; and only 40 had significant CNS structural/functional abnormalities. When the more rigorous 4-Digit Code was applied to the 69 with a gestalt diagnosis of FAS only 9 of the 69 retained a diagnosis of FAS. Twelve were reclassified to Partial FAS; 18 were reclassified to Static Encephalopathy /Alcohol Exposed (SE/AE); 26 were reclassified to Neurobehavioral Disorder / Alcohol Exposed (ND/AE); and 4 were not even on the spectrum (exposure unknown).

1B The 4-Digit Code detected clinically important correlations between growth, face, brain, and alcohol that the gestalt method failed to detect.

Inter-correlations between growth, face, brain, and alcohol, confirmed to exist in laboratory-based studies of alcohol teratogenicity[29,39], were completely absent in our clinical population when the gestalt method was used, and strongly significant when the 4-Digit Code was used. For example, the hypothesis that the full-scale intelligence quotient (FSIQ) decreases with increasing magnitude of expression of the FAS facial phenotype was tested among 216 patients who had been diagnosed by both the gestalt and 4-Digit diagnostic systems.[4] Of the 216 patients, 31 were identified as having the gestalt FAS facial phenotype. The difference in the mean FSIQ between the patients with and without the gestalt FAS facial phenotype (82.3 and 85.0 respectively) was not statistically significant ($t = -1.56$, $p = 0.13$). In contrast, when the same 216 patients were classified by their 4-point Likert rank reflecting the magnitude of expression of the 4-Digit Code FAS facial phenotype, the difference in the mean FSIQ between the patients with and without the full FAS facial phenotype (78.5 and 87.7 respectively) was statistically significant ($t = 2.3$, $p = 0.02$). More importantly, a statistically significant, inverse, linear association was revealed. The mean FSIQs among the patients

with FAS Facial Ranks of 4 (severe), 3 (moderate), 2 (mild), and 1 (absent) were 78.5, 83.8, 84.8 and 87.7 respectively (f = 4.1, p = 0.04). Thus, a clinically important linear association between face and brain that was detected by the 4- Digit Code, failed to be detected by the gestalt method of diagnosis. This illustrates two important points: First, in the absence of specific case definitions, the gestalt approach results in diagnostic misclassification. This explains why the mean FSIQs for the groups with and without the gestalt FAS facial phenotype did not differ significantly. Individuals who truly did not have the FAS facial phenotype were misclassified as having the gestalt FAS face. Their inclusion in the gestalt FAS group erringly elevated the mean FSIQ for that group. Note the mean FSIQ for the gestalt FAS facial group was 82.8 while the mean FSIQ for the 4-Digit Rank 4 FAS facial group was 78.5. Second, the gestalt method of diagnosis records the FAS facial phenotype on a dichotomous scale (present, absent). The 4-Digit Code records the FAS facial phenotype on a 4-point Likert scale (Rank 1. Absent; Rank 2. mildly present; Rank 3. moderately present; Rank 4. severely present). In reality, growth, face, brain and alcohol all present along clinically meaningful continuums. The 4-Digit Code captures all outcomes and exposures on ordinal or continuous scales. Ordinal and continuous scales have far greater statistical power than dichotomous (e.g., present, absent) scales to detect important correlations that will not only advance our understanding of FASD, but provide us with more sensitive diagnostic tools. For example, one challenge in FASD diagnosis is to confirm or rule-out CNS dysfunction in children too young to participate in comprehensive neuropsychological testing. We now know that the subset of young children at greatest risk for CNS dysfunction is the subset who present with a Rank 2, 3 or 4 FAS facial phenotype. The higher the facial rank, the higher the risk.[9,25] The face is such a strong predictor of underlying CNS dysfunction, we recommend these children receive early intervention based on the presence of this physical risk factor. Postponing intervention until CNS dysfunction manifests would deny the child access to the benefits of early intervention. The correlation between the magnitude of expression of the 4-Digit FAS facial phenotype and CNS abnormality is presented more fully in section 2B.

<u>1C</u> The 4-Digit Code had confirmed high inter-rater and intra-rater reliability.

A core goal of the 4-Digit Code was to establish a diagnostic system that was reproducible (reliable) across clinicians and clinics. No matter where a patient was seen, they would receive the same FASD diagnostic outcome. This diagnostic precision and accuracy were achieved through the development of objective, quantitative measurement scales (e.g. Lip-Philtrum Guides) and specific, operational case definitions. The creation of the FAS Facial Photographic Analysis Software[33,40], web-based instructional videos and animations, and the FASD 4-Digit Code Online accredited course[41] further enhanced diagnostic precision and accuracy. This rigorous, case-defined approach is what sets the 4-Digit Code apart from the gestalt approach to diagnosis. The Code's reliability was confirmed to be high prior to its publication.[4] The 4-Digit Codes of 20 randomly selected patient files were re-derived independently by two clinicians, while masked to the original 4-Digit code that had been derived 1-4 years ago by the University of Washington diagnostic team. The re-derived codes matched the original 4-Digit Codes across all four digits for all 20 subjects (inter- and intra-rater reliability was 100%, (Kappa = 1.0, p = 0.000). The 4-Digit Codes for the 20 randomly selected patients spanned the entire spectrum of Neurobehavioral Disorder to Partial FAS (1124 to 1444). Inter-rater reliability between the six FASDPN regional clinics and the University of Washington FASDPN Core clinic resulted in an exact match across all four digits on 15 of 16 (94%) patients (Kappa = 0.93, p = 0.000) and an exact match on Diagnostic Category on all 16 (100%) of the patients (Kappa = 1.0, p = 0.000). The one 4-Digit code that did not match was coded by the regional FASDPN clinic as 1223 and the University FASDPN clinic as 1123. The mismatch in the facial score was due to the network physician not pulling the epicanthal fold back before measuring

the palpebral fissure length resulting in an underestimate of the length. Diagnostic inter-rater reliability between the six FASDPN regional clinics and the University of Washington FASDPN Core clinic continues to be high (93% match in FASD Diagnostic Category across 677 patients over the next 18 years (Kappa = 0.92, p = 0.000)).

1D The Rank 4 FAS facial phenotype was confirmed to have high sensitivity and specificity to FAS and prenatal alcohol exposure.

Prior to the creation of the 4-Digit Code, a decade of research was conducted to empirically identify and case-define the cluster of minor facial anomalies that were most sensitive and specific (>95%) to FAS and prenatal alcohol exposure.[15,25,28-30,32] This is described more fully below.

2 The quintessential role of the FAS facial phenotype.

The FAS facial phenotype is the cornerstone of FASD diagnostic guidelines (Table 5). Two core principles are important to understand: 1) The high sensitivity and specificity of the full FAS facial phenotype is essential to the validity of all diagnoses under the umbrella of FASD, not just the diagnosis labeled FAS. 2) The FAS face is not simply present or absent. It presents on a clinically meaningful continuum that is highly predictive of underlying structural and functional brain abnormalities. Each of these principals is discussed more fully below.

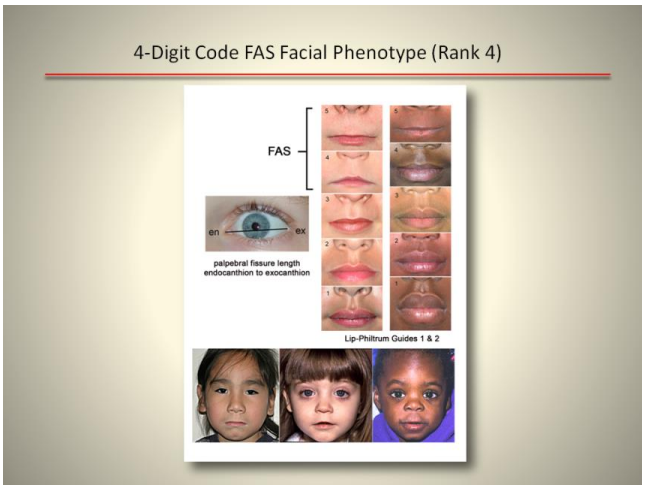
TABLE 5 4-Digit Code FAS facial phenotype fundamentals.

1. Empirically identified and case-defined 18 years ago.
2. Presents along a clinically meaningful continuum (absent, mild, moderate, severe: Facial Ranks 1,2, 3, 4 respectively).
3. This continuum is significantly correlated with (predictive of) brain abnormality. The more severe the face, the more severe the underlying structural and functional brain abnormality.
4. This face can be identified across all ages and races and does not diminish with age.
5. The Rank 4 FAS Face is confirmed to be highly sensitive and specific (>95%) to FAS and prenatal alcohol exposure. This high specificity is the only reason a diagnosis of FAS to be rendered when alcohol exposure is unknown.
6. If the criteria for the FAS facial phenotype are relaxed, sensitivity and specificity are substantially reduced.
7. A diagnosis of (FAS/Alcohol Exposure Unknown) cannot be made if the FAS facial phenotype used to render that diagnosis is not highly specific to prenatal alcohol exposure. Specificity must be empirically confirmed, not assumed.
8. The full continuum of the 4-Digit Code FAS facial phenotype is easily and accurately measured from a 2D digital photo using a $60 piece of software (FAS Facial Photographic Analysis Software). This ease, accuracy, and low cost of measurement is why 2D was selected over 3D.
9. The most accurate and efficient method to screen for full FAS is to identify the Rank 4 facial phenotype from a 2D digital facial photo (as demonstrated by the 10-year foster care FAS screening program in Seattle).

2A The full (Rank 4) FAS facial phenotype.

The full (Rank 4) FAS facial phenotype, as defined by the 4-Digit Code, is the simultaneous expression of the following three minor facial anomalies: 1) short palpebral fissure lengths (PFL) (2 or more SDs below the mean ($\leq$ 2.5th percentile)); 2) Smooth philtrum (Rank 4 or 5 on the Lip-Philtrum Guide); and 3) thin upper lip (Rank 4 or 5 on the Lip-Philtrum Guide) (Figure 3).[4]

FIG. 3 The full (Rank 4) FAS facial phenotype, as defined by the 4-Digit Code, is the simultaneous expression of the following three minor facial anomalies: 1) short palpebral fissure lengths (PFL) (2 or more SDs below the mean); 2) Smooth philtrum (Rank 4 or 5 on the Lip-Philtrum Guide); and 3) thin upper lip (Rank 4 or 5 on the Lip-Philtrum Guide)[3]. The FAS facial phenotype does not vary by race, as demonstrated in photos of three children with the Rank 4 FAS facial phenotype (Native American, Caucasian, and African American).



2A.1 The full FAS facial phenotype (Rank 4) is highly sensitive and specific (>95%) to FAS and prenatal alcohol exposure and does not vary by race, gender or age.

If the Rank 4 FAS facial phenotype is truly unique to prenatal alcohol exposure (e.g., alcohol is the only agent that can cause this facial phenotype) and is unique to the diagnosis of FAS (e.g., this exact phenotype is not present in any other medical condition), then one would expect to observe the following: 1) this facial phenotype would be highly sensitive to FAS (e.g., individuals with FAS would have the FAS facial phenotype), 2) this face would be highly specific to FAS (e.g., individuals without FAS would not have the FAS facial phenotype), and 3) this face would be highly specific to prenatal alcohol exposure (e.g., individuals with confirmed absence of prenatal alcohol exposure would not have the FAS facial phenotype). The Rank 4 FAS facial phenotype, as defined by the 4-Digit Code, demonstrates all three of these qualities. [24,25,28-30]

Empirical studies were conducted over the course of 10 years to identify and case-define the cluster of minor facial anomalies that had the highest sensitivity and specificity to FAS.[15,25,28-30,32,42] The Rank 4 FAS facial phenotype is > 95% sensitive and specific to FAS and prenatal alcohol exposure.[28,30] Sensitivity and specificity were

confirmed to be unaffected by race, gender, and age.[25] The Rank 4 FAS facial phenotype presents across all races, is identifiable at birth, and does not diminish with age.[9] Twenty years of FASD clinic and 10 years of FAS screening in foster care bear this out. This FAS facial phenotype has been accurately measured and diagnostically classified in thousands of individuals across every race (e.g., 1,958 Caucasian, 596 African American, 360 Native American, 254 Hispanic, 48 Asian) and combination of race without limitation This is achieved by using measurement scales normalized to race, gender, and age, as appropriate. And, although it has been a long held belief in this field "*that some FAS craniofacial anomalies may be less evident at birth, become more conspicuous during early infancy and childhood, and often diminish or even disappear during adolescence and adulthood"*[5], our experience over 20 years confirms this does not hold true.[26] This belief stemmed largely from three studies published in the 1980s and 90s that assessed the qualitative change in facial features among children who presented with gestalt features of FAS.[43-45] Back then an ever growing list of minor facial anomalies was being attributed to FAS. Most of the features that were reported to diminish with age (flat nasal bridge, epicanthal folds, short upturned nose, and retrognathia): had never been confirmed to be sensitive or specific to prenatal alcohol exposure; and were remarkably consistent with descriptions of normal facial growth. Enlow and Hans[46] report that when one compares the face of a normal child to that of a normal adult, the child's nose is short and upturned, the nasal bridge is low, often resulting in epicanthal folds, and the mandible is small and retrusively placed. Interestingly, the FAS features reported not to change with age (short PFL, smooth philtrum, and a thin upper lip) are the only features that the 4-Digit Code will subsequently confirm to be sensitive and specific to prenatal alcohol exposure, and match the features originally identified as defining the face of FAS by David Smith, M.D. back in 1979. As stated by Smith.[47] "*As far as the diagnosis is concerned, perhaps the most important point to emerge in the last few years is that the facial abnormalities seen in affected infants are the key cluster of features that tend to make FAS a clinically discernible entity. Many disorders result in mental and growth deficiency, but in FAS the deficiencies are typically present in a patient whose face has short palpebral fissures, a hypoplastic upper lip with a thinned vermilion border and a smoothed or absent philtrum. Up to now, the descriptions of the facial features of FAS that have appeared in the literature have not always emphasized the same abnormalities. This has led to some confusion, but inspection of the photographs accompanying these reports leaves no doubt about the facial similarities of FAS patients*." Further evidence that the FAS facial phenotype (as defined by the 4-Digit Code) does not diminish with age stems from our experience conducting FASD diagnostic evaluations on thousands of individuals over 20 years.[26] Although we typically see individuals just once to render a diagnosis, we have seen over 100 children at two time points, typically as toddlers and again as adolescents. No child had a FAS facial phenotype that diminished with age when measured using reliable measurement techniques (eg. Lip-Philtrum Guides and FAS Facial Photographic Analysis Software[33]). We also routinely request childhood (or younger) facial photos of all patients requesting an FASD diagnostic evaluation. Among the 1,279 patients providing us with younger pictures of themselves, again, we have never seen the FAS facial phenotype (as defined by the 4-Digit Code) diminish with age.

When the diagnostic criteria for the FAS facial phenotype are relaxed, the phenotype is no longer sufficiently sensitive and specific to FAS and prenatal alcohol exposure. If the specificity falls below 95%, two fundamental problems arise. First, the diagnostic label FAS is rendered medically invalid. If you label the patient's outcome FAS, you are declaring a patient has a syndrome caused by their mother's consumption of alcohol during pregnancy.[9] But if the face is not specific to alcohol, you have no medical or scientific evidence to support this declaration of causation in an individual patient. Second, a diagnosis of FAS can no longer be made in the absence of a confirmed prenatal alcohol exposure. All current FASD diagnostic guidelines allow a

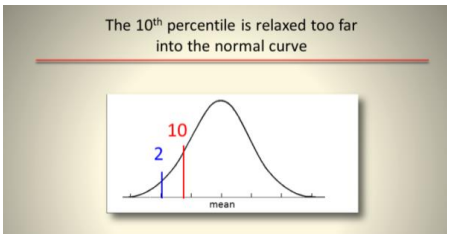
diagnosis of FAS to be rendered when prenatal alcohol exposure is unknown because the guidelines assume the FAS facial phenotype is specific to alcohol and thus can serve as confirmation of exposure. But the specificity cannot be assumed. It has to be confirmed and it has to be confirmed high. The 4-Digit Code Rank 4 face is the only FAS facial phenotype with sufficiently high specificity (>95%) to allow the outcome to be labeled FAS and allow the diagnosis to be rendered in the absence of confirmed exposure.

Two FAS/D diagnostic guidelines published subsequent to the 4-Digit Code (CDC[6] and the revised IOM[8]) relaxed the criteria for the FAS facial phenotype. Both guidelines relaxed the PFL criteria from $\leq 2^{nd}$ percentile to $\leq 10^{th}$ percentile. The revised IOM went one step further, reducing the number of required facial features from 3 to 2. Although relaxation of the criteria will reduce the specificity of the facial phenotype to FAS and prenatal alcohol exposure, neither guideline reported the specificity of their relaxed FAS facial phenotypes.

Evidence that the FAS PFL criteria should be kept at $\leq 2^{nd}$ percentile, not relaxed to $\leq 10^{th}$ percentile.

In a recently published study of 922 patients with documented prenatal exposure histories, who were evaluated by a dysmorphologist between 1978 and 2005; 1st trimester alcohol exposure correlated significantly with the presence of a smooth philtrum and thin upper lip.[48] No pattern of prenatal alcohol exposure correlated with a PFL $\leq$ 10%. The authors noted this later finding was unexpected. We too were surprised to see no correlation between short PFLs and prenatal alcohol exposure because we have always found strong correlations between these two variables. One plausible explanation for the absence of a correlation was the criterion they used to define a short PFL. The 4-Digit Code defines a short PFL as $\leq 2^{nd}$ percentile. Feldman used a more relaxed criterion; $\leq 10^{th}$ percentile. This relaxation may have relaxed the PFL too far into the normal curve (Figure 4A). To test this hypothesis, we replicated this analysis using our dataset of 1,400 patients with confirmed prenatal alcohol exposure who had undergone a FASD evaluation in the WA State FASDPN between 1993 and 2005 (Figure 4B). When the definition of a "short" PFL was relaxed to $\leq$ 10%, no correlations were found with any pattern of prenatal alcohol exposure. When the definition of a "short" PFL was set back to $\leq$ 2% (the criteria used by the 4-Digit Code), strong, significant correlations were found with quantity, frequency, and duration of alcohol exposure (Figure 4B). This provides strong evidence that the PFL criterion for the FAS facial phenotype should be set at $\leq 2^{nd}$ percentile, not relaxed to $\leq 10^{th}$ percentile.

FIG. 4AB When a short PFL is defined as ≤ 2nd percentile (as reflected in the 4-Digit Code), significant correlations are detected with prenatal alcohol exposure. When the definition is relaxed to ≤ 10th percentile (as reflected in the CDC and Revised IOM guidelines), no correlations with prenatal alcohol exposure are detected. These findings were reported by Feldman, et al[48] and replicated here using our FASDPN dataset.



A

Prenatal alcohol exposure not correlated with PFL when criteria relaxed to ≤ 10th percentile

		4-Digit PFL		CDC & Revised IOM PFL	
Prenatal Alcohol Exposure		≤ 2%	> 2%	≤ 10%	> 10%

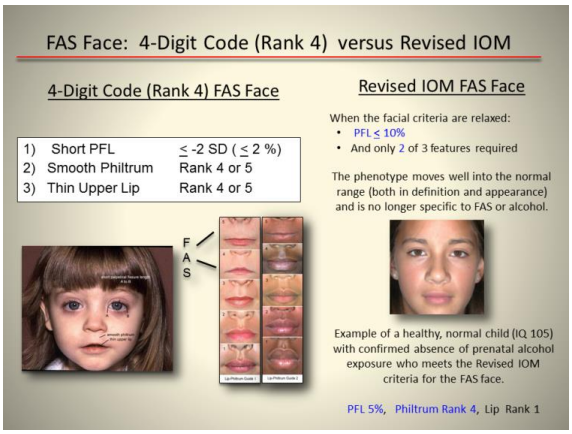
B

Evidence that the FAS facial criteria require all 3 features, not just 2 of the 3.

The Revised-IOM[8] criteria for the FAS facial phenotype relaxed the PFL to ≤ 10th percentile and requires only 2 of the 3 facial features be present. A 2006 study[23] confirmed these relaxations in the facial criteria rendered the Revised-IOM FAS facial phenotype non-specific to both prenatal alcohol exposure (specificity 75%) and FAS (specificity 68%). For reference, a specificity of 50% is equivalent to random chance; the predictive equivalent of flipping a coin. The specificity of the 4-Digit Code FAS facial phenotype to FAS and prenatal alcohol exposure is >95%. In the 2006 study, the performance of the Revised-IOM FAS criteria was assessed by applying them to two populations: 1) 952 alcohol-exposed patients evaluated in the WA FASDPN clinics, and 2) 16 healthy, high-functioning children with confirmed absence of prenatal alcohol exposure enrolled as controls in a magnetic resonance study. In this study a substantial number of patients in the FASD clinics met the Revised-IOM criteria for the full FAS facial phenotype (35%; 330 of 952 subjects), but very few of them met the Revised-IOM criteria for a diagnosis of FAS (11.8%; 39 of 330 subjects). If the Revised-IOM FAS facial phenotype were specific to FAS, then it would be expected that the vast majority of those with the FAS face would have FAS. But just the opposite was observed. The vast majority of those with the FAS face (88.2%; 291 of 330 subjects) did not

have FAS. If the Revised-IOM FAS face were specific to (caused only by) prenatal alcohol exposure, then individuals could not have the FAS face if they had not been exposed to alcohol. However, this study found that 25% of the high-functioning children with confirmed absence of prenatal alcohol exposure met the criteria for the Revised-IOM FAS face. When the facial criteria are relaxed as specified in the Revised IOM criteria, the phenotype moves well into the normal range (both in definition and appearance) and is no longer specific to FAS or prenatal alcohol exposure (Figure 5).

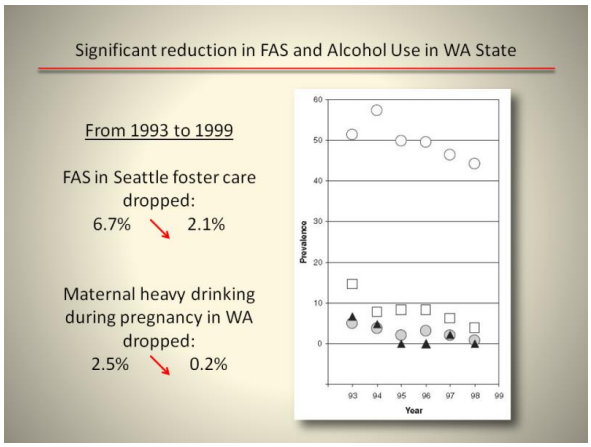
FIG. 5 When the FAS facial phenotype is relaxed[8] (photo on the right), the phenotype moves well into the normal range (both in definition and appearance) and is no longer specific to FAS or prenatal alcohol exposure.



2A.2. The Rank 4 face is so specific to FAS, it alone was used to accurately screen for FAS in a 10-year, foster care FAS screening program. This, in turn, allowed us to track the prevalence and prevention of FAS in WA State.

The high specificity of the Rank 4 FAS facial phenotype to FAS and prenatal alcohol exposure was further confirmed through a 10-year, active case-ascertainment, foster care FAS screening program conducted in Seattle.[15] If the Rank 4 FAS facial phenotype is truly highly specific to FAS and prenatal alcohol exposure, then one should be able to screen for FAS using nothing more than a facial photograph. Our 10-year foster care FAS screening program confirmed this to be true. All children entering a foster care program had their 2D digital facial photograph analyzed with the FAS Facial Photographic Analysis Software.[33,40] All children with the Rank 4 FAS facial phenotype were classified as screen-positive for FAS and received an interdisciplinary FASD diagnostic evaluation using the 4-Digit Code. The screening tool (presence of the Rank 4 FAS facial phenotype in a 2D facial photograph) performed with 100% sensitivity, 99.8% specificity, 85.9% predictive value positive and 100% predictive value negative for FAS. Over 2,500 children were screened over a period of 10 years (1999-2009) with 98% participation. This 10 year active-case-ascertainment screening program confirmed 1/100 children in foster care in the Seattle area had FAS. Data from this study would go on to confirm that the prevalence of FAS in this foster care population decreased significantly (6.7% to 2.1%)[24,34] (across successive birth cohorts) as the prevalence of heavy maternal drinking during pregnancy in WA State decreased significantly (2.5% to 0.2%) in those same years[24] (Figure 6).

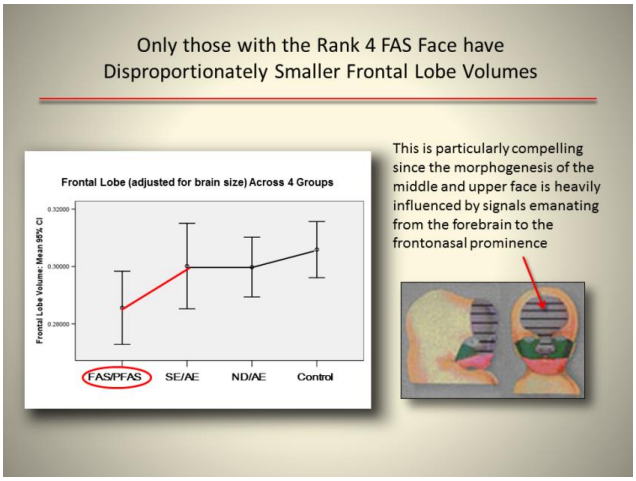
FIG. 6 The prevalence of FAS dropped significantly from 6.7% to 2.1% among children in Seattle foster care born between 1993 and 1999. This correlated with a significant decline (2.5% to 0.2%) in the prevalence of women drinking during pregnancy in WA State during those same years[24]. Key: Decline in the prevalence of alcohol use by women in Washington State from 1993 to 1998: (○) Any level of alcohol use 3 months prior to pregnancy; (□) Any level of alcohol use in the third trimester of pregnancy; (●) Heavy alcohol use (>14 drinks/week) 3 months prior to pregnancy.[34] (▲) Prevalence of FAS among children in a Seattle foster care program born from 1993 to 1998.[24]



2A.3. Individuals with the Rank 4 FAS face have significantly and disproportionately smaller frontal lobe volumes. This is particularly compelling since the forebrain plays an important role in the normal morphogenesis of the midline facial features and laboratory studies of alcohol teratogenesis report midventral forebrain deficiencies associated with facial dysmorphia in both mice and primates.

In an MRI study comparing brain volumes among children with 4-Digit Code diagnostic classifications of FAS/PFAS, SE/AE, and ND/AE, and a healthy, unexposed control group, the mean volume of the frontal lobe was significantly and disproportionately smaller in the FAS/PFAS group compared with each of the other groups.[16] (Figure 7). The FAS/PFAS group was the only group with the full Rank 4 FAS facial phenotype. This is a particularly compelling and validating finding when one considers the morphogenesis of the middle and upper face is heavily influenced by signals emanating from the forebrain to the frontonasal prominence.[49] The correlation between median facial malformations and underlying brain malformation has been known for decades.[50] The FAS facial features (short palpebral fissure lengths, a smooth philtrum and a thin upper lip) are midline anomalies derived from the anterior frontal neural crest primordia of the early forebrain.[51] Deficiencies in the numbers of crest cells most frequently affect development of the frontonasal derivatives and are usually associated with defective forebrain and eye development.[51] It has long been speculated that some extreme forms of midline facial anomalies (i.e., cyclopia, holoprosencephaly, arhinencephaly) are pathognomonic of brain malformation.[50] This speculation was further supported by the presence of a proportional increase in midventral forebrain deficiencies and the severity of facial dysmorphia in mice[52-54], nonhuman primates[29,55], and now humans.[16]

FIG. 7 The mean volume of the frontal lobe was significantly ($p < 0.05$) and disproportionately smaller in the FAS/PFAS group compared with each of the other study groups (SE/AE, ND/AE and unexposed healthy controls).[16] The FAS/PFAS group is the only group with the full FAS facial phenotype. Morphogenesis of the middle and upper face is heavily influenced by signals emanating from the forebrain to the frontonasal prominence.[49] The frontonasal prominence is the striped region in the insert depicting a 5-week (left) and 10-week (right) fetus.[56]



2A.4. The high specificity of the Rank 4 FAS facial phenotype is quintessential to the validity of all diagnoses under the umbrella of FASD, not just those labeled FAS.

Why are the criteria used to define the FAS facial phenotype so important to the medical validity of all diagnoses under the umbrella of FASD, not just the diagnosis of FAS? When one makes a diagnosis of FAS, one is stating implicitly that the individual has a syndrome caused by prenatal alcohol exposure.[9] One is also stating implicitly that the biological mother drank alcohol during pregnancy and, as a result, harmed her child. These are bold conclusions to draw and are not without medical, ethical, and even legal consequences. What happens when the FAS face is not at least 95% specific to FAS and prenatal alcohol exposure? The whole FASD diagnostic system collapses like a house of cards. Here is why.

a. The term FAS is rendered invalid. If the face is not specific to (caused only by) alcohol, it is no longer medically valid or medically ethical to label the condition fetal alcohol syndrome. You can no longer confirm alcohol is causally linked to any of the outcomes (growth, brain, or face) in an individual patient.
b. The diagnosis FAS/alcohol-exposure-unknown is also rendered invalid. If the face is not specific to (caused only by) alcohol, the FAS face can no longer serve as the confirmation of alcohol exposure when the exposure history is unknown.
c. FAS is no longer distinct from ARND. ARND is "FAS without the face". But if there is no FAS face, there is no distinction between FAS and ARND. Thus, you can no longer justify classifying FAS and ARND separately.
d. The term "ARND" remains invalid. Since ARND has no feature specific to prenatal alcohol, you are in no position to declare the Neurodevelopmental Disorder is "Alcohol-Related" (ARND) in an individual patient. This is discussed more fully below.

2B. Principle 2: The FAS facial phenotype presents along a clinically meaningful continuum.

2B.1. The FAS facial phenotype is not just present or absent. It presents along a continuum that is significantly correlated with (predictive of) abnormal brain structure and function.

The more severe the FAS face, the more severe the CNS structural/functional abnormality (Figure 8); growth deficiency (Figure 9), and duration of alcohol exposure (Figure 10).[9,26,27] We predicted back in 1999[29] that if the FAS facial phenotype was measured on a continuum, it would serve as a more sensitive indicator of teratogenic outcome than the previous practice of recording the FAS facial phenotype as simply present or absent as documented in the IOM FASD guidelines.[5] Figures 8 and 9 clearly confirm this to be true. The statistically significant linear correlations observed between the magnitude of expression of the FAS facial phenotype and brain structure and function: 1) further validate that short PFLs, a smooth philtrum, and a thin upper lip are the key diagnostic facial features, 2) are consistent with the clinical literature that midline facial defects predict underlying brain dysfunction[4,25,29,30,47,50], and 3) provide evidence that an intermediate expression of the FAS facial phenotype serves as an important clinical risk factor for brain damage caused by prenatal alcohol exposure. This continuum is important in predicting the risk for CNS dysfunction among young children who present with some or all of the FAS facial features, but are too young to engage in a comprehensive assessment of brain function.[9] The correlations between face and brain (Figure 8) also demonstrate that individuals with the full FAS facial features do have CNS structural and functional abnormalities that are significantly more severe than individuals with milder expressions of the FAS facial phenotype.[16] This is not an artifact of the criteria used to define the different FASD diagnostic subgroups. In accordance with the 4-Digit Code, FAS/PFAS and SE/AE must meet the same diagnostic threshold for severe dysfunction (CNS Rank 3 and/or 4). That said; those who meet that threshold and have the FAS facial phenotype (FAS/PFAS) have significantly more severe dysfunction, on average, than those who meet that threshold and do not have the FAS facial phenotype (SE/AE) (Fig 17). Not all published studies identify statistically significant contrasts in CNS abnormality between alcohol-exposed individuals with and without the FAS facial phenotype. This may be a reflection of the criteria used to define the FAS facial features in those studies.[57-60] We too failed to observe any correlation between face and brain when we used less rigorous methods of defining and measuring the face (e.g., the gestalt FAS facial phenotype) prior to the establishment of the 4-Digit Code.[4] When the facial criteria of the 4-Digit Code are used, significant contrasts are observed between alcohol-exposed groups with and without the FAS facial phenotype.[61]

FIG. 8 Data from the WA FASDPN clinics[26] and the MRI studies[16] confirm that the more severe the FAS facial phenotype (4-Digit Code Facial Rank 1 = no features, 2 = mild features; 3 = moderate features; 4 = severe features, presented on the x axis) the more severe the abnormalities in CNS structure and function (FSIQ; head circumference centile; visual motor integration standard score; Quick Neurological Screen Test score; prevalence of significant developmental delay; and number of significantly impaired domains of function, presented on the y axis). These statistically significant linear correlations serve to validate the 4-Digit Code FAS facial phenotype.

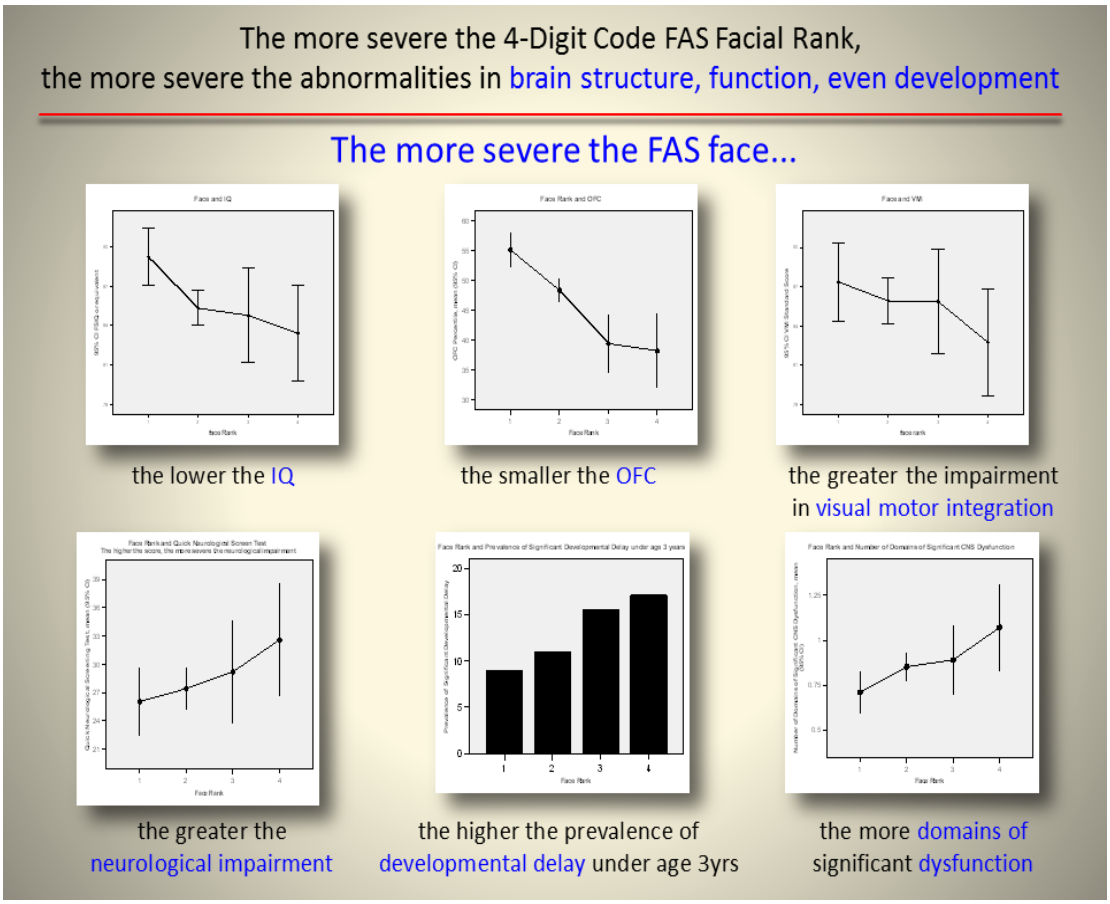


FIG. 9. Data from the WA FASDPN clinics[26] document the more severe the 4-Digit FAS facial phenotype (Facial Ranks 1-4), the more severe the growth deficiency (birth weight and length percentiles as well as weight and height percentiles at the time of the FASD diagnostic evaluation. Pictured are statistically significant linear trends.

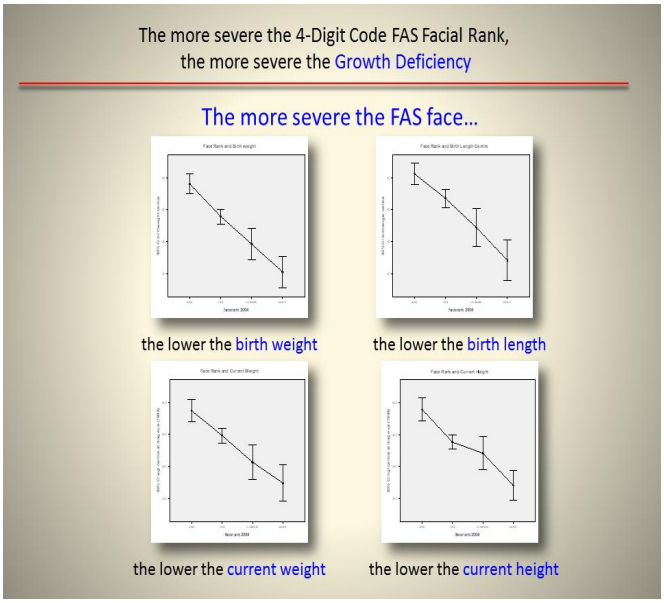

FIG. 10 Data from the WA FASDPN clinics[26] document the more severe the 4-Digit FAS facial phenotype (Facial Ranks 1-4), the greater the number of days/week of drinking during pregnancy (significant linear trend, F=10.7, p = 0.001).

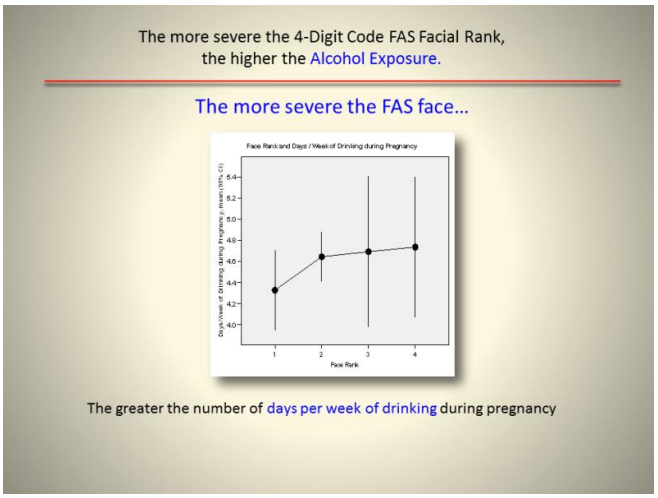
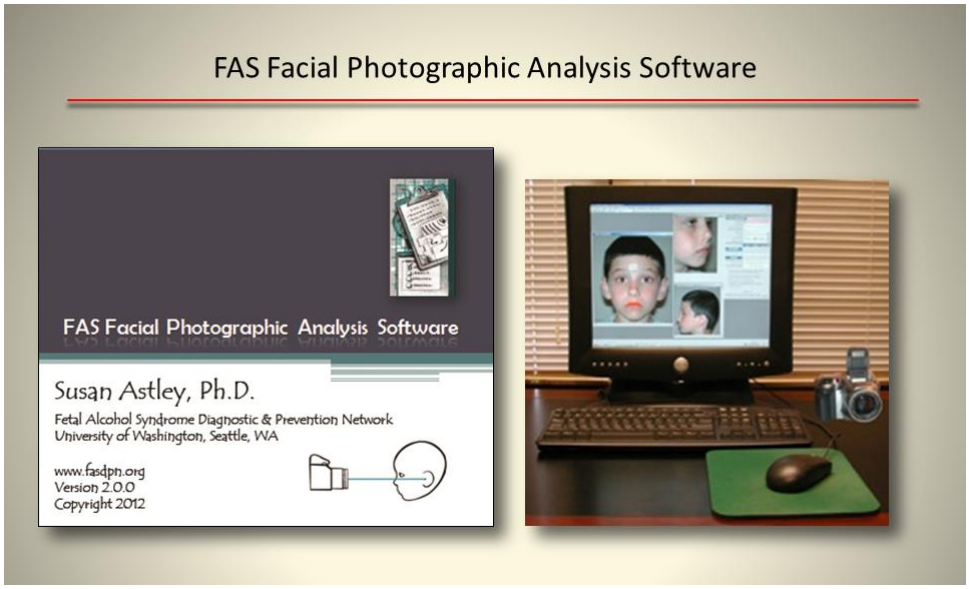


2B.2. The FAS facial features can be accurately measured from a 2D digital photo using the FAS Facial Photographic Analysis Software.

The full continuum of the FAS facial features can be easily and accurately measured from 2D digital facial photographs using the FAS Facial Photographic Analysis Software.[33,40] (Figure 11). This Windows-based software is both inexpensive ($60 USD) and User friendly. This ease, accuracy, and low cost of measurement are why a 2-dimentional (2D) format was selected over a 3D format back in 2004. This software has been used to measure and diagnostically classify the facial features of all patients (> 2,550) evaluated in the WA State FASD clinics over the past 20 years.[26] It was also used to screen over 2,000 children participating in a 10-year foster care FAS screening program in Seattle.[15] The software was used to generate the Canadian PFL normal growth charts in 2010.[62] These Canadian PFL charts were subsequently incorporated into Version 2.0 of the software in 2012.[33] The software is currently in use worldwide. A video demonstration of the software is posted on the FASDPN website.

FIG. 11 The FAS Facial Photographic Analysis Software (Version 2.0)[33] is a Windows-based program that provides accurate measurement of FAS facial features from a 2D digital facial photograph. The software has been distributed worldwide since 2004.



3. The 4-Digit Code's method for case-defining the highly variable CNS dysfunction that typifies FASD demonstrates high construct validity.

3A. The 4-Digit Code's method for classifying CNS dysfunction (CNS Ranks 1, 2, and 3) successfully predicts underlying CNS structural abnormality as it was designed to do.

An important contribution of the 4-Digit Code was the method used to case-define the highly variable, nonspecific CNS dysfunction that typifies FASD. It was important to establish a method that quantified the breadth and magnitude of dysfunction (e.g., the number of domains of function 2 or more SDs below the mean as measured by standardized psychometric tools administered by a clinician) without unduly constraining which domains must be impaired. CNS dysfunction is ranked on a 3-Point likert scale (Figure 12A). Ranks 1, 2, and 3 reflect none, 1 to 2, and 3 or more domains of dysfunction respectively. The 3 CNS Ranks in the 4-Digit Code were case-defined to predict increasing likelihood of underlying structural brain abnormality[4,9,16,26] (Figure 12B). Alcohol is a teratogen that interferes with the structural development of the fetal brain. This, in turn, can lead to abnormal function. We postulated in 1997… "*The greater the dysfunction, the higher the probability of underlying structural brain abnormality*".[1] In 2009, our MRI study confirmed this to be true![16] Many significant correlations were identified between CNS dysfunction and brain region volumes, but perhaps most striking was the significant, inverse, linear correlation between increasing CNS dysfunction (CNS Ranks 1,2 and 3) and decreasing caudate volume (Figure 12C). This is powerful evidence (construct validity) that the CNS Ranking system used by the 4-Digit Code is clinically and scientifically valid.

FIG. 12 A. The 4-Digit Code ranks CNS dysfunction on a 3-point scale (none, moderate, severe). B. The 3 CNS Ranks were case-defined to predict increasing likelihood of underlying structural brain abnormality.[4] C. MRI confirmed this to be true.[16] The more severe the CNS dysfunction (Rank 1, 2, 3), the smaller the caudate volume (significant linear trend F=13.5; p<.001; Duncan range test confirms each CNS group is significantly distinct from the others).

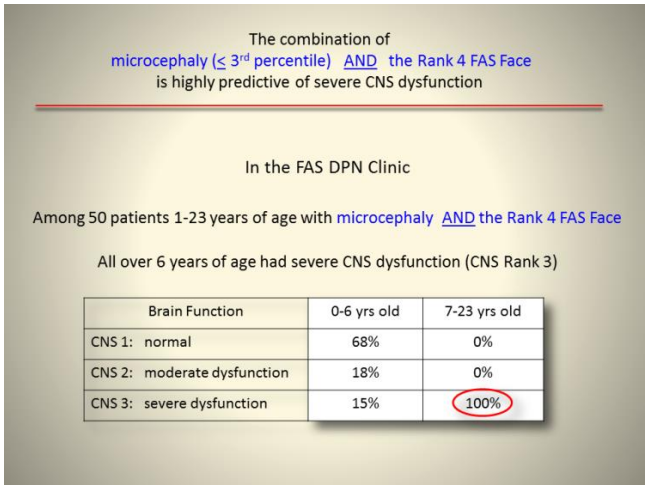
3B. Microcephaly predicts severe CNS dysfunction among infants/toddlers who present with the full Rank 4 FAS facial phenotype.

One area of discordance between current FASD diagnostic guidelines is the CNS criteria for FAS.[9] Some guidelines allow microcephaly alone to meet the CNS criteria, some guidelines do not. If severe functional abnormality is required, a diagnosis of FAS cannot be rendered in a child who is too young (typically < 6 years old) to participate in a comprehensive assessment of function (IQ, language, memory, executive function, etc). Is it clinically cogent to render a diagnosis of FAS in an infant who presents with structural evidence of CNS abnormality (microcephaly), but is too young to assess and confirm the presence of CNS dysfunction? Is the presence of microcephaly (an occipital frontal circumference (OFC) 2 or more SDs below the mean) in an infant with the Rank 4 FAS facial phenotype predictive of brain dysfunction that will not be revealed until the infant is old enough to participate in higher level functional assessments? The answers to both questions are yes.[9,26] In a cross sectional look at the first 1,400 patients evaluated in the WA FASDPN, 154 patients were diagnosed with FAS/PFAS.[26] Of the 154 patients, 69 (44.8%) had microcephaly. Of the 69 with microcephaly, 36 (52%) had no evidence of brain dysfunction (Rank 1), 14 (20%) had moderate (Rank 2) brain dysfunction, and 19 (28%) had severe (Rank 3) brain dysfunction. Did the 52% with no evidence of brain dysfunction, truly have normal function, or were they too young to accurately/comprehensively assess function? The data would suggest they were too young to assess. The subset with no evidence of brain dysfunction (Rank 1) had a mean age of 4.7 (6.0 SD) years. The subset with Rank 2 moderate dysfunction had a mean age of 7.5 (5.9 SD) years. And the subset with Rank 3 severe dysfunction had a mean age of 10.3 (5.9 SD) years. The older the patient, the more likely they revealed evidence of moderate to severe dysfunction (ANOVA F=5.8 (df 2), p=.005). Another way to look at this using our current dataset of 2,550 patients with FASD is as follows. Of all 50 patients, 1-23 years of age, who presented with microcephaly and the Rank 4 FAS facial phenotype, only 15% of the group $\leq$ 6 years of age presented with severe dysfunction (CNS Rank 3), but 100% > 6 years of age had severe CNS dysfunction (Figure 13). These analyses strongly support that rendering a diagnosis of FAS in a newborn/infant that presents with microcephaly, but is too young to assess/confirm brain dysfunction, is clinically sound. The combined presence of the Rank 4 FAS facial phenotype, microcephaly ($\leq 3^{rd}$ percentile), and prenatal alcohol exposure are highly predictive of brain dysfunction. The significant linear correlations between increasing magnitude of expression of the 4-Digit FAS facial phenotype and 1) increasing CNS dysfunction, and 2) decreasing head circumference further support this (Figure 8). Children with FAS are born with FAS. Early diagnosis affords early intervention. Postponing an FAS diagnosis in children with microcephaly, who were not old enough to participate in higher-level functional assessments, could lead to missed opportunities for early intervention.[63]

FIG. 13 Is microcephaly a sufficient measure of brain abnormality in children too young to assess for brain dysfunction? Data from the WA FASDPN clinics confirm that the combination of microcephaly and the Rank 4 FAS facial phenotype in children ≤ 6 years old is highly predictive of severe CNS dysfunction that will be evident later in childhood/adolescence once they are old enough to assess.



4. The 4-Digit Code generates four distinct diagnostic subgroups (FAS, PFAS, SE/AE, and ND/AE) under the umbrella of FASD.

4A. FAS, PFAS, SE/AE and ND/AE are clinically distinct diagnostic subgroups that span the full continuum of FASD:

The WA FASDPN clinics have conducted FASD diagnostic evaluations on 2,550 patients with prenatal alcohol exposure over 20 years (Figures 2, 14).[26] They range in age from newborn (2 days old) to adult (53 years old), with the vast majority being school-aged. The 4-Digit Code produces diagnostic subgroups (FAS, PFAS, SE/AE, and ND/AE) that are confirmed to be clinically and statistically distinct.[9,16,26,27,35] (Figures 14-17). For example, FAS presents with growth deficiency (height and/or weight ≤ 10th percentile); PFAS does not. Only FAS/PFAS have the FAS facial phenotype, significantly ($p < 0.05$) smaller frontal lobe volumes[16] (Fig 15a), and reduced choline neurometabolite levels[35] (Fig 16). Only FAS/PFAS and SE/AE (the only two groups with severe CNS dysfunction (Ranks 3) have significantly ($p < 0.05$) smaller caudate volumes.[16] (Fig 15b). FAS/PFAS have, on average, more severe CNS structural and functional abnormalities than SE/AE even though FAS/PFAS and SE/AE must meet the same diagnostic threshold for severe dysfunction (CNS Rank 3 or 4).[16] (Figures 15, 17). Those who meet that threshold and have the FAS facial phenotype (FAS/PFAS) have more severe outcomes than those who meet that threshold and do not have the FAS facial phenotype (SE/AE). SE/AE has more severe CNS dysfunction than ND/AE (Figures 15). SE/AE have more severe CNS dysfunction and a higher prevalence of CNS structural abnormalities (58%) than ND/AE. And 43% of ND/AE have, on average, one or more significantly small brain region volumes, despite their more moderate CNS dysfunction.[16] (Figure 15c).

Although functional impairment typically becomes more severe as one advances from ND/AE to SE/AE to FAS/PFAS, the one domain that is comparably and significantly impaired

across all diagnostic subgroups is adaptive function.[26] (Figure 18). Not only are the diagnostic subgroups distinct based on standardized measures of CNS structure and function, even caregivers can distinguish between these diagnostic subgroups.[26] (Figure 19). A structured 2-hour interview is conducted with the caregivers by the medical doctor paired with the psychologist or social worker. The 4-Digit Code Caregiver Interview Form (p.6 of the Diagnostic Form[3]) is used. The interview takes place before a diagnosis has been rendered and before the clinicians have even met the child. Thus the results are not biased. The outcomes presented in Figure 19 serve to validate the clinical utility of the semi-structured caregiver interview developed and used by the 4-Digit Code.

FIG. 14. A) Sociodemographic profile and B) distribution of FASD 4-Digit Code diagnostic outcomes of the 2,550 patients with prenatal alcohol exposure evaluated in the WA FASDPN Clinics over the past 20 years.

FIG. 18 Although functional impairment typically becomes more severe as one advances from ND/AE to SE/AE to FAS/PFAS, the one domain that is comparably and significantly impaired across all diagnostic subgroups is adaptive function.[26]

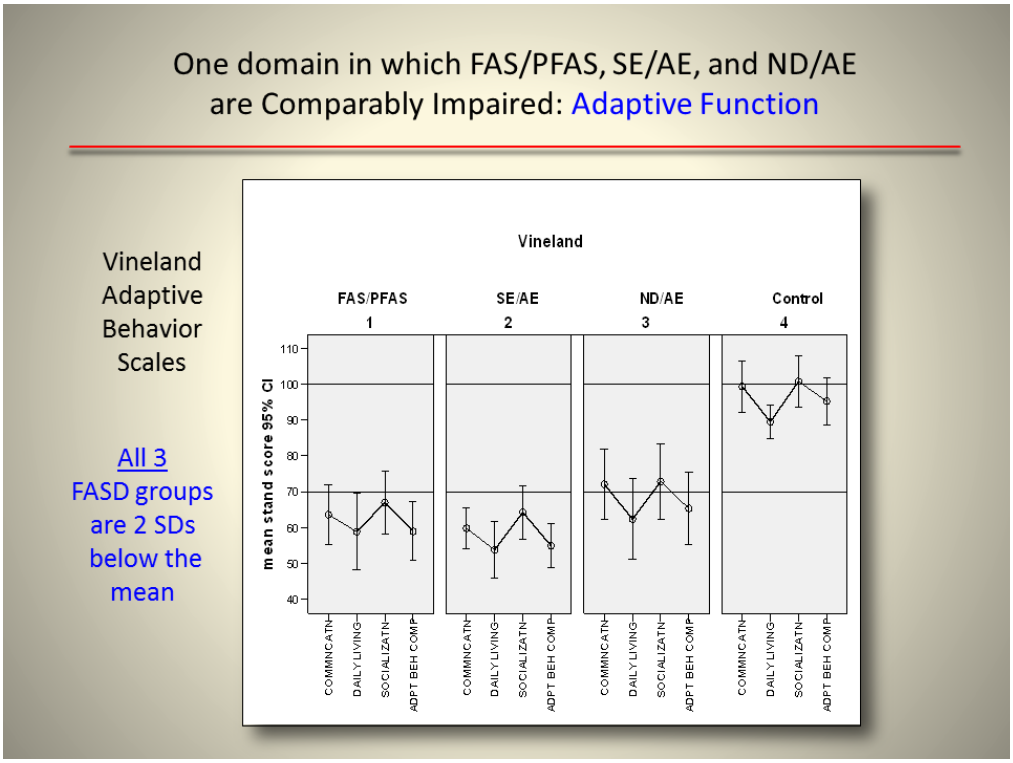

FIG. 19 Even caregivers can detect behavioral differences between the 4-Digit Code Diagnoses FAS/PFAS, SE/AE, and ND/AE.[26] A structured 2-hour interview is conducted with the caregivers by the medical doctor and psychologist using the 4-Digit Code Caregiver Interview Form (p.6 of the Diagnostic Form). The higher the bar, the more severe the child's behavioral problem reported by the caregiver.

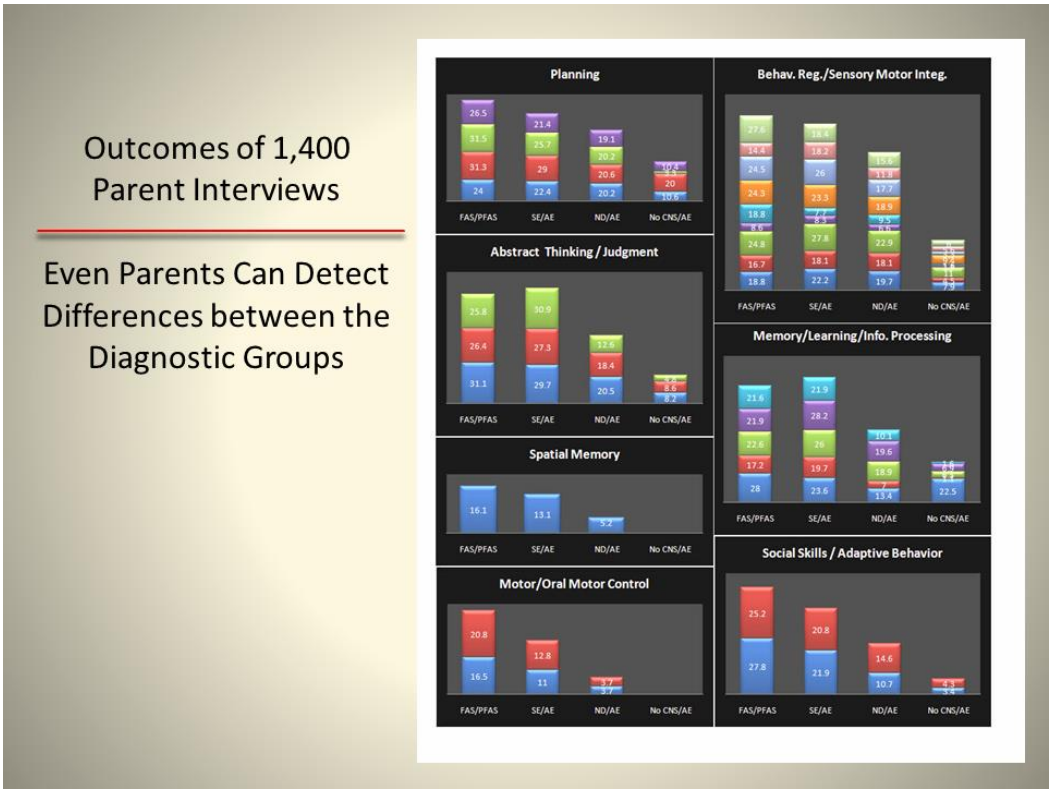

4B. Extensive evidence supports the inclusion of individuals with moderate dysfunction (ND/AE) under the umbrella of FASD.

Prenatal alcohol exposure causes the full spectrum of CNS dysfunction from moderate to severe.[17,26,64] Individuals that present with CNS dysfunction, but no physical features of FAS, are often referred to as having Alcohol-Related Neurodevelopmental Disorder (ARND).[5] The Canadian[7] and Revised IOM[8] guidelines use the term ARND to classify individuals who present with severe CNS dysfunction. Neither guideline includes a diagnostic category for individuals that present with moderate dysfunction. In contrast, the 4-Digit Code[3] has two diagnostic categories to capture the full spectrum of dysfunction: 1) Neurobehavioral Disorder/Alcohol Exposed (ND/AE) for moderate dysfunction (CNS Rank 2), and 2) Static Encephalopathy/Alcohol Exposed (SE/AE) for severe dysfunction (CNS Ranks 3 and/or 4). The evidence that supports inclusion of ND/AE (moderate dysfunction) under the umbrella of FASD is as follows. First, and most importantly, thousands of laboratory-based studies, including our nonhuman primate studies[65,66], confirm prenatal alcohol exposure causes moderate dysfunction. Not only does it cause moderate dysfunction, but moderate dysfunction is the most common outcome. Of the

2,550 alcohol-exposed patients evaluated at the WA FASDPN clinics over the past 20 years, 44% met the criteria for ND/AE[26] (Figure 20). ND/AE was the most common outcome, exceeding the prevalence of FAS/PFAS (10%) and SE/AE (24%) combined. It is important to note that alcohol is not the only risk factor contributing to adverse outcomes in our patient population.[26] (Figure 21). So what would the diagnostic distribution look like if alcohol was the only risk factor? To answer that question, we applied the 4-Digit Code to the outcomes observed in our primate model of FASD[66] (Figure 20). Remarkably, the distribution of FAS/PFAS (4%), SD/AE (30%) and ND/AE (57%) was near identical to that observed in our FASD clinical population with ND/AE being the most common outcome. And just like in our primate model, individuals with ND/AE have alcohol exposures as high as those with FAS/PFAS and SE/AE.[26] (Figure 22). Are these moderate impairments in brain function associated with underlying CNS structural abnormalities? Again, the answer is yes. Our MRI study confirmed at least 43% of individuals with ND/AE have significant CNS structural abnormalities.[16] (Figure 15C). Our extensive experience in the WA FASDPN confirms that it is the children with moderate dysfunction that fair the worst and are often in most need of diagnostic identification and intervention. These are the children that typically slip through the cracks. Their disabilities are often not severe enough in the cognitive domain to qualify them for services (only 3% have an IQ less than 70)[26], but severe enough across many other domains (Figure 23) to adversely impact their ability to fully engage in school and live productive, independent lives. Children with ND/AE received as many intervention recommendations as children with FAS/PFAS and SE/AE.[67] (Figure 24) and caregivers reported the interventions worked as well for their children as did caregivers of children with FAS/PFAS and SE/AE.[26] (Figure 31). It is important to clarify that, when we report above that there is extensive evidence to support inclusion of ND/AE under the umbrella of FASD, we are not stating that all individuals who meet the criteria for ND/AE have FASD. By definition all individuals with Fetal Alcohol Spectrum Disorder have a disorder caused, at least in part, by their prenatal alcohol exposure. But not all individuals with ND/AE necessarily have a FASD. Only the subset of individuals whose neurobehavioral disorder was caused, at least in part, by their prenatal alcohol exposure, have a FASD. This is a current inherent weakness in the umbrella term FASD. In the absence of a biomarker that can causally link an individual's alcohol exposure with their neurodevelopmental disorder, there is no way to identify which individuals with ND/AE have FASD. This same argument applies to the diagnostic classification of SE/AE and ARND. Not all individuals who meet the criteria for SE/AE (or meet the criteria for ARND using the IOM or Canadian Guidelines) necessarily have FASD. Only the subset of individuals whose CNS abnormalities were caused, at least in part, by their prenatal alcohol exposure has FASD. And once again the field of FASD currently has no way (no biomarker) to identify this subset. Until such a biomarker is identified, if such a biomarker exists, the 4-Digit Code elects to label these categories with terms that do not imply causality.

FIG. 20 Individuals with moderate dysfunction (ND/AE) make up the majority of patients (44%) seen in the WA FASDPN clinics. Alcohol is capable of causing moderate dysfunction, as demonstrated in our primate study of alcohol teratogenicity.[66] When the 4-Digit Code was applied to the outcomes in the primate study, ND/AE was the most prevalent outcome (57%). The distribution of diagnostic outcomes observed in the primate study were near identical to the distribution observed in our clinical population.

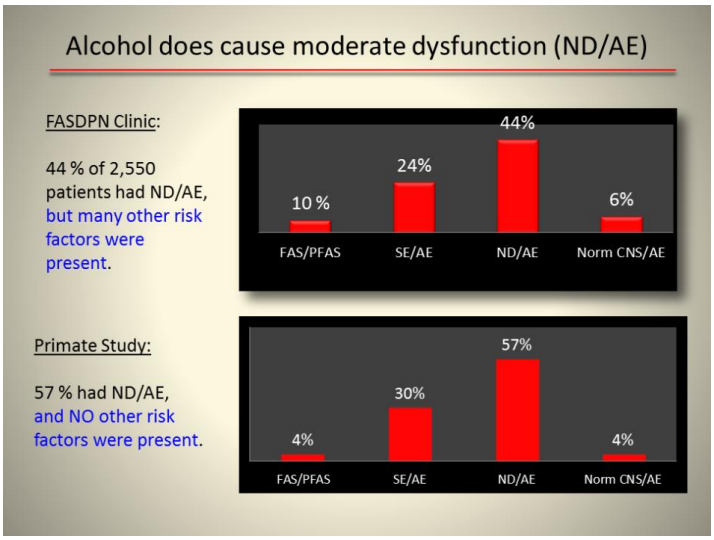

FIG. 21 Alcohol is never the only risk factor for abnormal development in a FASD clinical population. The prevalence of other risk factors among the 2,550 patients evaluated at the WA FASDPN clinics is substantial.[26]

Risk Factors Among 2,550 FASD Patients	
Prenatal alcohol exposure	100%
No prenatal care	31 %
Maternal learning disabilities	36 %
Other adverse prenatal exposures	93 %
Prenatal tobacco	62 %
Prenatal crack/cocaine	37 %
Perinatal difficulties	53 %
Foster/adoptive care	85 %
Physical abuse	34 %
Sexual abuse	24 %
Neglect	64 %
Home placements (average #)	3

FIG. 22 Among the first 1,400 alcohol-exposed patients evaluated in the WA FASDPN clinics, those with moderate CNS dysfunction (ND/AE) had alcohol exposures as high as those with severe CNS dysfunction (FAS/PFAS and SE/AE).[26]

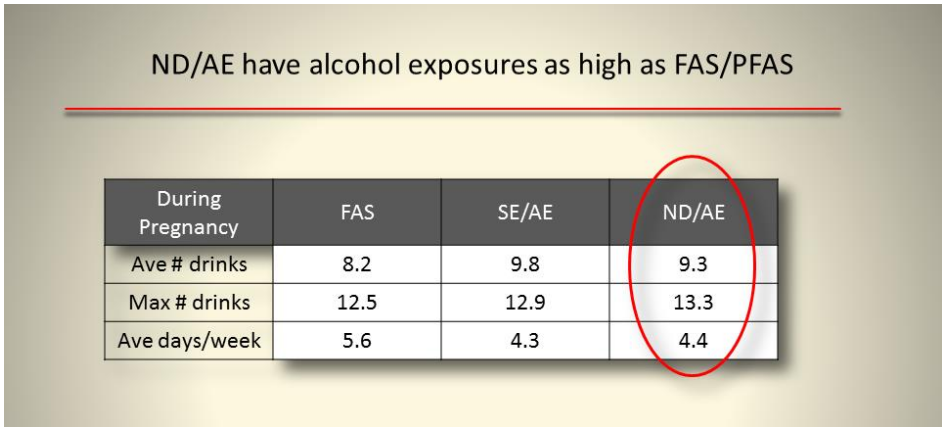

FIG. 23 Although individuals with ND/AE have less severe CNS dysfunction than FAS/PFAS or SE/AE, their disabilities span the full continuum. Their disabilities are often not severe enough in the cognitive domain to qualify them for services (only 3% have an IQ less than 70)[26], but severe enough across many other domains to adversely impact their ability to fully engage in school and live productive, independent lives.[26]

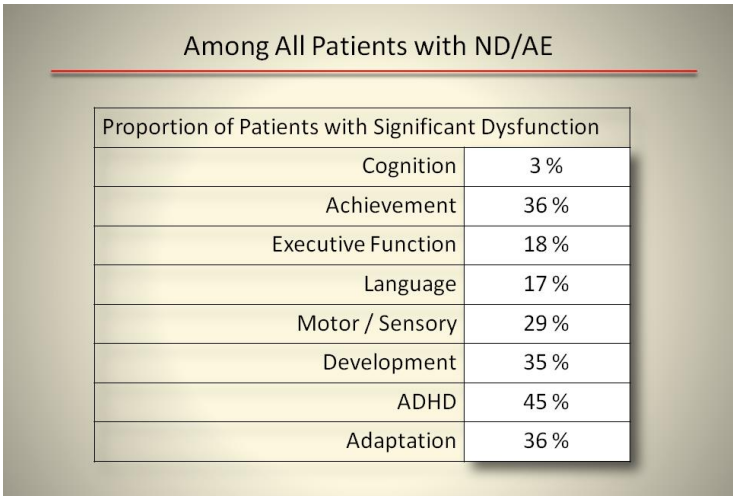

FIG. 24 Among patients evaluated in the WA FASDPN clinics, those with ND/AE received as many intervention recommendations as those with FAS/PFAS and SE/AE.[67]

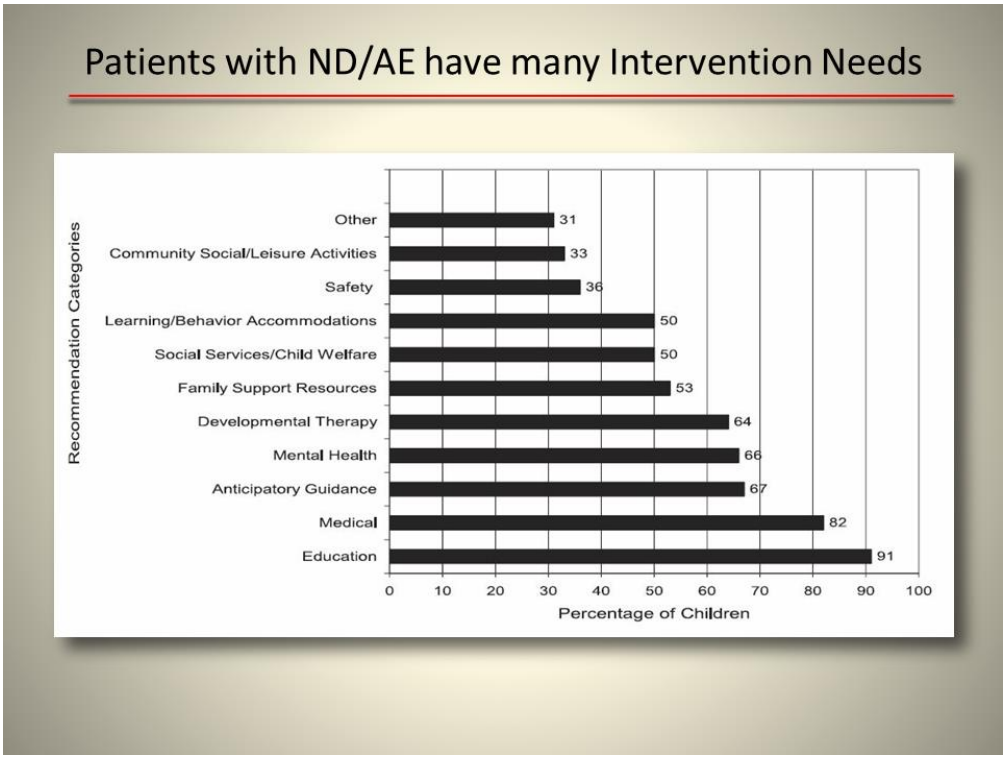

4C. The term ARND (like Fetal Alcohol Effects (FAE)) should be abandoned and replaced with medically valid terms like SE/AE and ND/AE.

The field continues to struggle with what to label the condition characterized by prenatal alcohol exposure and CNS abnormalities when the FAS facial phenotype is absent.[9] The problem with the diagnostic terms used to date (Fetal Alcohol Effects (FAE)[12] and Alcohol-Related Neurodevelopmental Disorder (ARND)[5]) is they imply that the patient's outcomes are *alcohol effects or alcohol-related.* They imply *alcohol caused the patient's* outcomes. But this presumption in an individual patient is medically invalid because the CNS abnormalities are not specific to (caused only by) prenatal alcohol exposure. There are many other known and unknown risk factors that may be partly or even fully responsible for the patient's outcome. In the absence of the FAS facial phenotype, current medical technology has no ability to confirm or rule-out the causal role of alcohol in an *individual patient*. And it is never just alcohol. There are many other known and unknown risk factors that may be partly or even fully responsible for the patient's outcome.[26] (Figure 21).

The solution to this problem is to replace the term ARND with ND/AE and SE/AE. In 1995, Aase, Jones, & Clarren proposed discontinuation of the term Fetal Alcohol Effects (FAE). "*We propose abandoning the clinical use of the term FAE with its implications of causation. A diagnosis that implies causation should not be applied unless the relationship can be proven. If prenatal alcohol exposure has taken place, but FAS cannot be substantiated, the exposure still should be indicated, and any nonspecific abnormalities or problems noted. Several*

unfortunate consequences may result from inappropriately using the term FAE: Women are stigmatized for having damaged their children by drinking during pregnancy when it is by no means certain that they have done so."[21] But, in 1996, the term Alcohol Related Neurodevelopmental Disorder (ARND) was introduced with all the same limitations of FAE.[5] In 1997, the 4-Digit Code introduced the following terms to replace ARND[1] ND/AE Neurobehavioral Disorder / Alcohol Exposed and SE/AE Static Encephalopathy / Alcohol Exposed One need not confirm a causal link between a patient's alcohol exposure and neurobehavioral disorder to provide effective intervention [26,27,63,67,68] and prevention.[24,38] Access to services should be based on a person's disability, not on what caused their disability.[9,21] Most recently, the DSM-5[69] included this FASD diagnostic subgroup under conditions for further study and chose to label it Neurobehavioral Disorder Associated with Prenatal Alcohol Exposure (ND-PAE). And the recently published recommendations for the Australian FASD diagnostic guidelines chose to label this group Neurodevelopmental Disorder-Alcohol Exposed (ND-AE).[70]

When one uses a term like ARND, one finds themself wanting/needing to require an excessive exposure to alcohol to increase the odds that the child's impairments might in fact be caused, at least in part, by their alcohol exposure. This is a dangerous road to go down. 1) Setting a threshold of excessive exposure for Alcohol-Related Neurodevelopmental Disorder (ARND) does not confirm the patient's alcohol exposure is related to their neurodevelopmental disorder. 2) Alcohol is never the only risk contributing to the neurodevelopmental disorder (Figure 21). 3) One is sending a dangerous message that lower levels of alcohol exposure are safe. 4) And one is blaming a woman for harming her child, when they have no ability to make/defend such a claim. These claims have medical, ethical and even legal consequences.

The WA FASDPN has effectively case-defined, diagnosed, and referred children with "ARND" for intervention services using the 4-Digit Code for 20 years, without calling it ARND. Of the 2, 550 patients with FASD diagnosed in the first 20 years.[26]

- 1,122 were diagnosed with ND/AE (moderate "ARND)
- 612 were diagnosed with SE/AE (severe "ARND)
- 100% have confirmed alcohol exposure, most with exposures as high as those with FAS (Figure 22).
- All risk factors are documented and reported in the medical record, not just the alcohol exposure (Figures 25, 26).
- All receive comprehensive intervention recommendations (Figure 24).[67]
- It is a child's disability, not their exposure that qualifies them for services.
- 84% of families report the intervention services met all or most of their needs. (Figure 31)

The term ARND is not needed to qualify a patient for services. There tends to be a strong belief among some families and clinicians that the only diagnosis that will qualify a child for services is FAS. Along the same lines, it is also believed that the outcome must be blamed on (linked to) the alcohol (e.g., ARND) for a child to qualify for services. Twenty years of family surveys in the WA State FASD clinics confirm that a diagnosis of FAS or ARND is not required to access and benefit from services. Families whose children received a diagnosis of SE/AE or ND/AE were as likely to access and benefit from services as families whose children received a diagnosis of FAS or PFAS.[26] (Figure 31)

FIG. 25 The 4-Digit Code provides generic descriptions of all FASD diagnostic subgroups, including the text above for SE/AE.[3] It is a standard of practice with the 4-Digit Code to clearly state that alcohol is not the only risk factor that could be contributing to a patient's outcomes.

Medical Summary

Final Diagnosis: Static encephalopathy / Alcohol exposed

Fetal Alcohol Syndrome (FAS) is defined by evidence of growth deficiency, a specific set of subtle facial anomalies, and evidence of central nervous system (CNS) damage/dysfunction occurring in patients exposed to alcohol during gestation. Not all individuals exposed to alcohol during gestation have FAS.

In this patient's case, no growth deficiency or characteristic set of facial features were found so the patient does not have FAS, but there was evidence of significant CNS damage/dysfunction as you will see noted on the attached pages. There was also a clear history of exposure to significant amounts of alcohol during gestation. In this situation, we use the term "static encephalopathy" to describe the patient's condition. On the attached sheets are the specific findings in this patient's case that led us to this conclusion. The diagnosis of static encephalopathy does not mean that alcohol is the only cause of the problem. A number of other factors could be contributing to the present issues such as the patient's genetic background, other potential exposures or problems during pregnancy, and various experiences since birth. These kinds of differences may partly explain why there is so much variability in the kinds of specific difficulties that patients with static encephalopathy face.

Individuals with significant CNS abnormalities have structural, neurological, and/or cognitive/behavioral evidence of CNS damage/dysfunction, and should be viewed as individuals with disabilities. The diagnosis of static encephalopathy has implications for educational planning, societal expectations, and health. On the attached sheet you will find a list of specific problems that have been identified that need attention.

5. The 4-Digit Code's method of documenting prenatal alcohol exposure not only detects significant correlations between exposure and outcomes, but also detects exposure patterns that distinguish the diagnostic subgroups.

5A. The 4-Digit Code form used to document prenatal alcohol exposure is both effective and sensitive.

The 1-page standardized form (Figure 26) used to record prenatal alcohol exposure effectively addresses the challenges inherent in obtaining these exposure histories.[3] Full, accurate exposure information is rarely available in a FASD diagnostic clinical setting (Figure 29). Nevertheless, significant correlations are detected between prenatal alcohol exposure and measures of growth deficiency, facial phenotype, and CNS structural and functional abnormalities.[26] For example, frontal lobe volume was found to decrease significantly with increasing number of drinks per drinking occasion and duration of exposure during pregnancy.[16] (Figure 27A). Even patterns that significantly distinguish FAS/PFAS from SE/AE are detected.[9,26] (Figure 27B). And when measures of prenatal alcohol exposure among the 2,550 patients evaluated at the FASDPN clinics over the past year are assessed, the prevalence of drinking all three trimesters declines significantly when plotted across the patients' 30 birth cohorts dating back to 1980 (Figure 27C). As noted above, when the gestalt method of diagnosis[13] was practiced in the FASDPN in the early 1990's, no correlations between alcohol and patient outcomes were detected.[4]

FIG. 26 The 4-Digit Code provides a 1-page standardized form (page 8 of the Diagnostic Form) to record prenatal alcohol exposure that effectively addresses the challenges inherent in obtaining these exposure histories.[3]

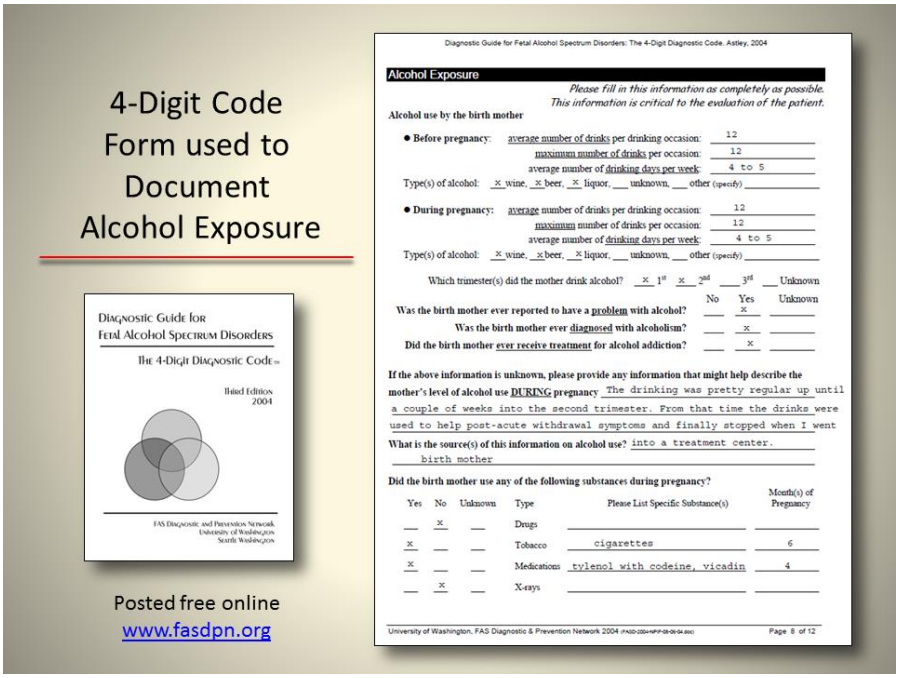

FIG. 27 The 4-Digit Code's method of documenting prenatal alcohol exposure: (A) not only detects statistically significant correlations between exposure and outcomes[16], but also (B) detects statistically significant exposure patterns that distinguish the diagnostic subgroups[26], and (C) detects significant declines in exposure over time.

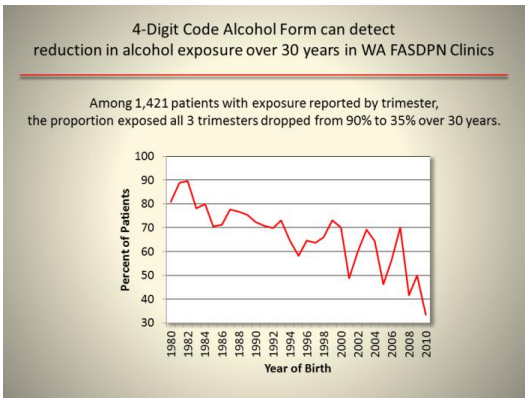
B

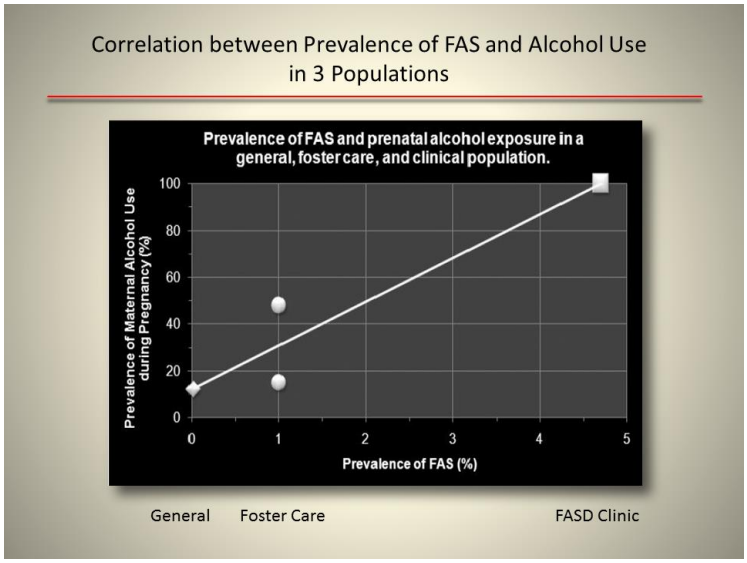


C

5B. The prevalence of maternal alcohol use during pregnancy correlates with the prevalence of FAS as defined by the 4-Digit Code

Two studies document a significant correlation between the prevalence of maternal alcohol use during pregnancy and prevalence of FAS as defined by the 4-Digit Code. In a 10-year active case-ascertainment FAS screening program of foster care in Seattle, WA, the prevalence of maternal drinking during pregnancy in Washington State measured through PRAMS declined significantly (p <0.001) from 1993 to 1998 as did the prevalence of fetal alcohol syndrome among foster children born across those same years (P <0.03) (Figure 6).[24] In a second study, the correlation between the prevalence of FAS to the prevalence of prenatal alcohol exposure across three population bases (the FASDPN clinic, a Seattle foster care program, and the general U.S. population), a significant linear trend was revealed (Figure 28).[26]

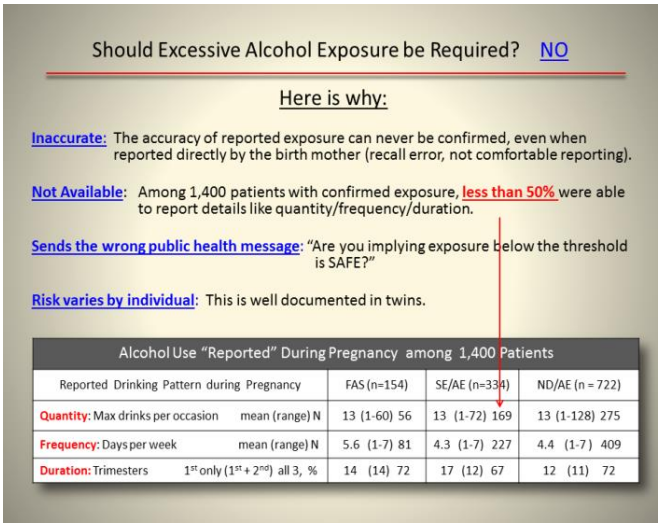
FIG. 28 Prevalence of FAS and prevalence of maternal alcohol use during pregnancy in three populations.[26] ◆General U.S. population (FAS = 0.2%[70], alcohol use = 12.2%). ●King County WA foster care population (FAS = 1%, alcohol use = 15% to 48%).[24] ■ WA FASDPN clinical population (FAS = 4.7%, alcohol use = 100%).[26] Best fit linear trend line: y = 18.989x + 12.352; R-squared = 0.89.



5C. An 'excessive' alcohol exposure history should not be required for a diagnosis the umbrella of FASD.

There remains no clear scientific consensus on what quantity, frequency, and duration of exposure is toxic to the fetus. There are a multitude of reasons for this.[9] 1.) As our tools for measuring outcome become more sensitive, our ability to identify adverse outcomes at lower exposures increases.[72] 2.) Risk from alcohol exposure varies between fetuses[73], even between fraternal twins with ostensibly identical exposure.[74,75] It is not uncommon for one fraternal twin to have full FAS, while the other appears unaffected. Identical twins are typically identically affected. 3.) From a public health perspective, requiring excessive exposure implies lower levels of exposure are 'safe'. Safe for who? 4.) From a research perspective, artificially linking outcome to a threshold level of high exposure prevents assessing the true relationship between exposure and outcome. 5.) From a clinical perspective, if an "excessive" exposure is required, it would be difficult to rationalize why an individual with all the features of FAS would receive a diagnosis of FAS if their exposure was unknown, but would fail to receive a diagnosis of FAS if their exposure was confirmed, but reportedly not excessive. This implies that practitioners have the ability to confirm the accuracy of exposure histories. They do not. Even a birth mother can have difficulty accurately recalling her alcohol use during a pregnancy, especially if that pregnancy was years ago. Among the first 1,400 patients with a confirmed prenatal alcohol exposure evaluated in the WA FASDPN clinics, less than half had measures of quantity, frequency, and duration of alcohol exposure available.[26] This information would be required if an excessive exposure history had to be confirmed. "Excessive"alcohol exposures should not be required for FASD diagnoses (Figure 29). To minimize incorrectly linking a prenatal alcohol exposure to an outcome in an individual patient, diagnostic guidelines should confirm their definition of the FAS facial phenotype is highly specific to prenatal alcohol exposure, avoid use of terms like ARND that imply causality, and report all risk factors that may be contributing to an individual's outcomes, not just the alcohol.

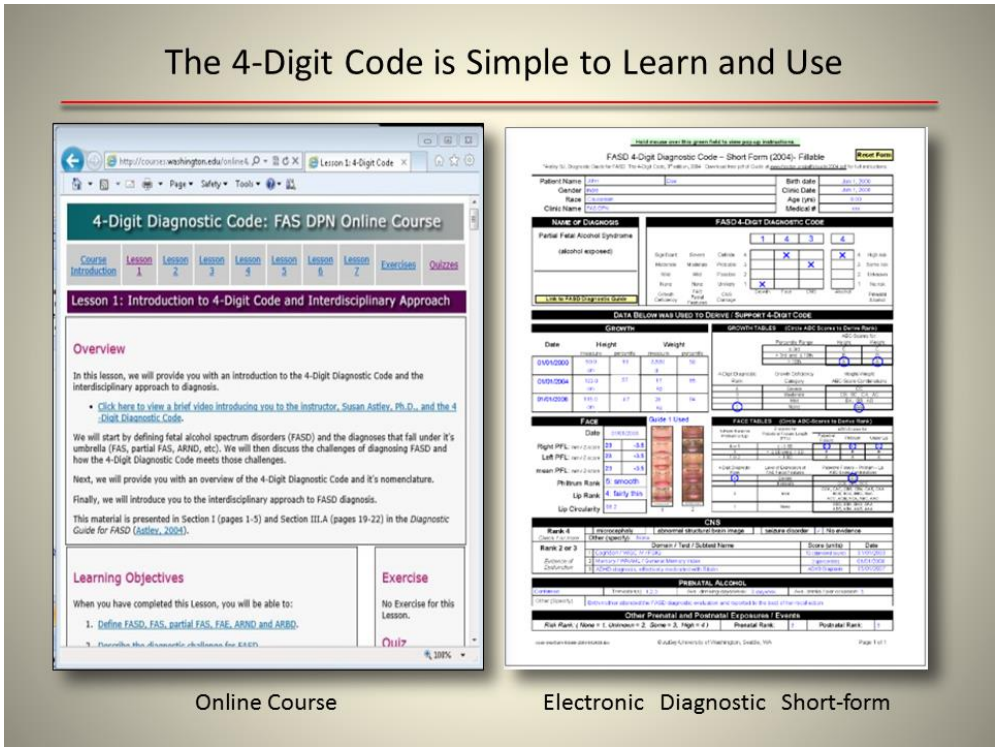
FIG. 29 Four reasons why an FASD diagnostic guidelines should not require 'excessive' prenatal alcohol exposure.[9]



6. The 4-Digit Code has been effectively and efficiently taught to interdisciplinary FASD diagnostic teams worldwide through an inexpensive Online Course.

Clinicians report high satisfaction with the 4-Digit Code. The 4-Digit Code was designed to be a self-taught coding system that could be implemented by simply following the directions provided in the FASD 4-Digit Diagnostic Guide.[1-3] For clinical teams who prefer a more comprehensive introduction to FASD diagnosis and instruction on the use of the 4-Digit Code, the FASD 4-Digit Code Online Course was developed in 2004.[41] (Figure 30A). The Online course is an individual-start, self-paced, fully online program that includes readings, exercises, self-grading quizzes and videos of an entire FASD diagnostic evaluation conducted by the UW FASD interdisciplinary team. Over 700 professionals worldwide have completed the accredited course. Surveys of hundreds of clinicians over 20 years confirm: 93% of professionals describe the 4-Digit Code as clear and 99% of professionals report they would recommend it to others. The 4-Digit Diagnostic Code is practical to use. The Code can be administered using nothing more than the Lip-Philtrum Guides and the 1-page 4-Digit Code Short Form programmed to derive the 4-Digit Code from data entered (Figure 30b) (available free online).

FIG. 30 A. The FASD 4-Digit Code Online Course.[41] B. The 4-Digit Code Short Form is a free pdf posted online that is programmed to generate the 4-Digit Code from data entered into the form.



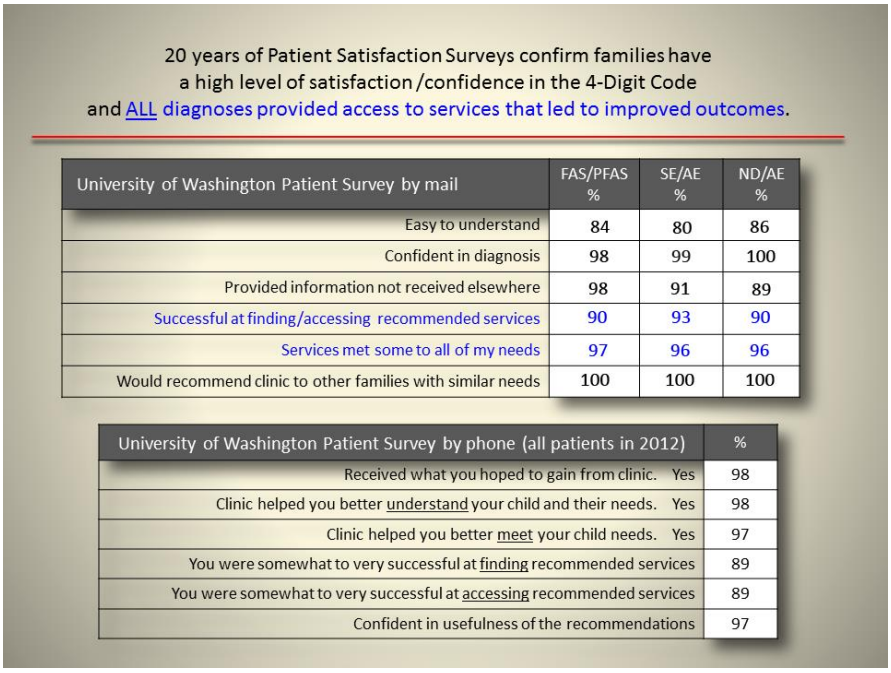
7. The 4-Digit Code has high inter-rater reliability (reproducible) across clinics.

Inter-rater reliability was confirmed to be high prior to the release of the 4-Digit Code, as described above in section 1D, and continued to be high over the next 18 years. Inter-rater reliability between the seven WA FASD Network clinics and the University of Washington Core clinic resulted in an exact match on diagnostic category for 93% of the 677 FASD diagnostic evaluations they conducted over 18 years (Kappa = 0.92, p = 0.000). The most common source of error was facial measurement when the FAS Facial Photographic Analysis software was not used. For example, when clinician's used the six inch plastic ruler to measure the PFL, their measures were on average 1 to 2 mms below the measure derived using the FAS Facial Photographic Analysis Software. This is the direction of error that would be expected due to the slight curvature of the facial plane as demonstrated in an animation on the FASDPN website. A 1-2 mm error can have a significant impact on diagnostic classification accuracy. For example, if a 7 year old girl had PFLs that were truly well within the normal range (25 mm; only 0.4 SDs below the population mean for girls her age[76]), a 1 mm under-estimate (24 mm) would make the PFLs falsely appear to be 1.3 SDs below the mean and thus falsely appear to meet the PFL criteria for the FAS facial phenotype using the CDC or Revised IOM FASD guidelines ($\leq 10^{th}$ percentile or $\geq$ 1.28 SDs below the mean). A 2 mm under-estimate (23 mm) would make the PFLs falsely appear to be 2.1 SDs below the mean and thus falsely appear to meet the PFL criteria for the FAS facial phenotype using the 4-Digit Code ($\leq$ 2 SDs below the mean). Measuring PFLs with a handheld ruler has been confirmed to be highly inaccurate and variable based on data collected over 20 years at the WA FAS DPN. Among eight clinicians measuring PFLs directly with a ruler on 52 to 322 patients each, 12% to 50% of their measurements were 1 or more mm above or below the PFL measured from the child's facial photo using the Facial Software. Six clinicians routinely under-estimated the PFL, two routinely over-estimated the PFL, and one was as likely to overestimate the PFL as underestimate the PFL. The FAS Facial Photographic Analysis Software[33] was developed to overcome these measurement errors and is used by the WA FASDPN as a standard of medical practice for all diagnostic evaluations.

8. Families report high satisfaction and confidence with the interdisciplinary approach to FASD diagnosis using the 4-Digit Code.

Twenty years of patient satisfaction surveys confirm families have a very high level of satisfaction and confidence in the 4-Digit Code administered by an interdisciplinary team.[26] (Figure 31). A 10-question patient satisfaction survey has been sent to all patients evaluated at the UW FASDPN clinic since 1993. The survey may be completed anonymously and comes with a stamped, addressed return envelope to maximize participation in the survey. Patients universally expressed high satisfaction for the FASD diagnostic services provided by the University of Washington (Figure 31). One hundred percent would recommend the Clinic to other families with similar needs. Overall, 92% said they received information they were unable to obtain elsewhere, despite the fact the clinic is located in a large metropolitan area (Seattle) with many genetic, neurodevelopmental, and psychological evaluation services available. Overall, 83% found the explanation of the diagnosis using the 4- Digit Code easy to understand.

FIG. 31 Twenty years of patient satisfaction surveys confirm families have a very high level of satisfaction and confidence in the 4-Digit Code administered by the University of Washington interdisciplinary diagnostic team.[26] Family's whose child received a diagnosis of SE/AE or ND/AE were as likely to report successfully accessing and benefiting from recommended intervention services as family's whose child received a diagnosis of FAS/PFAS.



9. Patient follow-up surveys report all FASD diagnoses (FAS, PFAS, SE/AE, and ND/AE) provided equal access to intervention services that led to improved outcomes.

Perhaps most informative; family's whose child received a diagnosis of SE/AE or ND/AE were as likely to report successfully accessing and benefiting from recommended intervention services as family's whose child received a diagnosis of FAS/PFAS.[26] (Figure 31). This is in contrast to the oft stated belief that a family will not qualify for services if the diagnosis is not FAS/PFAS or at least given a name that implies alcohol is the causal agent (e.g., ARND). Overall, 82.1% of families reported being somewhat to very successful in finding the recommended intervention services and 83.7% reported these services met some to all of their needs.

CONCLUSION

Accurate, reliable, diagnoses across the full continuum of FASD have been available to families and clinicians for over a decade. As medical technology and our understanding of FASD advance, so must our diagnostic methods and tools. It is imperative that advancements in diagnostic methods be guided by an evidence base of rigorously designed, implemented, and peer-reviewed research. When a diagnosis under the umbrella of FASD is made, two individuals are affected directly; the child and the birth mother. The consequences of an incorrect diagnosis for

both mother and child must be considered carefully. Diagnostic guidelines should guide professionals in rendering an accurate diagnosis. A diagnosis reflects the condition of a patient; however, because a diagnosis serves many purposes (e.g., treatment, prevention, communication among specialists, and qualification for services), the process of rendering a diagnosis can sometimes be influenced by those different purposes. The only diagnosis that serves all purposes most effectively is a correct diagnosis. Access to services should be based on an individual's disabilities and not on what caused their disabilities. Services should be available for individuals across the full continuum of FASD, not just those with FAS.

Acknowledgments

The WA FAS DPN has been supported over the past two decades by the following organizations: Centers for Disease Control and Prevention (1992-1997); Western Washington Chapter of the National March of Dimes Birth Defects Foundation (1995); Washington State Department of Social and Health Services, Division of Alcohol and Substance Abuse through the passage of Senate Bill SB5688 (1997-present); and the Chavez Memorial Fund (2002-present). Support has also received from the Center on Human Development and Disability, University of Washington since 1993 (National Institute of Child Health and Human). The creation of the FAS DPN clinical dataset would not have been possible without the extensive clinical efforts and support of the interdisciplinary diagnostic teams and community health/social service agencies in Seattle, Everett, Federal Way, Tacoma, Yakima, Spokane, and Pullman. And finally, special thanks are extended to the patients and their families for their benevolent contributions to the WA FAS DPN dataset.

What Is a TIP?

The Treatment Improvement Protocol (TIP) series, which has been published by the Substance Abuse and Mental Health Services Administration (SAMHSA) within the U.S. Department of Health and Human Services (HHS) since 1993, has generally offered best-practices guidelines for the treatment of substance use disorders. For this TIP, the Center for Substance Abuse Prevention (CSAP), a sub-agency within SAMHSA, has drawn on the experience and knowledge of clinical, research, and administrative experts. As behavioral health disorders are increasingly recognized as a major problem, the audience for the TIPs is expanding beyond public and private treatment facilities to include practitioners in mental health, criminal justice, primary care, public health, and other healthcare and social service settings.

The recommendations contained in each TIP are grounded in an evidence base. Evidence includes scientific research findings and the opinion of the TIP consensus panel of experts that a particular practice will produce a specific clinical outcome (measurable change in client status). In making recommendations, the consensus panel engages in a process of "evidence-based thinking" in which they consider scientific research, clinical practice theory, practice principles, and practice guidelines, as well as their own individual clinical experiences. Based on this thinking, they arrive at recommendations for optimal clinical approaches for given clinical situations. Relevant citations (to research outcome reports, theoretic formulations, and practice principles and guidelines) are provided.

TIP Format

This TIP is organized into three parts:

- Part 1 for behavioral health practitioners focuses on providing appropriate counseling methods and frameworks.
- Part 2 for program administrators focuses on providing administrative support to implement adoption of the counseling recommendations made in Part 1.
- Part 3 for clinical supervisors, program administrators, and interested practitioners is an online literature review that provides an in-depth look at relevant published resources. Part 3 will be updated regularly following publication of the TIP.

Ideally, it is envisioned that a supervisor might assemble a small group of counselors, distribute copies of this TIP (which are free), and begin a series of six or so meetings where the materials in the TIP would be reviewed, discussed, and in other ways used as an educational and training vehicle for the improvement of treatment skills (with the particulars of how this training would

be done determined by the individual supervisor, based upon her or his unique situation, needs, and preferences). Thus, after a relatively short period of time and with only limited additional resources, this TIP could help to meet the challenge of fostering a specific kind of improvement in service delivery.

Development Process

The need for this TIP was identified through a collaborative discussion with leadership from each of SAMHSA's three Centers; CSAP, the Center for Substance Abuse Treatment (CSAT), and the Center for Mental Health Services (CMHS). Two consensus panels of experts were convened; one for clinical issues, and the other for administrative guidelines. The TIP was then field reviewed by an external group of subject matter experts, who provided suggestions for further refining the document (see appendix J).

TIPs Online

TIPs can be accessed via the Internet at **http://store.samhsa.gov/home**. The online *Addressing Fetal Alcohol Spectrum Disorders: Part 3, A Review of the Literature*, which will be updated periodically, is available at **http://store.samhsa.gov/home**.

Terminology

Throughout the TIP, the term "behavioral health" is used to refer to both substance abuse treatment and mental health settings. (The term can, in fact, refer to many types of health settings, but the primary audiences for this TIP are substance abuse treatment and mental health providers.) The term "substance abuse" has been used to refer to both substance abuse and substance dependence (as defined by the *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* [DSM-5] [American Psychiatric Association 2013]). This term was chosen partly because substance abuse treatment professionals commonly use the term "substance abuse" to describe any excessive use of addictive substances. In this TIP, the term refers to the use of alcohol as well as other substances of abuse. Readers should note the context in which the term occurs in order to determine what possible range of meanings it covers; in most cases, however, the term refers to all varieties of substance use disorders described by the DSM-V.

Foreword

The Treatment Improvement Protocol (TIP) series supports SAMHSA's mission of building resilience and facilitating recovery for people with or at risk for mental or substance use disorders by providing best practices guidance to clinicians, program administrators, and payors to improve the quality and effectiveness of service delivery and, thereby, promote recovery. TIPs are the result of careful consideration of all relevant clinical and health services research findings, demonstrated experience, and implementation requirements. Clinical researchers, clinicians, and program administrators meet to debate and discuss their particular areas of expertise until they reach a consensus on best practices. This panel's work is then reviewed and critiqued by field reviewers.

The talent, dedication, and hard work that TIP panelists and reviewers bring to this highly participatory process have helped bridge the gap between the promise of research and the needs of practicing clinicians and administrators to serve, in the most scientifically sound and effective ways, people who abuse substances. We are grateful to all who have joined with us to contribute to advances in the substance abuse treatment field.

How This TIP Is Organized

This TIP is divided into three parts:

- *Addressing Fetal Alcohol Spectrum Disorders, Part 1: Background and Clinical Strategies for FASD Prevention and Intervention*
- *Addressing Fetal Alcohol Spectrum Disorders, Part 2: Administrator's Guide to Implementing FASD Prevention and Intervention*
- *Addressing Fetal Alcohol Spectrum Disorders, Part 3: Literature Review*

Parts 1 and 2 are presented in this publication; Part 3 is available only online, at **http://store.samhsa.gov/home**. Each part is described below.

Part 1 of the TIP is for behavioral health providers and consists of three chapters:

- Chapter 1 discusses approaches to preventing FASD; that is, assisting women who are in treatment settings and are pregnant or may become pregnant to remain abstinent from alcohol. In providing these guidelines, this TIP adopts the Institute of Medicine (IOM) model for prevention, which sees prevention as a step along a continuum that also incorpo rates treatment and maintenance.
- Chapter 2 discusses methods for identifying individuals in treatment who have or may have an FASD, referring them for diagnosis where possible, and providing appropriate interventions to meet their needs.
- Chapter 3 provides clinical vignettes designed to realistically portray the provider–client interactions that might take place when providing FASD prevention or interventions.

Part 2 is an implementation guide for program administrators and consists of two chapters.

- Chapter 1 lays out the rationale for the approach taken in chapter 2 and will help readers understand how administrators can provide support for programs and counselors as they address FASD. It is hoped that this knowledge will enhance the ability of treatment programs to address FASD concurrently with other behavioral health needs; addiction, mental health issues, etc.
- Chapter 2 provides detailed information on how to achieve high-quality implementation of the recommendations in ***Part 1***.

Part 3 of this TIP is a literature review on the topic of FASD and is available for use by clinical supervisors, interested counselors, and administrators. *Part 3* includes literature that addresses both clinical and administrative concerns. To facilitate ongoing updates, the literature review will only be available online at **http://store.samhsa.gov/home**.

Preface

Giving Voice to a Hidden Population

- A woman gives birth to a child with a Fetal Alcohol Spectrum Disorder (FASD); no one told her that alcohol consumption during pregnancy could harm the baby.
- A man is repeatedly kicked out of various forms of treatment for noncompliance; he never means to be noncompliant, his special needs and lack of understanding are simply never recognized.
- A teen-aged girl doesn't receive appropriate screening for alcohol use during her pregnancy; her child is removed when she's identified with a substance use disorder, and her child is later found to have an FASD.
- A man repeatedly loses jobs because he can't "follow orders;" he ends up homeless and cycles repeatedly through the social service system.

These stories are not unusual. They are not "worst case scenarios." They are the all-too-common realities of people with an FASD, or women who wanted to have a healthy child but weren't given the basic help they needed before and during pregnancy. And sometimes these realities overlap.

Addressing Fetal Alcohol Spectrum Disorders was written to help you offer hope to these individuals when they present in your setting. This TIP will not ask you to implement a whole new way of treating clients, although you may discover alternative approaches that you want to explore. Rather, it asks you to see people who have or may have an FASD as you see any individual in your care with a significant co-occurring life issue that should be recognized and incorporated into treatment planning. This TIP also asks you to see pregnant women who consume alcohol not through a lens of judgment but as women in need, for whom even a few minutes of information and education can make a lifetime of difference for their health and the health of their babies.

This TIP is also about hope for you as a substance abuse or mental health treatment professional because it gives you another way to view the clients who "just don't get it" or who seem to want to succeed in treatment but can't follow directions, don't make it to appointments, grow restless in group sessions, or generally seem "resistant" with no clear explanation. You can "reframe" your thinking about these clients. Not all of these cases will be explained by FASD, obviously, but making FASD awareness a part of the culture of your agency widens the net of understanding that you can offer to your clients and increases your staff's capabilities for achieving positive outcomes with a higher percentage of them.

Ultimately, SAMHSA's goal is to provide knowledge and assistance to help substance abuse and mental health treatment programs better serve their clients. Providing FASD-informed services is a part of that mission, and is the guiding principle behind the publication of this TIP. Thank you for taking the time to read this publication, and for potentially making a difference for a population that should not remain hidden any longer.

Executive Summary

Introduction

About FASD

Overview

Fetal Alcohol Spectrum Disorders (FASD) is a non-diagnostic umbrella term describing the range of effects that can occur in an individual whose mother consumed alcohol during pregnancy. These effects may include physical, mental, behavioral, and/or learning disabilities with possible lifelong implications. As is discussed in greater detail later in this TIP, these disorders often co-occur with substance abuse and mental health issues, and generally require treatment modifications for successful outcomes. They are 100 percent preventable, however, if those at risk of consuming alcohol during pregnancy are identified and effective prevention strategies are used.

Possible diagnoses within the spectrum include Fetal Alcohol Syndrome (FAS), Partial Fetal Alcohol Syndrome (pFAS), Alcohol-Related Neurodevelopmental Disorder (ARND), Static Encephalopathy/Alcohol-Exposed (SE/AE), and Neurobehavioral Disorder/Alcohol Exposed (ND/AE). (See box, *FASD: Key Terms*, for a fuller description of the disorders within the spectrum and related terminology.)

FASD: Key Terms

- *Fetal Alcohol Spectrum Disorders (FASD)*: Umbrella term referring to a group of disorders caused by prenatal exposure to alcohol; a particular condition on the fetal alcohol spectrum is referred to as "an FASD." Now generally considered to refer to Fetal Alcohol Syndrome (FAS), partial FAS (pFAS), Alcohol-Related Neurodevelopmental Disorders (ARND), Static Encephalopathy/Alcohol-Exposed (SE/AE), and Neurobehavioral Disorder/Alcohol Exposed (ND/AE). See below for all. A variety of diagnostic approaches exist for the disorders within the spectrum; the five most commonly used approaches are included in the key terms below, and are summarized/compared in Appendix E.

Disorders currently or previously described as forms of FASD (in alphabetical order):

- *Alcohol-Related Birth Defects (ARBD)*: Term used to describe individuals who present with congenital defects (including malformations and dysplasia), but not the growth or cognitive/behavioral impairments typically seen in FAS (see definition below). Now less used, although diagnostic guidelines still exist through the Institute of Medicine (IOM; see *Fetal Alcohol Syndrome: Diagnosis, Epidemiology, Prevention, and Treatment*, below in this box).
- *Alcohol-Related Neurodevelopmental Disorder (ARND)*: Term created by the IOM to describe individuals with prenatal alcohol exposure and neurodevelopmental abnormalities, but no

FAS facial phenotype. The neurodevelopmental abnormalities are characterized by a complex pattern of behavioral or cognitive conditions inconsistent with developmental level and not explained by genetic background or environment. Problems may include learning disabilities; school performance deficits; inadequate impulse control; social perceptual problems; language dysfunction; abstraction difficulties; mathematics deficiencies; and judgment, memory, and attention problems. The term ARND presents with the same limitations as the discontinued term Fetal Alcohol Effects (see definition below), as one cannot confirm that the neurodevelopmental disorder present in a child with prenatal alcohol exposure was caused by the alcohol exposure in the absence of the FAS facial phenotype. Some diagnostic systems replace the term ARND with Static Encephalopathy/Alcohol-Exposed and Neurobehavioral Disorder/Alcohol Exposed (SE/AE and ND/AE; see definitions below).

- *Fetal Alcohol Effects (FAE)*: Term introduced in the late 1970's to describe less complete partial expressions of FAS (see definition below) in individuals with prenatal alcohol exposure (Clarren & Smith, 1978). Aase, Jones, and Clarren (1995) expressed concern about the validity of the term FAE and proposed abandoning its clinical use, as it implied a causal association (between prenatal alcohol exposure and abnormalities observed in an individual patient) that could not actually be confirmed.
- *Fetal Alcohol Syndrome (FAS)*: Term for what is generally considered to be the most recognizable form of FASD. These individuals exhibit the FAS facial phenotype, impaired growth, and cognitive and behavioral abnormalities.
- *Neurobehavioral Disorder/Alcohol Exposed (ND/AE)*: Term used to describe individuals with prenatal alcohol exposure, moderate cognitive/behavioral impairment (equivalent to moderate ARND), and no FAS facial phenotype.
- *Partial FAS (pFAS)*: Term applied to individuals who exhibit FAS without growth deficiency, or exhibit FAS with most but not all of the facial features.
- *Static Encephalopathy/Alcohol Exposed (SE/AE)*: Term used to describe individuals with prenatal alcohol exposure and severe cognitive/behavioral impairment (equivalent to severe ARND), but no FAS facial phenotype.

Additional terms are presented in alphabetical order:

- *Alcohol-Exposed Pregnancy (AEP)*: Any pregnancy during which the woman drinks any amount of alcohol at any time during the pregnancy. This exposure does not mean the offspring has been affected in any way, but it does place the offspring at some degree of risk for an array of developmental difficulties, including damage to the brain and central nervous system, retardation of growth and other physical effects, and cognitive and behavioral impairments.
- *Diagnosis*: In the context of this TIP, "diagnosis" refers to the formal identification of an FASD by a qualified team and/or dysmorphologist (someone who specializes in structural, or birth, defects). When the TIP discusses the primary diagnosis that brought the client into your substance abuse or mental health setting, or for which your setting is primarily assessing or treating the client, it will be referred to as the "primary treatment issue."
- *Diffuse Brain Damage*: Damage to the brain that is not localized or necessarily the result of a specific traumatic incident to one part of the brain. Such damage can arise from other sources besides alcohol or occur from multiple sources including alcohol. As an AEP (see definition above) can impair the development of multiple parts of the brain of the fetus over the period of pregnancy, an FASD can be considered a manifestation of diffuse brain damage. However, not all diffuse brain damage is the result of alcohol and its expression does not always qualify as an FASD.
- *FASD 4-Digit Diagnostic Code* (Astley, 2004b): Comprehensive, reproducible method for diagnosing the full spectrum of outcomes of patients with prenatal alcohol exposure. First

developed in 1997 by the Washington State FAS Diagnostic and Prevention Network (FAS DPN), the Code was revised in 1999 and again in 2004. Summarized in Appendix E.

- *Fetal Alcohol Spectrum Disorder: Canadian Guidelines for Diagnosis* (Chudley et al., 2005): Canadian guidelines for the diagnosis of FAS, pFAS, and ARND. Summarized in Appendix E.
- *Fetal Alcohol Syndrome: Diagnosis, Epidemiology, Prevention, and Treatment* (Stratton, Howe, Battaglia, & the Committee to Study Fetal Alcohol Syndrome, 1996): Diagnosis and treatment guidelines developed by the IOM and published in 1996. These guidelines would be revised by Hoyme, May, and Kalberg (2005) in *A Practical and Clinical Approach to the Diagnosis of Fetal Alcohol Spectrum Disorders: Clarification of the Institute of Medicine Criteria*. Each is summarized in Appendix E.
- *Fetal Alcohol Syndrome: Guidelines for Referral and Diagnosis* (Bertrand et al., 2004): FAS diagnosis and referral guidelines developed by the Centers for Disease Control and Prevention (CDC). Summarized in Appendix E.
- *Intervention*: In the context of this TIP, 'intervention' describes 1) a brief methodology for informing women of childbearing age about the results of alcohol screening and the dangers of alcohol use during pregnancy, or 2) the selection of an appropriate treatment methodology to best meet the needs of a client who has or may have an FASD, and any accompanying modifications or accommodations in treatment planning.
- *Screening*: 'Screening' is a familiar term in mental health and substance abuse treatment settings. Validated screening instruments for identifying alcohol use among women are available, and no modification to the basic understanding of screening is necessary for their use. To accomplish the important goal of screening for an individual with an FASD in your setting, formalized tools are limited. However, this TIP does provide indicators to look for, and screening may need to be done more informally through guided observation and/or diagnostic interviewing. In most cases, screening for an FASD will need to occur over time, rather than being a process that can be completed through the use of a simple, brief instrument administered once (e.g., at intake).
- *Static Encephalopathy*: Permanent or unchanging brain damage. Effects on development depend on the part(s) of the brain involved and the severity of the damage.
- *Teratogen*: Any substance that can damage a developing fetus. Common teratogens include alcohol, tobacco, lead, radiation, and exposure to infectious disease.

Prevalence

The prevalence of FAS in the United States has been estimated at 1–3 per 1,000 live births among the general population (Stratton et al., 1996) and 10–15 per 1,000 in some higher-risk populations, such as children residing in foster care (Astley, Stachowiak, Clarren, & Clausen, 2002; Astley, 2004a). The prevalence of the full spectrum of FASD in the general population is estimated at 9.1 per 1,000 live births, though a review of in-school screening and diagnosis studies suggest that the national rate could potentially be closer to 50 per 1,000 (May et al., 2009). In addition, recent retrospective analyses of hospital admissions data indicate that under-reporting of alcohol misuse by women may further disguise true prevalence (Morleo et al., 2011).

Although prenatal alcohol exposure has been clearly established as a causal factor for FASD in animal models, the amount of alcohol required to cause damage to the fetus remains in question, and may differ based on the individual. Factors such as dose of alcohol, pattern and timing of exposure, genetics, whether the mother also smoked and/or used other drugs, general health and nutrition of the mother, her level of stress and/or trauma, and her age all may play a role in the impact that alcohol has on the developing fetus (Guerri, Bazinet, & Riley, 2009). Animal studies do suggest that binge drinking (four or more drinks on one

occasion) is associated with more severe effects (Bonthius & West, 1988; Clarren, Astley, Gunderson, & Spellman, 1992), and it is generally asserted that there is no known 'safe' level of alcohol consumption during pregnancy (Office of the Surgeon General, 2005; Hicks & Tough, 2009; Feldman et al., 2012).

Not every woman who consumes alcohol during pregnancy will give birth to a child with an FASD. However, because science has not determined a safe level of alcohol that may be consumed during pregnancy, the possibility of an FASD is created any time a woman consumes alcohol while pregnant.

Due to the range of deficits—and variability in degree of severity of each deficit—within the diffusely damaged brain, FASD can present as functionally different in each individual that is affected. However, certain cognitive, behavioral, and adaptive functioning problems are common across the spectrum, including lower IQ, impaired learning ability, and difficulty processing information (such as not being able to remember or follow instructions, or poor verbal receptive skills) (Streissguth, Barr, & Bookstein, 1996; Bertrand et al., 2004; Streissguth et al., 2004; Astley et al., 2009a; Astley, 2010). Physical abnormalities and facial dysmorphology (i.e., congenital malformation) are only common with FAS. Other functional issues regularly observed include attention deficit (Nanson & Hiscock, 1990; Lee, Mattson, & Riley, 2004), decreased proficiency in cognitive planning (Kodituwakku, Handmaker, Cutler, Weathersby, & Handmaker, 1995; Kodituwakku, Kalberg, & May, 2001; Rasmussen, 2005), reduced working memory (Burden, Jacobson, Sokol, & Jacobson, 2005; Astley et al., 2009b; Green et al., 2009), reduced response inhibition (Noland et al., 2003; Mattson, Crocker, & Nguyen, 2011), socially inappropriate behaviors (Bishop, Gahagan, & Lord, 2007; Jirikowic, Kartin, & Olson, 2008; Mattson, Crocker, & Nguyen, 2011), and deficits in fine motor (Kalberg et al., 2006; Jirikowic et al., 2008) and visual-spatial functions (Chiodo, Janisse, Delaney-Black, Sokol, & Hannigan, 2009; Mattson et al., 2010).

Cost Factors

Estimates of the cost to raise a child with an FASD vary depending on the source and the factors included in the analysis, and detailed cost estimates are generally only available in relation to the specific condition of FAS. Nonetheless, these costs are significant. In an analysis of medical expenditures for pediatric Medicaid enrollees, Amendah, Grosse, and Bertrand (2010) found that, for a child with identified FAS, incurred health costs were nine times higher than for children without an FASD. Astley, Bailey, Talbot, and Clarren (2000a) further isolated cost factors in a demonstration of primary FAS prevention in an FASD diagnostic clinic that targeted high-risk women; using this approach, the cost of raising a child with FAS was found to be roughly 30 times higher than the cost of preventing FAS in the child.

The most widely acknowledged estimate of the lifetime cost of care for an individual with an FAS is that of Lupton, Burd, and Harwood (2004), who adjusted figures originating with Harwood and Napolitano (1985) for 2002 dollars to suggest that the figure was roughly $2 million (including medical treatment, special education, residential care for persons with mental retardation, and productivity losses; in 2012 dollars, this would be over $2.5 million). The overall annual cost of FAS to the U.S. healthcare system (based on an assumption of 2 cases per 1,000 live births) is estimated at $5 billion (Lupton et al., 2004).

Part 3 of this TIP, the online Literature Review, contains additional information on FASD surveillance and cost factors, as well as the impact of alcohol on the brain and behavior.

Historical Background

FASD is often described as a 'new' or 'recent' discovery. In fact, references to the harmful effects of maternal drinking on infant outcome date back to biblical times: "Behold, thou shalt conceive, and bear a son; and now drink no wine or strong drink" (Judges 13:7, as noted in Clarren & Smith, 1978). In addition, several comprehensive descriptions were compiled by physician groups in the 18th and 19th centuries (Royal College, 1726; Sullivan, 1899; Goodacre & Mercer, 1965). The more recent history commonly referred to begins in 1968, when Lemoine, Harousseau, Borteyni, and Menuet from France published an article describing children with distinctive facial features and other symptoms related to prenatal alcohol exposure. In 1970, unaware of the Lemoine publication, Ulleland and colleagues published similar observations describing a small group of alcohol-exposed infants admitted to several high-risk maternal-child health clinics at the University of Washington (Ulleland, Wennberg, Igo, & Smith, 1970; Ulleland, 1972). This work would eventually lead to a seminal, collaborative article describing the pattern of outcomes associated with prenatal alcohol exposure (Jones, Smith, Ulleland, & Streissguth, 1973), as well as the publication that coined the term FAS (Jones & Smith, 1973).

In the roughly 40 years that have followed, extensive study has been conducted on alcohol's teratogenic effects, as well as on interventions for women of childbearing age who consume alcohol, leading to several significant federal milestones in addressing FASD. In 1996, the Institute of Medicine (IOM) published *Fetal Alcohol Syndrome: Diagnosis, Epidemiology, Prevention, and Treatment* (Stratton et al., 1996), leading the National Institute on Alcohol Abuse and Alcoholism (NIAAA) to establish the Interagency Coordinating Committee on FASD (originally Interagency Coordinating Committee on FAS) to address that publication's recommendations. Then, in 2000, Congress set forth mandates related to children's health, including FASD, leading the Centers for Disease Control and Prevention (CDC) to establish the National Task Force on FAS and FAE (completed in 2007), and SAMHSA to establish the FASD Center for Excellence in 2001.

In the decade since the Congressional mandates, the research and knowledge base around FASD has expanded greatly. According to Goodlett (2010), a PubMed search of FAS-, FASD-, or fetal alcohol-specific terminology at the end of 2010 returned nearly 3,900 articles published since 1973, of which more than 38 percent had been published since 2000. This growth is translating to practice: Since 2001, the FASD Center for Excellence alone has funded more than 70 subcontractors across the United States to carry out pilot efforts to implement FASD-related services into existing programs, including substance abuse and mental health treatment settings.

This body of work has revealed an unfortunate paradox: Individuals with an FASD require more intensive and personalized services, and early diagnosis and intervention have been identified as critical to improved outcomes and minimized secondary disabilities (Streissguth et al., 2004; Astley, 2010). Yet, individuals with an FASD often go undiagnosed or are misdiagnosed (Greenbaum, Stevens, Nash, Koren, & Rovet, 2009), are difficult to identify early and may not receive appropriate early intervention (Olson, Jirikowic, Kartin, & Astley, 2007), and often receive services that do not account for their disabilities and thus may result in poor outcomes.

Audience: Who Should Read This TIP?

This TIP is designed for use by behavioral health providers, particularly substance abuse and mental health treatment professionals, not only because these are the primary constituencies of SAMHSA but also because individuals with FASD experience higher rates than the general population of both substance abuse and mental health issues (Streissguth et al., 1996; O'Connor et al., 2002; Streissguth et al., 2004; Clark, Lutke, Minnes, & Quellette-Kuntz, 2004; Astley, 2010). In addition, individuals with an FASD exhibit higher rates of life problems commonly encountered in substance abuse and mental health treatment populations, including higher risk of suicide (Huggins, Grant, O'Malley, & Streissguth, 2008), exposure to multiple traumas throughout the lifespan (Henry, Sloane, & Black-Pond, 2007; Greenbaum et al., 2009), homelessness (Fryer, McGee, Matt, Riley, & Mattson, 2007), and increased interaction with the criminal justice system (Streissguth et al., 1996; Streissguth et al., 2004).

This TIP is also important because there are great opportunities for FASD prevention in mental health and substance abuse treatment settings. According to the 2009 *National Survey on Drug Use and Health* (NSDUH), 17.1 percent of women age 18 or over in the U.S. received mental health treatment or counseling in 2009, compared to only 9.2 of men in the same age group (Center for Behavioral Health Statistics and Quality [CBHSQ], 2010), while the *Treatment Episode Data Set* (TEDS) indicates that 33.0 percent of admissions to substance abuse treatment facilities in 2011 were female, more than half of whom (50.5 percent) indicated alcohol as a primary, secondary, or tertiary substance of abuse (CBHSQ, 2013). Thus, these settings provide ideal opportunities to implement brief, effective approaches to preventing an AEP.

Part 1 of this TIP is for frontline personnel and consists of three chapters:

- *Chapter 1* discusses approaches to FASD prevention; that is, assisting women who are in treatment settings and are pregnant or may become pregnant to remain abstinent from alcohol. In providing these guidelines, this TIP adopts the IOM model for prevention, which sees prevention as a step along a continuum that also incorporates treatment and maintenance.
- *Chapter 2* discusses methods for identifying individuals in treatment who have or may have an FASD, referring them for diagnosis where possible, and providing appropriate interventions to meet their needs. These clients are assumed to be adolescent or older, as they would need to be capable of presenting in treatment on their own (although the TIP strongly recommends including the family in treatment, when possible).
- *Chapter 3* provides clinical vignettes designed to realistically portray the provider–client interactions that might take place when providing FASD prevention or interventions.

Part 2 provides administrators with strategies and tools for undertaking the activities that will support treatment professionals and clients and for making the changes required to incorporate FASD prevention and/or intervention in daily practice. Part 2 also includes methods, materials, resources, and examples to assist administrators with quality improvement and ongoing evaluation of the necessary programmatic changes.

At the same time, the clinical and administrative guidance set forth in this TIP has strong applicability across healthcare and social service settings. While the client interactions

described generally involve substance abuse and mental health treatment, any provider assisting women at risk of an AEP or assisting individuals who may have an FASD can implement the majority of these recommendations if they adapt them for that professional's setting. This is particularly the case if the setting in question overlaps with the life issues that more frequently occur among individuals with an FASD, as discussed above (i.e., criminal justice, housing, primary care).

Barriers to Treatment: The Need for the TIP

For a variety of reasons, including the somewhat hidden nature of many of the symptoms, individuals with an FASD are frequently misdiagnosed or their condition is not recognized (Olson et al., 2007; Greenbaum et al., 2009). This, in turn, leads to care that is not matched to the patient's needs and strengths, increasing the risk for secondary disabilities (Streissguth et al., 2004).

Added to this, recent statistics on drinking among pregnant women show that AEP prevention is as serious an issue as appropriate services for individuals who have an FASD (see box, *Drinking Rates Among Pregnant Women*, in the next chapter). AEP prevention may not be a familiar goal in mental health and substance abuse treatment settings. Yet these are ideal settings in which to prevent prenatal alcohol exposure, as behavioral health professionals routinely work with women of childbearing age (age 10–49 years). Treatment can then have a positive affect not only on the client, but on his or her family and generations to come.

Ideally, this TIP will help to alleviate many barriers to providing successful treatment for these two populations, including:

- The application of treatment approaches that, while effective with general populations, may not be ideally suited to the needs of individuals with an FASD;
- A lack of awareness among treatment professionals of the rapid developments in the field of FASD services over the last decade; and
- Helping clients deal with feelings of shame, loss, or fear of discrimination.

Lack of Success With Typical Treatment Approaches

Prenatal exposure to alcohol has many teratogenic effects, among them that it can alter brain structure and function, meaning that people with an FASD do not process information in the same ways that those without an FASD do. These effects are permanent; an FASD cannot be 'cured.' Processing differences that may affect treatment can take many forms, including:

- Poor receptive language skills (difficulty with complex language and multiple instructions);
- Difficulty with social cognition and accurately understanding social cues;
- Difficulty taking in new information, and in generalizing learning to new settings; and
- Not always connecting cause and effect (particularly if the effect is delayed).

Expert consensus suggests that treatment approaches that rely on an assumption of 'normal' functioning of these cognitive processes are likely to be less effective with individuals with an FASD. This appears to be true for both mental health and substance abuse treatment settings.

Cognitive–Behavioral Therapy (CBT) models, for instance, are verbally based insight therapies designed to reduce target symptoms, and are based on the idea that inaccurate thoughts are linked to maladaptive feelings and behaviors. However, CBT approaches do not fit well

given that individuals with an FASD have biologically based cognitive deficits (O'Connor et al., 2002). Behaviors of individuals with an FASD may result from errors in thinking that are difficult to change because of underlying diffuse brain damage. Modification to CBT, and adding other approaches, will be needed to maximize treatment efficiency and success.

The disease model of substance abuse treatment, which advocates lifelong abstinence from alcohol, also relies on the assumption that a client has normative function. Behavioral health professionals assume that the client can comprehend that he or she has a 'disease' and also that he or she can plan ahead to recognize why it is important to achieve abstinence. For an individual with an FASD, this link may be difficult to make, and so his or her substance abuse or mental health target symptoms may be harder to change (and change harder to maintain) because of the underlying diffuse brain damage.

Rapid Developments in the Field

The tremendous growth in FASD-related research and the establishment of the SAMHSA FASD Center for Excellence have practical implications for behavioral health professionals, in that the field of FASD-related practices is growing dynamically. Much of the practical guidance in this TIP has emerged only over the last 5 to 10 years. Even professionals who have had some form of FASD training in the past are likely to discover new and useful strategies in this TIP that can be effectively applied in their programs.

Treatment Barriers

Despite their unique treatment needs, clients with an FASD or pregnant women at risk of an AEP still share with any other client a significant, common barrier to treatment success: The impact of negative self-perception. An individual with an FASD or a woman who has consumed alcohol during pregnancy may perceive themselves negatively, either because of internal feelings of shame, a sense of not belonging, or due to experiencing external shaming or judgment. These internal feelings and external experiences can each become a barrier to treatment (Astley, Bailey, Talbot, & Clarren, 2000b; Salmon, 2008).

When implementing the practices recommended in this TIP, behavioral health professionals are urged to keep sight of the importance of addressing the client's feelings and experiences, as well as the need for sensitivity to issues such as gender, ethnicity, cultural background, and sexuality, as these factors impact treatment success among individuals with an FASD and women of childbearing age as significantly as any other treatment population.

"We must move from viewing the individual as failing if s/he does not do well in a program to viewing the program as not providing what the individual needs in order to succeed."

Dubovsky, 2000

1 Prevention of Alcohol-Exposed Pregnancies Among Women of Childbearing Age

IN THIS CHAPTER

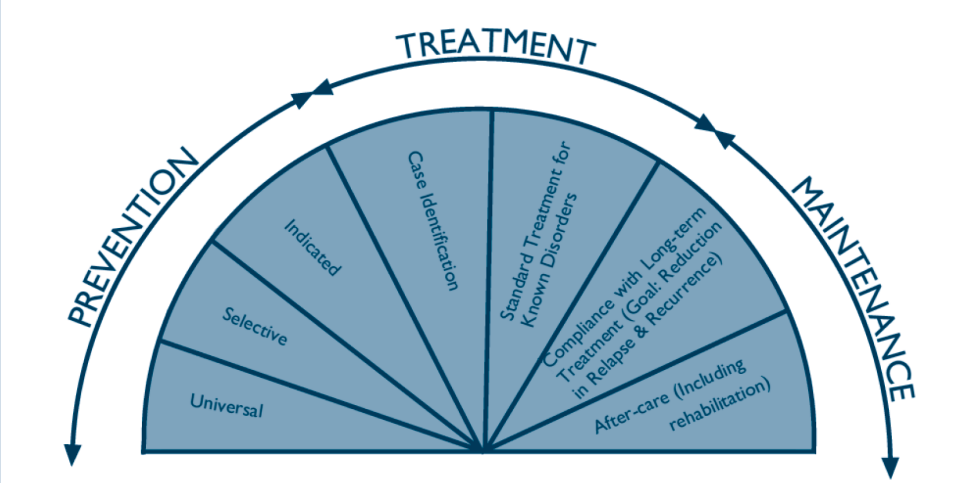
Introduction

One act of AEP prevention can positively impact the life of the mother and the life of the unborn child. One change in how services are provided can multiply that impact many times over.

This TIP adopts the IOM continuum of care model, which sees prevention as a step along a continuum that also incorporates treatment and maintenance (see Figure 1.1, below). The IOM model defines three types of prevention: universal, selective, and indicated.

- *Universal prevention* "[a]ddresses [the] general public or [a] segment of [the] entire population with average probability, risk or condition of developing [a] disorder" (Springer & Phillips, 2007). Universal prevention can take a variety of forms, including media campaigns, large-scale health initiatives (e.g., immunization), point-of purchase signage, and warning labels on products.
- *Selective prevention* is designed for a "[s]pecific sub-population with risk significantly above average, either imminently or over [his or her] lifetime" (Springer & Phillips, 2007), and can include "screening women for alcohol use, training healthcare professionals, working with family members of pregnant women who abuse alcohol, developing biomarkers, brief interventions, and referrals" (Grant, 2011).
- *Indicated prevention* "[a]ddresses identified individuals with minimal but detectable signs or symptoms suggesting a disorder" (Springer & Phillips, 2007), such as pregnant women who drink heavily, or women who have already given birth to a

Figure 1.1: The IOM Continuum of Care Model



Source: Springer & Phillips, 2006; 2007.

child with FASD and continue to drink. Indicated prevention can include some of the same methods applied in selective prevention, but applied more intensively based on the severity of the alcohol-related problem.

For the purposes of the AEP prevention discussion in this chapter, women of childbearing age (i.e., females age 10–49) in your treatment setting should receive AEP prevention based on the following:

- *Universal prevention*: A woman who is not pregnant, and either reports no alcohol use or does not screen positive for at-risk alcohol use;
- *Selective prevention*: A woman of childbearing age who reports alcohol use but has only one of the two indicators for an indicated intervention; she is either pregnant but does not screen positive for at-risk alcohol use, or she screens positive for at-risk alcohol use but is not pregnant; or
- *Indicated prevention*: A woman of childbearing age who screens positive for at-risk alcohol use and is pregnant.

This chapter will first discuss screening, then appropriate brief interventions for AEP prevention in each of the three categories, before discussing treatment issues and referral. In each category, screening is a vital starting point before moving on to appropriate prevention, treatment, or referral.

Professional Responsibility to Screen

As the box "Risk Factors for an AEP" (next page) makes clear, a variety of factors can impact a woman's consumption of alcohol during pregnancy. These and other factors make it critical to inquire about alcohol use among *all* women of childbearing age in behavioral health settings for alcohol consumption:

- There is *no* known safe level of alcohol consumption during pregnancy, and even low levels of prenatal alcohol exposure have been shown to negatively impact a fetus (Chang, 2001).

- Screening facilitates the implementation of appropriate interventions, at the earliest possible point (Leonardson, Loudenburg, & Struck, 2007).
- Prevented AEP can result in significant cost savings through prevented cases of FASD and reduced use of the health and social services systems (Abel & Sokol, 1991; Astley et al., 2000a; Lupton et al., 2004; Astley, 2004a).
- Screening is an ethical obligation, one that should be conducted equally of men and women regardless of race and economic status, and which should be performed with women using instruments that are designed for women (Committee on Ethics of the American College of Obstetricians and Gynecologists [ACOG], 2008). Additionally, in an FASD prevention study assessing the feasibility of identifying high-risk women through the FASD diagnostic evaluation of their children, Astley and colleagues (2000a) concluded that these women are not only at high risk for producing more children damaged by alcohol exposure, but they themselves often face serious adverse social, mental, and physical health issues, as well. Thus, one could argue that it would be unethical to ignore their existence and ignore opportunities to provide them with advocacy support and primary prevention intervention.
- Awareness *does* create change: Statistics from SAMHSA's NSDUH (May 21, 2009) suggest that drinking rates among women drop considerably during pregnancy, particularly in the second and third trimesters when there is a much higher awareness of pregnancy status.

In addition, screening:

- Gives the client permission to talk about drinking;
- Helps to identify and or clarify co-occurring issues;
- Minimizes surprises in the treatment process; and
- Can mean more effective treatment.

Risk Factors for an AEP

Substance Abuse/Mental Health Factors

- *History of alcohol consumption (NIAAA, 2000; Bobo, Klepinger, & Dong, 2007)*
- *Family background of alcohol use (Stratton et al., 1996; Leonardson et al., 2007)*
- *History of inpatient treatment for drugs or alcohol and/or history of inpatient mental health treatment (Project CHOICES Research Group, 2002)*

Personal/Sexual/Family Factors

- *Previous birth to a child with an FASD (Kvigne et al., 2003; Leonardson et al., 2007)*
- *Lack of contraception use/unplanned pregnancy (Astley et al., 2000b)*
- *Physical/emotional/sexual abuse (Astley et al., 2000b)*
- *Partner substance use/abuse (Stratton et al., 1996; Leonardson et al., 2007)*
- *Multiple sex partners (Project CHOICES Research Group, 2002)*
- *Smoking (CDC, 2002; Leonardson et al., 2007)*
- *Never having been tested for HIV (Anderson, Ebrahim, Floyd, & Atrash, 2006)*
- *Lack of education, income, and/or access to care (Astley et al., 2000a)*

Drinking Rates Among Pregnant Women

According to SAMHSA's 2010 NSDUH, "Among pregnant women aged 15 to 44, an estimated 10.8 percent reported current alcohol use, 3.7 percent reported binge drinking, and 1.0 percent reported heavy drinking. These rates were significantly lower than the rates for non-pregnant women in the same age group (54.7, 24.6, and 5.4 percent, respectively). Binge drinking during the first trimester of pregnancy was reported by 10.1 percent of pregnant women aged 15 to 44" (Office of Applied Studies [OAS], 2011). All of these estimates are based on data averaged over 2009 and 2010. (Binge drinking for women has been defined by NIAAA as four or more drinks on one occasion [2004]).

In telephone interviews with 4,088 randomly selected control mothers from the CDC's National Birth Defects Prevention Study who delivered live born infants without birth defects during 1997–2002, Ethen and colleagues (2009) found even higher numbers: 30.3 percent of respondents reported alcohol use during pregnancy, with 8.3 percent reporting binge drinking during pregnancy (approximately 97 percent of those indicating binge drinking stating that it was during the first trimester).

In addition, one study of stool and hair samples of neonates who had been prenatally exposed to heavy ethanol use suggested that these children were also 3.3 times more likely to have been exposed to amphetamines and twice as likely to have been exposed to opiates, both of which can also impair long-term child development (Shor, Nulman, Kulaga, & Koren, 2010). Another recent study found that, among 1,400 patients with prenatal alcohol exposure attending an FASD diagnostic clinic in Washington state, 62 percent were prenatally exposed to tobacco, 37 percent were prenatally exposed to marijuana, and 38 percent were prenatally exposed to crack cocaine (Astley, 2010).

Statistics from SAMHSA's TEDS and from SAMHSA's NSDUH indicate a potentially greater need to address the FASD issue specifically in substance abuse treatment settings: More than 22 percent of pregnant women admitted into treatment from 1992 to 2006 indicated alcohol as their primary substance of abuse (OAS, 2006).

Lastly, 49 percent of all pregnancies in the United States are unintended (Finer & Henshaw, 2006). As a result, many women will consume alcohol without knowing that they are pregnant.

Procedures for Screening

Behavioral health settings are busy, and screening procedures must be efficient. Figure 1.2, *Screening Decision Tree for AEP Prevention*, provides a procedure for an opening question about alcohol use, moving on to screening (if necessary), suggested instruments for screening, and next steps. The goal of screening is to determine, as quickly and as accurately as possible, whether a client is at risk and therefore brief intervention and treatment or referral is warranted.

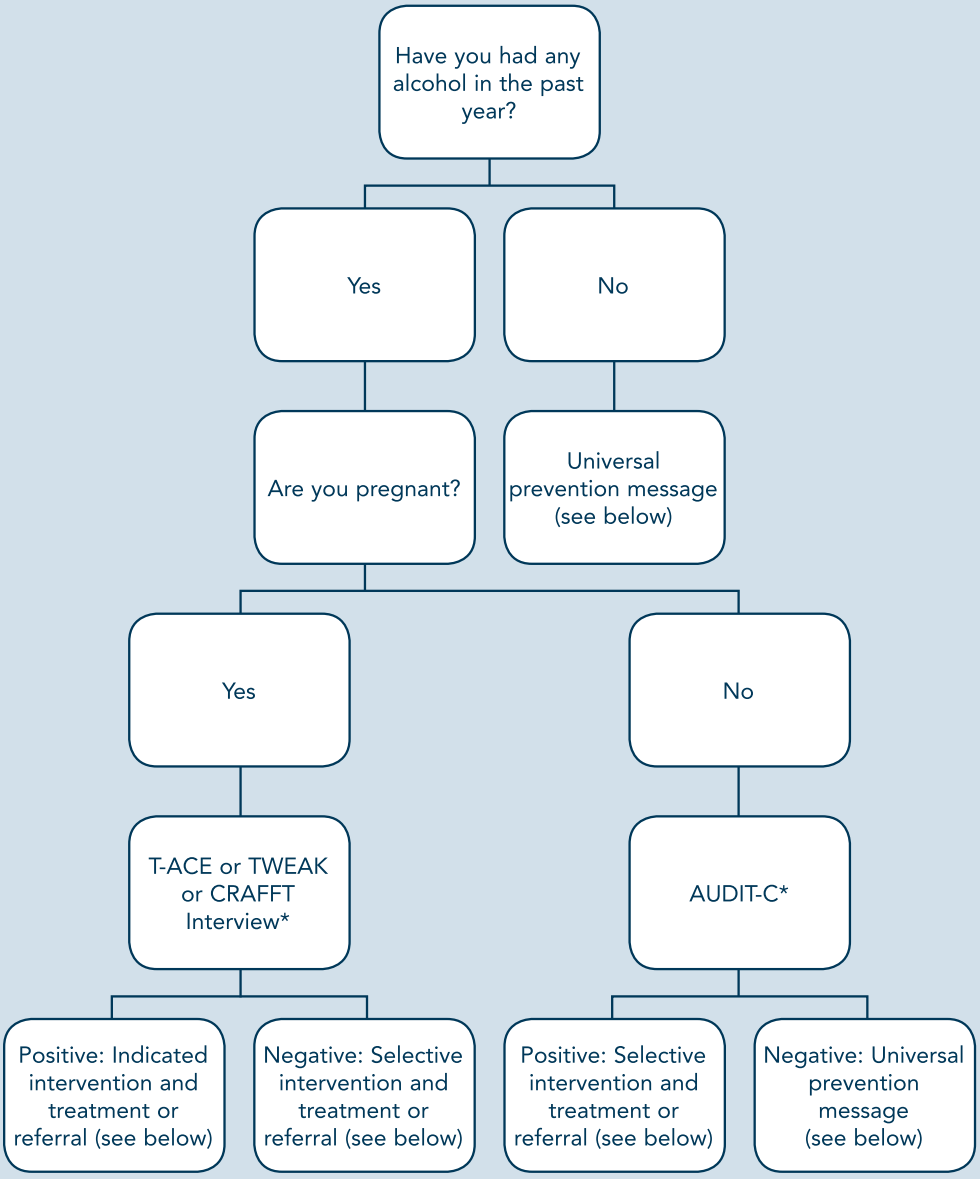
The screening instruments recommended in Figure 1.2 are not the only options available for determining client alcohol use, but are validated as indicated in the decision tree (Sokol & Clarren, 1989; Russell, 1994; Chang, 2001). Nonetheless, if your agency does not use these instruments or does not have a 'perfect' alternative, it is better to screen with what is available to your program than to not screen women of childbearing age at all.

Part 3 of this TIP, the online Literature Review, includes further discussion of these and other alcohol screening instruments for use with women.

Screening should be done with sensitivity to the client's level of health literacy, or, "the degree to which people have the capacity to

Figure 1.2: A Screening Decision Tree for AEP Prevention

AEP prevention can be simple and brief. The TIP consensus panel developed the following Screening Decision Tree for AEP Prevention to help behavioral health providers quickly touch upon the topic of alcohol use with all women of childbearing age, and then provide brief but effective prevention or intervention.



* The T-ACE and TWEAK are validated for use with pregnant women. The CRAFFT Interview may be more helpful when assisting adolescent clients. The AUDIT-C is validated for use with non-pregnant women. All of these instruments are reprinted in Appendix B of this TIP.

obtain, process, and understand basic health information and services needed to make appropriate health decisions" (Parker, Ratzan, & Lurie, 2003; Liechty, 2011). More than a third of adults in the United States do not have adequate health literacy (Kutner, 2006; Liechty, 2011), so the prevention message may need to be simplified and reinforced by asking the client on several occasions and in a variety of ways. This means that your agency will likely need to screen at several different points in time.

In addition, talking about alcohol use or seeking help for an alcohol-related problem can be potentially embarrassing or difficult for the client (NIAAA, 2005). Counselors should be conscious of this risk, and be respectful when raising the issue of alcohol use. Additional sources of information that can help to identify alcohol use include collateral reports from family and friends of the client, and client medical/court records.

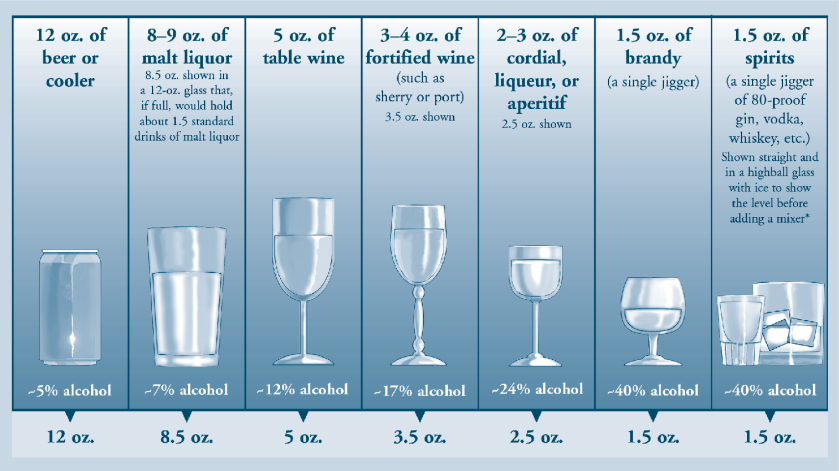
Vignette #2 in Part 1, Chapter 3 incorporates discussion of drink size and the use of a visual aid with a client.

Selecting an Appropriate Prevention Approach

Based on the results of your client screening, the next step is to decide on an appropriate brief approach: Universal prevention message or selective or indicated brief intervention. Brief interventions are associated with sustained reduction in alcohol consumption by women of childbearing age, and those discussed have shown promise for being adaptable to various settings and needs (Fleming, Barry, Manwell, Johnson, & London, 1997; Manwell, Fleming, Mundt, Stauffacher, & Barry, 2000; Burke, Arkowitz, & Menchola,

What Is a Standard Drink?

All clients being screened for alcohol consumption should be given a clear indication of what constitutes a 'standard drink.' A standard drink in the United States is any drink that contains about 14 grams of pure alcohol (about 0.6 fluid ounces or 1.2 tablespoons). Below are U.S. standard drink equivalents. These are approximate, since different brands and types of beverages vary in their actual alcohol content.



Source: *Helping Patients Who Drink Too Much: A Clinicians Guide* (Updated 2005 Edition), NIAAA, p. 24. NIH Publication No. 07-3769.

2003; Project CHOICES Intervention Research Group, 2003; Chang et al., 2005; Grant, Ernst, Streissguth, & Stark, 2005; O'Connor & Whaley, 2007).

When using these prevention approaches, counselors should remember that no intervention constitutes full treatment of a woman's alcohol use. Each is designed simply to encourage a dialogue about alcohol and begin a process of change. Each should be the basis for ongoing evaluation and an informed approach to treatment or referral. For programs that do not have existing approaches to substance abuse treatment, procedures for appropriate referral are discussed after the brief interventions.

Universal Prevention

As indicated in Figure 1.2, *Screening Decision Tree for AEP Prevention*, a woman who is not pregnant, and either reports no alcohol use or does not screen positive for at-risk alcohol use, can receive a simple universal prevention message. Consider the following scripted messages.

Universal AEP Prevention Statement and Possible Follow-Up Questions

"It's great that you're choosing not to drink alcohol. I know you aren't currently pregnant or planning to become pregnant, but you are in the primary childbearing years right now. If you change your mind about pregnancy or discover in the future that you are pregnant, or you do begin to drink, please keep in mind that research has shown a link between drinking during pregnancy and the baby having an FASD. A child with an FASD can have physical and behavior problems, as well as cognitive problems (or, problems with the brain). These effects are caused by the alcohol, and they don't go away, although they can be treated. There is no known safe amount of alcohol to consume during pregnancy, and any type of alcohol can cause FASD.

Can I give you a brochure [or Web address, such as **www.fasdcenter.samhsa.gov**] *to take with you? This will explain more about FASD and how to have a healthy baby. Even if you aren't planning to become pregnant, you could share it with a friend or family member who is."*

*****

If asked: Why is there no known safe amount of alcohol that a woman can have during pregnancy?

Answer: The amount of alcohol required to damage an unborn baby differs based on the individual. Things like how much alcohol a woman drinks, how often she drinks during pregnancy, and which trimesters she drinks in all play a part. It also depends on genetics, whether the woman smokes or uses other drugs, her general health and nutrition, her age, and her levels of stress or trauma. That's why the Surgeon General recommends that pregnant women not drink any alcohol at all.

If asked: What kinds of alcohol should I avoid?

Answer: All alcohol can harm a baby while you're pregnant, not just beer, wine, and hard liquor. Wine coolers and 'alco-pops' also count. Anything with alcohol. Even some over-the-counter medications have a lot of alcohol in them; if you're pregnant or thinking of becoming pregnant, you should be careful about those, too.

If asked: Where can I find more information about FASD?

Answer: In addition to the SAMHSA FASD Center for Excellence (**www.fasdcenter.samhsa.gov**), the CDC (**http://www.cdc.gov/ncbddd/fasd/index.html**) provides extensive information about FASD.

Whether asked for more information or not, the universal AEP prevention message should be accompanied by appropriate awareness materials, either in print or via a Web address. The SAMHSA FASD Center for Excellence provides a series of consumer fact sheets called *What You Need to Know* that provides helpful information about how to have a healthy baby. Appendix C, *Public and Professional Resources* on FASD, has links to additional information resources.

At the same time, counselors should keep in mind with universal AEP prevention that, in some situations, women may deny using alcohol, but a combination of signs and symptoms suggest otherwise. In such cases, it may be prudent to re-screen frequently (Taylor, Bailey, Peters, & Stein, 2009).

Selective Prevention

The following section discusses two brief interventions for AEP prevention that are appropriate with women of childbearing age who report alcohol use but have only one of the two indicators for an indicated intervention; they are either pregnant but do not screen positive for at-risk alcohol use, or they screen positive for at-risk alcohol use but are not pregnant. These are organized in terms of the time required to perform the intervention effectively. As with universal prevention, each of these approaches should be accompanied by appropriate FASD information material, such as the *What You Need to Know* fact sheets, either in hard copy or through a Web link.

FLO (Feedback, Listen, Options)

1.	Provide **F**eedback about screening results. If possible, confirm the results with additional screening and provide information about recommended drinking limits. (For women who are—or are planning to become—pregnant, the ideal goal is abstinence.)
2.	Ask clients for their views about their own drinking and **L**isten carefully to encourage their thinking and decision-making process.
3.	Provide medical advice, and negotiate a decision about **O**ptions clients can pursue, including establishing a goal and developing an action plan.

Source: Higgins-Biddle, J., Hungerford, D., & Cates-Wessel, K. (2009). *Screening and brief interventions (SBI) for unhealthy alcohol use: A step-by-step implementation guide for trauma centers.* Atlanta: Centers for Disease Control and Prevention, National Center for Injury Prevention and Control. [Parenthetical in #1 added.]

The first selective intervention, called 'FLO' for short, is a simple, three-step approach (see box below). An example of using the FLO approach with a client is illustrated in Vignette #1 in Part 1, Chapter 3 of this TIP.

The second selective intervention, FRAMES, is a more established and slightly more detailed method for motivating a client toward change, and has demonstrated positive results in brief intervention situations (Miller & Sanchez, 1994; Miller & Rollnick, 2002). See the box on the following page.

Each of these brief interventions discusses 'action plans' or strategies for changing alcohol-related behaviors. For counselors who are not already well-versed in substance use-related change strategies, NIAAA has provided a brief guide to simple change strategies in the publication *Helping Patients Who Drink Too Much* (2007). Basic strategies to discuss with the client can include:

- What specific steps the client will take (e.g., not go to a bar after work, measure all drinks at home, alternate alcoholic and non-alcoholic beverages);
- How drinking will be tracked (diary, kitchen calendar);
- How the patient will manage high-risk situations; and

FRAMES

F	**Feedback** Compare the patient's level of drinking with drinking patterns that are not risky. She may not be aware that what she considers normal is actually risky (*or that **any** consumption during pregnancy creates risk*).
R	**Responsibility** Stress that it is her responsibility to make a change.
A	**Advice** Give direct advice (not insistence) to change her drinking behavior.
M	**Menu** Identify risky drinking situations and offer options for coping.
E	**Empathy** Use a style of interaction that is understanding, non-judgmental, and involved.
S	**Self-efficacy** Elicit and reinforce self-motivating statements such as, "I am confident that I can stop drinking." Encourage the patient to develop strategies, implement them, and commit to change.

Source: Miller, W. R., & Rollnick, S. (2002). *Motivational interviewing: Preparing people for change.* (2nd ed.) New York, NY: Guildford Press. [Italics in "Feedback" added.]

- Who might be willing to help the client avoid alcohol use, such as a significant other or a non-drinking friend.

Indicated Prevention: Alcohol Screening and Brief Intervention (SBI)

Alcohol Screening and Brief Intervention (SBI) is a workbook-based brief intervention that is appropriate with women of childbearing age who screen positive for at-risk alcohol use and are pregnant. SBI generally takes 10 to 15 minutes to complete, and has been shown to positively impact abstinence rates and key subsequent health factors in the newborn, including higher birth weight/length and lower mortality (O'Connor & Whaley, 2007).

The WIC Project Care: Health and Behavior Workbook was originally developed for Women, Infants and Children (WIC) programs, which provide support to current and expecting mothers, but the workbook can be used across settings. It is crafted in very simple language and uses traditional brief intervention techniques, including education and feedback, cognitive–behavioral procedures, goal-setting, and contracting. The care provider should go through the workbook *with* the client. As with both universal and selective prevention, the SBI approach should be accompanied by appropriate FASD print materials or a relevant and reliable Web link for further information.

The workbook can be downloaded for free in multiple languages from the WIC Web site: **http://www.phfewic.org/Projects/Care.aspx**

Providing Intervention/Treatment: Additional Factors to Consider

The following are factors to keep in mind when delivering a brief intervention for AEP prevention, as well as when delivering full substance abuse treatment (for agencies that are able to offer such care).

- Selective and indicated prevention services should be delivered by someone with motivational interviewing (MI) skills if at all possible. While a detailed discussion of MI techniques is outside the scope of this TIP, SAMHSA provides a Web site (**http://www.motivationalinterview.org/**) that contains extensive materials and training resources for providers looking to develop their MI skills. See also TIP 35, *Enhancing Motivation for Change in Substance Abuse Treatment* (SAMHSA, 1999).
- Consider the woman's age and circumstances, and how these impact intervention/treatment. For example, life factors and obstacles to abstinence (family responsibilities, work, other children, etc.) will probably be very different for a teen vs. an older woman.
- Consider cultural context, as well; the cultural factors that impact treatment may be very different for an African-American, Hispanic/Latina, Asian-American, or Native-American woman (or a woman of any other minority) than for a Caucasian woman.
- Be willing to make modifications (e.g., frequency, duration) to maximize opportunities for prevention and recovery.
- Include and engage families in treatment, including significant others, grandparents, guardians, and custodians.
- Include relapse prevention.
- Include family support skills.
- Consider additional counseling factors:
  - Parenting skills (that work for both the parent and the child)
  - Trauma and abuse
  - Co-occurring mental health issues
- Using a calendar with a client who is already pregnant may help her differentiate when she found out she was pregnant from when she actually became pregnant. She may have consumed alcohol for some time before knowing of the pregnancy, and showing that the drinking occurred even before she knew she was pregnant can help her feel less pressured and alleviate feelings of guilt. Clients may feel guilty and not tell the whole truth (or even withhold the truth). This means that getting an accurate picture of alcohol use may require multiple screenings. It is critical to build trust over several sessions. [Vignette #4 in Part 1, Chapter 3 demonstrates the use of a calendar with a client.]
- Watch for clients who 'shut down' on the topic of alcohol, and be understanding if the client experiences a sense of panic

Ensuring Effective Contraception

A woman who drinks alcohol at risky levels may not always follow prescribed procedures for effective contraception (Astley et al., 2000b). Review contraception use with her to ensure that she has full contraceptive coverage every time she has sexual intercourse. This might include providing secondary, back-up, or emergency contraception methods. For example, along with oral contraceptives, advise her to use condoms, which have the added benefit of reducing sexually transmitted diseases.

Source: *Division of Women's Health Issues. (2006). Drinking and reproductive health: A Fetal Alcohol Spectrum Disorders prevention tool kit. Washington, DC: American College of Obstetricians and Gynecologists.*

about what she may have unintentionally done to her baby.

- If the client is not pregnant but is drinking, and is not resistant to talking about contraception, qualified professionals can consider adding a discussion of effective contraception (see box, "Ensuring Effective Contraception") to discussions about drinking reduction.

Approaches to Resistance

With any approach to AEP prevention, counselors should keep in mind that, while a female client may feel safe enough to share about her alcohol use, she may not be ready to take the next step of comprehensive assessment and treatment (Astley et al., 2000b). A woman may present as resistant, reluctant, resigned, or rationalizing. The publication *Substance Abuse During Pregnancy: Guidelines for Screening* (Taylor et al., 2009) provides guidance on meeting these various forms of resistance. In addition, see the box below.

Procedures for Referral

If you believe, based on screening and interaction during intervention, that your client requires assistance that is best delivered in another care setting (or treatment in another setting becomes necessary due to factors such as criminal justice or social service involvement), you should discuss the benefits of treatment with the client and offer to provide her with a referral to a local substance abuse treatment center or other appropriate provider. A general list of treatment facilities can be searched through The SAMHSA Treatment Locator (**http://findtreatment.samhsa.gov**). Additional referral possibilities include the following:

- County substance abuse services;

Resistant, Reluctant, Resigned, or Rationalizing

• Resistant: "Don't tell me what to do."
Provider Response: Work with the resistance. Avoid confrontation and try to solicit the woman's view of her situation. Ask her what concerns her about her use and ask permission to share what you know, and then ask her opinion of the information. Accept that the process of change is a gradual one and it may require several conversations before she feels safe about discussing her real fears. This often leads to a reduced level of resistance and allows for a more open dialogue. Try to accept her autonomy but make it clear that you would like to help her quit or reduce her use if she is willing.
• Reluctant: "I don't want to change; there are reasons."
Provider Response: Empathize with the real or possible results of changing (for example, her partner may leave). It is possible to give strong medical advice to change and still be empathetic to possible negative outcomes to changing. Guide her problem-solving.
• Resigned: "I can't change; I've tried."
Provider Response: Instill hope, explore barriers to change.
• Rationalizing: "I don't use that much."
Provider Response: Decrease discussion. Listen, rather than responding to the rationalization. Respond to her by empathizing and reframing her comments to address the conflict between wanting a healthy baby and not knowing whether "using" is really causing harm.

DiClemente, C. C. (1991). Motivational interviewing and stages of change. In W. R. Miller & S. Rollnick (Eds.), *Motivational Interviewing: Preparing People to Change Addictive Behaviors* (pp. 191- 206). New York: Guilford.

Targeted Referral Options

Non-Pregnant Women: Project CHOICES

Project CHOICES is an evidence-based intervention (Project CHOICES Intervention Research Group, 2003; Floyd et al., 2007) that targets women at risk of having an AEP *before* they become pregnant. The goal is to reduce drinking and/or prevent pregnancy through contraception.

The target population for Project CHOICES is women ages 18 to 44 who are sexually active and drinking alcohol at risk levels. The model uses a four-session intervention approach based in MI methods, and discussions in each session are tailored to the client's self-rated readiness to change and interest in discussing alcohol use or contraception.

Project CHOICES programs exist in multiple settings, including residential and outpatient substance abuse treatment, community mental health treatment, jails, and community-based teen programs for girls. Eligibility criteria include 1) self-report of being sexually active, 2) being non-pregnant (but able to conceive), 3) high-risk drinking (8 or more drinks per week or 4 or more drinks in one occasion) in the past 30 days, 4) ineffective use of or no contraception, and 5) not currently trying to become pregnant or planning to try in the next 6 months.

Intervention Components:

- Four MI-based counseling sessions, including personalized feedback of risk, motivation to change one or both risk behaviors, decreasing temptation to engage in risk behaviors and increasing confidence to avoid them, goal-setting, and change planning; and
- One contraceptive counseling visit.

The CDC provides additional information about Project CHOICES at **http://www.cdc.gov/ncbddd/fasd/research-preventing.html**.

Pregnant Women: Parent-Child Assistance Program (PCAP)

The Parent-Child Assistance Program (PCAP) is a scientifically validated (Grant et al., 2005) paraprofessional case management model that provides support and linkages to needed services to women for 3 years following enrollment. The goal is to reduce future AEP by increasing abstinence from alcohol and drug use and/or improving regular use of reliable contraception among enrollees.

The target population for PCAP is pregnant or post-partum women (up to 6 months) who have had an AEP and will self-report drug and/or alcohol use during the target pregnancy. The model is based in Relational Theory, the Stages of Change, and harm reduction.

PCAP programs exist in a variety of settings, including substance abuse treatment and family support centers. Eligibility criteria include self-report of heavy alcohol or illicit drug use during pregnancy and ineffective or non-engagement with community social services.

Intervention Components:

- Paraprofessional home visitation;
- Goal-setting;
- Case management targeting alcohol use and contraception use; and
- Linkages to community services and programs.

Case management is provided at least twice monthly for up to 3 years following initial entry into the program.

To learn more about PCAP, including contact information, background materials, an implementation guide, and relevant forms and materials, visit **http://depts.washington.edu/pcapuw/**.

- 12-Step programs;
- Hospital treatment programs;
- Mental health programs; and
- Special pregnancy-related programs, which can be identified through your state health department by calling 800-311-BABY (2229), or 800-504-7081 for Spanish.

Programs throughout the United States have worked and are working directly with the SAMHSA FASD Center for Excellence to implement SBI (summarized above), Project CHOICES, or the Parent-Child Assistance Program (PCAP) (both summarized in the box "Targeted Referral Options," previous page). A program near you can be considered a source for possible referral or for guidance on locating a similar program. Please contact the FASD Center for Excellence for current program contact information (**www.fasdcenter.samhsa.gov**). Your local FASD State Coordinator may also be able to provide guidance on appropriate referrals. The National Association of FASD State Coordinators can be con¬tacted via the SAMHSA FASD Center for Excellence Web site: **http://fasdcenter.samhsa.gov/statesystemsofcare/nafsc.aspx**.

The feasibility of fully implementing SBI, Project CHOICES, or PCAP in your agency will depend on your staff skill set, your collaborative network, your funding, and a variety of other factors that are examined in greater detail in the Administrative section (Part 2) of this TIP.

Providing a Referral: Additional Factors to Consider

- Discuss possible strategies for the client to stop consuming alcohol; for example, individual counseling, 12-Step programs, and other treatment programs. Studies have shown that people given choices are more successful in treatment (Taylor et al., 2009).
- Use an advocate or special outreach services, if available, such as PCAP or Maternity Support Services (Taylor et al., 2009). Refer to Appendix C, *Public and Professional Resources on FASD*, for additional sources of information on community supports.
- Obtain information about costs, which health plans cover alcohol services (e.g., Medicaid, Medicare, state assistance, and public programs), who to contact to refer a patient, the phone numbers, and the necessary procedures for enrollment. This will allow you to tailor the referral to the client's needs and health insurance coverage (Higgins-Biddle, Hungerford, & Cates-Wessel, 2009).
- Identify the types of services available in your area (e.g., cognitive–behavioral, 12-Step, Motivational Enhancement Therapy) and the types of modalities (e.g., in-patient, outpatient), and prepare short descriptions of the available options so patients can understand the differences among alternative approaches (Higgins-Biddle et al., 2009).
- If possible, help the client make an appointment while she is in your office. If the woman is unwilling to make that commitment, ask if she would like some information to take with her if she should change her mind. Schedule the next visit, continue to maintain interest in her progress, and support her efforts to change. Monitor and follow up on any

Helping Your Clients Receive Culturally Competent Services

This TIP, like all others in the TIP series, recognizes the importance of delivering culturally competent care. Cultural competency, as defined by HHS, is…

"A set of values, behaviors, attitudes, and practices within a system, organization, program, or among individuals that enables people to work effectively across cultures. It refers to the ability to honor and respect the beliefs, language, interpersonal styles, and behaviors of individuals and families receiving services, as well as staff who are providing such services. Cultural competence is a dynamic, ongoing, developmental process that requires a long-term commitment and is achieved over time" (U.S. Department of Health and Human Services, 2003, p. 12).

This section discusses national information resources that are available on the topic of cultural competence or for providing care to specific cultural groups (listed alphabetically). However, the absence of a specific cultural group from this section is not meant to suggest that cultural competency is not an issue for that population. Individuals from all cultural backgrounds deserve respect and attention in a treatment environment, and the significance of culture needs to be recognized in relation to many different areas of a person's life; race, ethnicity, gender, sexual orientation, age, socioeconomic status, language, etc.

Chapter 3 of this TP, *Clinical Vignettes*, contains additional information on the essential elements of culturally competent counseling.

Hispanic/Latin Populations

If your agency is not fully capable in serving Hispanic/Latin clients or a Hispanic/Latin client requests culturally specific services, the National Council of La Raza provides a search tool (**http://www.nclr.org/index.php/nclr_affiliates/affiliate_network/**) that can direct clients to over 300 community-based organizations that provide a variety of health and general services for Hispanic/Latin populations.

In addition, SAMHSA's National Hispanic & Latino Addiction Technology Transfer Center (ATTC) offers a variety of products and resources focused on the health needs of Hispanics and Latinos. Visit their Web site at **http://www.attcnetwork.org/regcenters/index_nfa_hispaniclatino.asp**.

Native Populations

If your agency is not fully capable in serving native clients or a native client requests culturally specific services, the Indian Health Service (IHS) provides an interactive search map (**http://www.ihs.gov/findhealthcare/**) that can be used to find an IHS, Tribal, or Urban Indian Health Program (UIHP) facility. This search engine scans a variety of settings, including hospitals, behavioral health settings, village clinics, and school health facilities.

If you are unable to locate services through the map, the Health Resources and Services Administration (HRSA) provides the HRSA Health Center locator (**http://findahealthcenter.hrsa.gov/Search_HCC.aspx**) to determine if there are other culturally specific services available in your area.

Cultural Competency Training/Learning

The SAMHSA FASD Center for Excellence can provide training or technical assistance (TA) on cultural competency topics, or can put your agency in touch with a nearby specialist. Training and TA request forms can be accessed online (**http://www.fasdcenter.samhsa.gov**). Chapter 3 of this part of the TIP, Clinical Vignettes, also contains a checklist of core competencies for the culturally sensitive counselor.

In addition, the HRSA's Culture, Language and Health Literacy page (**http://www.hrsa.gov/culturalcompetence/index.html**) provides links to a range of resources on cultural competence when serving clients of differing cultures, genders, and sexual identities.

co-existing psychiatric conditions (Taylor et al., 2009).

- Maintain communication with the substance abuse treatment or other provider to monitor progress (Taylor et al., 2009).
- If immediate substance abuse treatment or other support is not available, the counselor or designated staff might meet with the woman weekly or bi-weekly to express concern and to acknowledge the seriousness of the situation (Taylor et al., 2009).

Working with Women Who May Have an FASD

When working with women of childbearing age, counselors may encounter clients who exhibit symptoms or characteristics suggesting that they themselves have an FASD. Research has identified intergenerational FASD as a pattern (Kvigne et al., 2003; May et al., 2005). Verifying the presence of an FASD is a process of observation, interviewing, and additional screening that takes time. The guidelines provided in the next chapter, *Addressing FASD in Treatment*, can prove helpful for counselors who want to pursue verification of a possible FASD in the client, and/or wish to modify their approach to delivering prevention or treatment/referral accordingly.

For more information on AEP prevention...

Vignettes 1–4 in Part 1, Chapter 3 illustrate scenarios where a counselor practices AEP prevention approaches. In addition, Part 3, the online literature review, also contains further discussion of screening and prevention interventions.

2 Addressing FASD in Treatment

IN THIS CHAPTER

Introduction

Value of Addressing FASD

Although the evidence base for effective substance abuse/mental health interventions with individuals who have or may have an FASD is limited (Premji, Benzies, Serrett, & Hayden, 2006; Paley & O'Connor, 2009), research has demonstrated that this population can and does succeed in treatment when approaches are properly modified, and that these modifications can lead to improved caregiving attitudes and reduced stress on family/caregivers as well as providers (Bertrand, 2009).

For the counselor, building competence with FASD has the obvious value of enhancing professional skills, as the counselor can provide FASD-informed care. For the client, addressing FASD has the potential to enhance the treatment experience for both the individual with an FASD and those around him or her, increase retention, lead to improved outcomes, reduce the probability of relapse (thus helping to break the cycle of repeated treatment, incarceration, displacement), and increase engagement rates in aftercare services. Access to FASD-informed interventions and accommodations, like those discussed in this chapter, has the potential to create protective factors for the client that can reduce secondary disabilities (Streissguth et al., 2004) and has been shown to lead to better outcomes (Bertrand, 2009).

For the client, addressing FASD provides an additional route to possible treatment success. Individuals with an FASD are a largely hidden population, yet these individuals frequently need services for substance abuse, and, especially, mental health (Streissguth et al., 1996). For every client that did not return for appointments, seemed noncompliant or resistant with no clear explanation of why, or just didn't seem to 'get it,' a knowledge of FASD could be an extra clue that helps solve that puzzle and enable success for both the client and the program.

Be Willing…

To effectively serve individuals who have or may have an FASD, what is needed most is a counselor who is willing. For many individuals with an FASD, it is not that they *can't* do the things necessary to succeed in treatment. Rather, it's that no one is willing to develop the understanding needed to help them succeed. While individuals with an FASD do present unique challenges, a willing counselor can make the difference between treatment success and treatment 'failure.'

- ***Be willing*** to understand the brain-based disabilities that are characteristic of these disorders: With any diffuse brain damage, including the damage that can result from prenatal alcohol exposure, some of the effects are permanent, and one cannot assume or teach the usual decision-making and self-care capabilities.
- ***Be willing*** to observe physical and behavioral factors and consider possibilities beyond defiance, noncompliance, or other more commonly diagnosed symptoms.
- ***Be willing*** to meet the client where they are and enable their growth.
- ***Be willing*** to set aside the false view that, because an FASD is permanent, "nothing can be done." Individuals with an FASD can and do respond positively to treatment that is modified to meet their unique needs.
- ***Be willing*** to develop treatment plans for this population with the identification and addressing of secondary disabilities as a built-in expectation, as research has shown that individuals with an FASD exhibit a unique prevalence of co-occurring disorders (O'Connor et al., 2002; Astley, 2010; Pei, Denys, Hughes, & Rasmussen, 2011; Kodituwakku & Kodituwakku, 2011).
- ***Be willing*** to redefine success and consider multiple treatment options and make modifications (frequency, duration, cultural issues, client strengths, etc.) to maximize the client's opportunities for recovery.
- ***Be willing*** to stretch the schedule. Success with a client who has an FASD can take longer, but it is achievable. Interventions should aim to "…support the life path of an individual with disabilities in a positive direction over time" (Olson, Oti, Gelo, & Beck, 2009).

It is important to note that this TIP is not encouraging counselors to forego the primary treatment issue that brought the client to their setting in the first place, in favor of treating FASD. This chapter is only providing a process for identifying FASD as a possible barrier to successfully addressing the primary treatment issue, and making appropriate modifications to your treatment approach to maximize the potential for positive outcomes. Even if the cognitive or behavioral barriers that you identify through this process do not ultimately result in a diagnosis or positive assessment for an FASD, these are still functional impairments presenting barriers to treatment, and thus the process remains valuable.

Identifying the Need for FASD Assessment, Diagnosis, and Services: Suggested Steps

The step chart on the next page illustrates a six-stage process that counselors can implement with clients for whom there are indications of an FASD. These steps will form the outline for the remainder of this chapter.

1. The Starting Point: Observing Indicators

Identifying Barriers and Causes

If there are indications of an FASD in the form of maladaptive behaviors, Step 1 represents a critical intermediate process: Be willing to consider the *root cause* of the behavior rather than just responding to the behavior. The

easiest way to think of Steps 1 and 2 is that Step 1 is the observation of a treatment barrier or group of barriers, Step 2 is the examination of a possible root cause (or causes).

So, in Step 1, you have a client who is not doing well in treatment, and you have exhausted your normal protocol of approaches for improving the efficacy of the treatment relationship. Since individuals with an FASD are at an increased risk of having substance use or mental health issues in the first place (Streissguth et al., 1996; Astley, 2010), what this step asks you to do is take a step back and consider whether the maladaptive behaviors that you are observing (e.g., frequently missed appointments) match the profile of an individual who may have an FASD (i.e., poor time management skills, memory problems).

When working with an individual who has an FASD, a counselor would be likely to observe problem indicators in the following functional domains:

- Planning/Temporal Skills
- Behavioral Regulation/Sensory Motor Integration
- Abstract Thinking/Judgment
- Memory/Learning/Information Processing
- Spatial Skills and Spatial Memory
- Social Skills and Adaptive Behavior
- Motor/Oral Motor Control

Problems in these domains will likely show up as deficits that interfere with treatment success, including:

- Inability to remember program rules or follow multiple instructions.
- Inability to remember and keep appointments, or to get lost on the way there.
- Inability to make appropriate decisions by themselves about treatment needs and goals.
- Inability to appropriately interpret social cues from treatment professionals or other clients.
- Inability to observe appropriate boundaries, either with staff or other clients.
- Inability to attend to (and not disrupt) group activities.

- Inability to process information readily or accurately.
- Inability to 'act one's age.'

When indicators occur in any these domains (and particularly when they occur across multiple domains), it is worthwhile to apply the FASD 4-Digit Code Caregiver Interview Checklist (Astley, 2004b) in Step 2 to determine if there is sufficient cause to 1) pursue evaluation for an FASD with this client, and 2) modify treatment to account for the client's functioning in these areas.

2. Functional Observation and History/Interviewing

An Appropriate Approach to Observation and Interviewing

If you have decided to move on to a fuller examination of the possible presence of an FASD based on indicators observed in Step 1, it is important to approach the topic with care and sensitivity. For the client, discussion of a possible FASD can cause feelings of shame, or possibly even anger or disbelief, about being identified with a "brain disorder." For the family of the individual, particularly for a birth mother, suggesting the possible presence of an FASD can lead to feelings of guilt or a feeling of being 'blamed,' and a perception that service systems are unhelpful or even a negative experience. It is critical for a counselor to take a no-fault, no-shame approach to the topic of FASD, continually reassuring the individual and the family that you are examining the possibility of an FASD only as a way to achieve the best possible treatment outcome.

The FASD 4-Digit Code Caregiver Interview Checklist

The FASD 4-Digit Code Caregiver Interview Checklist provided below is from the FASD 4-Digit Diagnostic Code (Astley, 2004b). The checklist is also reproduced in Appendix D, and can be considered for reproduction and inclusion in your treatment file for clients where you believe a form of FASD may be present.

However, please note: **This checklist is not presented as a validated FASD screening instrument**. It is simply provided as a tool that can be used over time to note typical problem areas for someone who might have an FASD (i.e., building a profile of FASD), and provides information that you can combine with your clinical judgment to make a better-informed decision about whether to direct a client toward a more extensive FASD assessment or diagnosis.

It should also be noted that the behaviors identified on this checklist can indicate other disorders, as well. Individuals with an FASD are frequently misdiagnosed (Greenbaum et al., 2009). Given their symptoms, they may be described as meeting criteria for Attention Deficit/Hyperactivity Disorder (ADHD), Attention Deficit Disorder (ADD), Oppositional Defiant Disorder (ODD), adolescent depression, or bipolar disorder. It is possible for FASD to co-occur with any of these diagnoses, but it is also possible that a condition on the fetal alcohol spectrum may better describe the pattern of target symptoms than these other diagnostic terms. A differential and comprehensive diagnosis is essential, whether in-house or through referral, and the information gathered through this checklist can help to inform a diagnostic process.

In a profile of the first 1,400 patients to receive diagnostic evaluations for an FASD at the Washington State FAS Diagnostic & Prevention Network (FAS DPN), caregivers completing an interview with a professional based in part on this checklist demonstrated an impressive ability to differentiate the behavior profiles of children with FAS/pFAS, children with severe ARND (SE/AE), and

The FASD 4-Digit Code Caregiver Interview Checklist

Severity Score: Severity of Delay/Impairment (Displayed along left margin)

Circle: **0** = Unknown, Not Assessed, Too Young **1** = Within Normal Limits **2** = Mild to Moderate **3** = Significant

Severity	Caregiver Observations
	Planning/Temporal Skills
0 1 2 3	Needs considerable help organizing daily tasks _____
0 1 2 3	Cannot organize time _____
0 1 2 3	Does not understand concept of time _____
0 1 2 3	Difficulty in carrying out multi-step tasks _____
0 1 2 3	Other _____
	Behavioral Regulation/Sensory Motor Integration
0 1 2 3	Poor management of anger/tantrums _____
0 1 2 3	Mood swings _____
0 1 2 3	Impulsive _____
0 1 2 3	Compulsive _____
0 1 2 3	Perseverative _____
0 1 2 3	Inattentive _____
0 1 2 3	Inappropriately [high or low] activity level _____
0 1 2 3	Lying/stealing _____
0 1 2 3	Unusual [high or low] reactivity to [sound touch light] _____
0 1 2 3	Other _____
	Abstract Thinking/Judgment
0 1 2 3	Poor judgment _____
0 1 2 3	Cannot be left alone _____
0 1 2 3	Concrete, unable to think abstractly _____
0 1 2 3	Other _____
	Memory/Learning/Information Processing
0 1 2 3	Poor memory, inconsistent retrieval of learned information _____
0 1 2 3	Slow to learn new skills _____
0 1 2 3	Does not seem to learn from past experiences _____
0 1 2 3	Problems recognizing consequences of actions _____
0 1 2 3	Problems with information processing speed and accuracy _____
0 1 2 3	Other _____
	Spatial Skills and Spatial Memory
0 1 2 3	Gets lost easily, has difficulty navigating from point A to point B _____
0 1 2 3	Other _____

Severity	Caregiver Observations
	Social Skills and Adaptive Behavior
0 1 2 3	Behaves at a level notably younger than chronological age _____
0 1 2 3	Poor social/adaptive skills _____
0 1 2 3	Other _____
	Motor/Oral Motor Control
0 1 2 3	Poor/delayed motor skills _____
0 1 2 3	Poor balance _____
0 1 2 3	Other _____

children with moderate ARND (ND/AE) (Astley, 2010).

In addition, the box "Risk Assessment Questions" contains a group of questions developed at the FAS Community Resource Center in Tucson, Arizona. These questions can further assist providers seeking to determine whether an evaluation for an FASD is warranted.

3. Assessment (External or Through an In-House Assessment Team)

Assessment for the presence of an FASD is an interdisciplinary process best accomplished through a team approach. The sad reality is that the existing network of qualified assessment teams and facilities in the United States is insufficient to meet demand, and behavioral health experts have repeatedly observed the urgent need for an increase in FASD

Risk Assessment Questions

Yes/No	Additional Areas of Consideration
	Client History
Y N	Are there alcohol problems in family of origin?
Y N	Was the client raised by someone other than the birth mother?
Y N	Has the client ever been in special education classes?
Y N	Has the client had different home placements?
Y N	Has the client ever been suspended from school?
Y N	Has the client ever been diagnosed as ADHD?
	How many jobs has the client had in past 2 years? _____
Y N	Can the client manage money effectively?
	Are the client's friends older or younger (for an individual with an FASD, friends will tend to be younger due to lag between physical age and functional age)? _____

Adapted from: Kellerman, T. (2005). Recommended assessment tools for children and adults with confirmed or suspected FASD. Tucson, AZ: FAS Community Resource Center. Accessed June 5, 2012 at **http://come-over.to/FAS/AssessmentsFASD.htm**.

assessment, diagnosis, and treatment capacity (Institute of Health Economics, 2009; Interagency Coordinating Committee on FASD, 2011).

However, many substance abuse and mental health treatment settings may have an interdisciplinary staff team and/or sufficient referral relationships to attempt FASD assessment internally, creating an opportunity to help fill a gap in the behavioral health field. If this is the case with your agency, this section discusses some of the essential elements of FASD assessment, as well as available resources that can help your agency develop this staff capability. (The first interdisciplinary FASD diagnostic clinic [the Washington State FAS Diagnostic and Prevention Network (FAS DPN)] was established in Washington State in 1993 as part of a CDC-sponsored FASD prevention study [Clarren & Astley, 1997]. A comprehensive description of the interdisciplinary model used by the Washington State FAS DPN is presented by Clarren, Carmichael-Olson, Clarren, and Astley [2000]; see Appendix A: *Bibliography*). In addition, for sites that cannot provide FASD capacity internally, referral options do exist, and this section will provide information on accessing those resources.

In-House FASD Assessment: The Essential Elements

Effective in-house assessment for FASD is built on three core components: 1) building the right team, 2) accessing the right resources, and 3) gathering the right information.

Building the Right Team

FASD assessment, as will be explained below, involves gathering information and making evaluations in a variety of functional areas, and is an involved process that can overwhelm the client and his or her family. This necessitates a wide range of professional skill sets, not only to perform the various clinical and observational tasks, but also to help the client and family navigate the process smoothly. The box "In-House FASD Assessment: An Ideal Core Team" describes an ideal in-house FASD assessment team and its functions.

Part 2, Chapter 2 of this TIP outlines appropriate processes if these professionals need to be added and/or accessed through referral relationships.

Accessing the Right Resources

Appendix C, *Public and Professional Resources on FASD*, provides information and links for accessing FASD information and training from a variety of national and regional sources.

In-House FASD Assessment: An Ideal Core Team

Case Coordinator	• Reviews history and current stability • Assesses needs of individual and caregiver • Post-diagnosis, connects individual/family to positive supports • Is often a social worker, but in this case could be the role of the counselor
Psychologist[1] and Speech Language Pathologist	• Assess basic and higher levels of brain function
Physical Therapist, Occupational Therapist, or Vocational Rehabilitation Counselor	• Assesses motor and sensory issues (including sensory-motor integration, and balance and gait issues)

Physician	• Assesses dysmorphology, neurological findings, and basic health determinants • Also contributes to behavioral health profile
Family Navigator	• Helps the family through the process • Ideally is an actual caregiver of someone with an FASD • Ideally is available to help the family connect with parent support and other needed resources

Based on TIP consensus panel recommendations and *Canadian Guidelines for Diagnosis* (Chudley, Conry, Cook, Loock, Rosales, & LeBlanc, 2005).

[1] The psychologist should be trained to do neuropsychological testing.

Among these are two excellent resources for agencies seeking to develop FASD capabilities; the Washington State FAS DPN and the CDC's FASD Regional Training Centers (RTCs).

- One of the primary sites for FASD assessment and diagnosis in the United States is the Washington State FAS DPN, based at the University of Washington in Seattle. Established in 1993 through Washington State Senate Bill 5688 and support from the CDC, March of Dimes, Chavez Memorial Fund, and the Washington State Department of Social and Health Services, the Washington State FAS DPN provides FASD diagnostic services as well as training in FASD. Training resources include the FASD 4-Digit Diagnostic Code Online Course and a 2-day FASD Diagnostic Team training for interdisciplinary clinical teams (or individual clinical team members) seeking to establish FASD services in their community. Visit the FAS DPN's homepage (**http://depts.washington.edu/fasdpn/**) to find out more about their services.
- The CDC's RTCs develop, implement, and evaluate educational curricula regarding FASD prevention, identification, and care, and incorporate the curricula into training programs at each grantee's university or college, into other schools throughout their regions, and into the credentialing requirements of professional boards. Visit the CDC's RTC homepage (**http://www.cdc.gov/ncbddd/fasd/documents/flyerfasd_rtcs.pdf**) to find out about currently funded RTC sites and available services.

Gathering the Right Information

A useful tool that your team can use to gather and organize the necessary information to support a formal FASD diagnosis is the *New Patient Information Form*. This form was developed by the Washington State FAS DPN and is part of the *Diagnostic Guide for Fetal Alcohol Spectrum Disorders: The 4-Digit Diagnostic Code* (Astley, 2004b, Third Edition, pp. 103-114). If your agency decides to refer a client for an FASD diagnosis, this information will provide a necessary foundation for the diagnostic process. The *New Patient Information Form* can be downloaded for free from (**http://depts.washington.edu/fasdpn/htmls/diagnostic-forms.htm**).

In addition to basic information about the client and your agency, the *New Patient Information Form* provides a template for gathering information in the critical areas of Growth; Physical Appearance and Health; Neurological Issues; Attention Deficit and

Hyperactivity; Mental Health Issues; School Issues; Alcohol Exposure; Information About the Patient's Biological Parents; Medical History of the Biological Family; Pregnancies of Birth Mother; Pregnancy, Labor, and Delivery of this Patient; List of Professionals Currently Involved in Patient's Care; Placements (foster, adoptive, etc.); and What to Bring to the [diagnostic] Clinic.

To further ensure collection of appropriate information and build staff knowledge and capabilities related to FASD, it will be valuable for your team to become familiar with the basic guidelines of the most widely used diagnostic approaches to the various disorders in the spectrum. A comprehensive comparison of the current FASD diagnostic systems is presented in a chapter entitled "Diagnosing FASD" (Astley, 2011), and is reprinted in Appendix E, *Comparison of Current FASD Diagnostic Systems* with the author's permission.

External: Assessment and Diagnosis

The reality for many programs will be that, for reasons of cost and/or lack of community resources, building an in-house FASD assessment team or diagnostic capability will be unrealistic. If this describes your agency, the FASD diagnosis and training sites discussed under *Accessing the Right Resources*, above, should be accessed so that you can refer your client to an appropriate provider. Agencies can also use the **Resource Directory** (**http://www.nofas.org/resource-directory/**) provided by the National Organization on FAS (NOFAS) to help locate FASD-related services.

At the same time, referral for assessment and diagnosis should be paired with treatment modifications and accommodations that are discussed in the next section. This can be done with or without a formal diagnosis of a form of FASD. If you and your clinical team have identified symptoms indicating an FASD through Steps 1 and 2 of this chapter, the methods discussed in the next section can still help the treatment process.

Many providers will not have an existing relationship with the FASD assessment or diagnosis provider to whom they refer a client. In such cases, it is vital to actively assist the client through the transition and provide regular follow-up to ensure client satisfaction and full and open communication between agencies and with the client. (Also the client's family, if they are involved in treatment.) The box "Overview of the Diagnostic Process (As Performed by the FAS DPN)" summarizes the phases of the diagnostic process as performed

Overview of the Diagnostic Process (As Performed by the FAS DPN)

A comprehensive description of the FAS DPN interdisciplinary FASD diagnostic process is presented by Clarren et al. (2000).

Phase	Description
Phase 1	• Clinical intake: Caregivers complete a comprehensive "New Patient Information Form" prior to the clinic visit to report current concerns and developmental, social and alcohol exposure history. Past medical, educational, psychological, social, and legal records are also obtained. • Record review: Psychologist reviews all available medical, developmental, clinical, educational, and other records, and presents a case summary to the FASD diagnostic team on the day of the diagnostic evaluation. Clients 18 and older are referred elsewhere for their neuropsychological evaluation.

Phase	Description
Phase 2	• Psychometric screening/evaluation: Diagnostic team members (occupational therapist, psychologist, speech–language pathologist) screen/assess the patient's current neurobehavioral performance (e.g., language and communication, executive function, cognition, sensory–motor skills). • Physical examination: Physician examines diagnostic parameters of growth and facial dysmorphology (and general health, sleep problems, medications used, etc.). • Caregiver(s) interview: Physician and psychologist conduct a caregiver interview (up to 2 hours) using the 4-Digit Code Caregiver Interview checklist.
Phase 3	• Diagnosis and intervention recommendations: Diagnostic team reviews and synthesizes data, derives the 4-Digit Code, and generates intervention recommendations. • Diagnostic summary: Diagnostic team shares the diagnosis and intervention recommendations with caregiver(s) in a brief case conference. Adolescent and adult clients are included in the case conference. • Diagnostic summary report: Diagnosis, assessment results, and intervention recommendations are integrated into a comprehensive 6- to-8-page diagnostic summary report (**http://depts.washington.edu/fasdpn/pdfs/4-digit-medsum-web-2006.pdf**) and submitted to the patient's medical record. • Follow-Up Debriefing: A private follow-up debriefing is conducted with the caregiver (and client, if old enough) to discuss the impact of the diagnosis and review specific recommendations.

Table originally appeared in Jirikowic, Gelo, & Astley (2010) with minor modifications.

by the Washington State FAS DPN. The phases of this process are likely to be similar in other interdisciplinary FASD diagnostic clinics.

When the Client Already Has a Diagnosis of an FASD

If a client has already been diagnosed with an FASD at the time of presentation to your setting, the guidelines in the next section should automatically be considered. In addition, as indicated in the table *Overview of the Diagnostic Process* in the previous section, the diagnosis report may also be a source of intervention and modification guidelines and should be thoroughly reviewed by the counselor with the client (and the family, if involved in the treatment process). A comprehensive summary of the types of intervention recommendations provided in relation to 120 youths following their FASD diagnostic evaluations at the Washington State FAS DPN is provided by Jirikowic et al. (2010).

At the same time, further assessment by medical, mental, and allied health professionals may still be needed to determine the client's current level of function in important areas, particularly if the diagnosis occurred years earlier. "Refreshing" the functional information will help the counselor tailor the treatment plan and counseling strategies to the client's strengths, needs, and preferences. Forms of re-testing and assessment can include the following:

- Being familiar with any medications the client is taking and observing any behaviors or physical symptoms that might indicate the need to reevaluate medication use or dosage;
- Hearing and speech tests to identify any progress in communication or barriers

that may affect the client's treatment and ongoing recovery;

- Occupational therapy and physical therapy evaluations to assess the client's daily living skills and motor function, vocational skills, and preferences and possibilities;
- Determining current achievement levels in reading, spelling, and math; and
- Use of an appropriate, standardized interview or questionnaire to determine how the client compares to peers in receptive, expressive, and written communication; personal, domestic, and community daily living skills; and interpersonal relationships, play and leisure time, and coping skills.

4. Tailoring Treatment for Individuals with an FASD

Introduction

This section will discuss appropriate approaches to modifying treatment and/or making necessary accommodations for clients who exhibit indicators suggesting an FASD, or who show cognitive and behavioral barriers to treatment success, as identified in Steps 1 and 2 of this chapter.

This discussion is divided into two sections; 1) general principles for working with individuals who have or may have an FASD (regardless of age), and 2) specific considerations for adolescents who have or may have an FASD. The chapter then moves on to Step 5, *Working With the Family*, and Step 6, *Transition and Connection to Community Supports*.

As noted above, if the individual already has a diagnosis of an FASD, the diagnostic report may also include recommendations for appropriate interventions and modifications to treatment. The counselor should review this report thoroughly, if it is available.

General Principles for Working with Individuals Who Have or May Have an FASD

Safety Considerations

Safety is a primary health issue for individuals of all ages with an FASD (Jirikowic et al., 2010). Starting a treatment process without first addressing safety issues is futile and potentially dangerous: The clinician must first evaluate physical safety for the adolescent or adult with an FASD. This includes issues of violence, harm to self (such as self-mutilation) or others, victimization, adequate housing, and food. In typical adolescents and adults, psychiatric severity can be significantly reduced when co-occurring issues are treated together and mental health and substance abuse treatment are provided as an integrated program (Hser, Grella, Evans, & Huang, 2006).

For older individuals who have or may have an FASD, there are special safety considerations. This population has a number of risk factors for accidents and injury; poor decision-making, impulsivity, impaired motor coordination, working memory, attention, emotional and sensory regulation, and susceptibility to peer pressure. Even seemingly routine tasks like crossing the street safely may be impossible for those who are more severely affected. Other examples of possible safety and health concerns in adolescents and adults with an FASD are remembering medication schedules, decisions about legal and illegal substances, driving, and risk-taking situations in which poor social problem-solving (McGee, Fryer, Bjorquist, Mattson, & Riley, 2008), impulsivity, and peer pressure combine to compromise safety.

Vignette #9 in Part 1, Chapter 3 of this TIP elaborates the process of working with a caregiver to develop a personalized Safety Plan on behalf of an individual with an FASD. In addition, Appendix F, *Sample Crisis/Safety Plan*, contains a sample plan that has been

adapted from the work of the *Families Moving Forward Program* (**http://depts.washington.edu/fmffasd/**), and can be printed and used with a client and/or their family member(s)/caregiver(s).

Risk for Abuse

Children with physical, psychological, and sensory disabilities—including FASD—are known to be more vulnerable to violence and maltreatment, or to be at a greater risk of these forms of abuse (Olivan, 2005). This vulnerability is brought about by a variety of factors, including dependence on others for intimate and routine personal care, increased exposure to a larger number of caregivers and settings, inappropriate social skills, poor judgment, inability to seek help or report abuse, and lack of strategies to defend themselves against abuse. Murphy and Elias (2006) report figures from the National Center on Child Abuse and Neglect indicating that children with disabilities are sexually abused at a rate 2.2 higher than that for children without disabilities. The United States Department of Justice reports that 68 to 83 percent of women with developmental disabilities will be sexually assaulted in their lifetimes, and less than half of them will seek assistance from legal or treatment services (Pease & Frantz, 1994). In a study of 336 males and females in treatment for alcohol abuse or dependence, more than 56 percent had also experienced childhood sexual or physical abuse (Zlotnick et al., 2006).

In one long-term study, 80 percent of young adults who had experienced abuse as a child met diagnostic criteria for at least one psychiatric disorder at age 21. These individuals exhibited many problems, including depression, anxiety, eating disorders, and suicide attempts (Silverman, Reinherz, & Giaconia, 1996). Other psychological and emotional conditions associated with abuse and neglect include panic disorder, dissociative disorders, attention-deficit/hyperactivity disorder, depression, anger, posttraumatic stress disorder, and reactive attachment disorder (Teicher, 2000; De Bellis & Thomas, 2003; Springer, Sheridan, Kuo, & Carnes, 2007).

Astley (2010) has documented a high prevalence of abuse, neglect, and multiple home placements among 1,400 patients identified with an FASD—70 percent were in foster/adoptive care and had experienced, on average, three home placements. In fact, in a separate study, Astley and colleagues (2002) identified a prevalence rate of FAS in foster care that was 10-times higher—1/100—than in the general population—1/1000. Children in foster care face a risk of maltreatment, which can affect their physical health and lead to attachment disorders, compromised brain functioning, inadequate social skills, and mental health difficulties (Harden, 2004). Another study among young women with FASD found that they had poor quality of life scores and high levels of mental disorders and behavioral problems relative to standardization samples and other at-risk populations (Grant et al., 2005).

Risk for Suicide

In addition, individuals with an FASD are at significant risk of suicide at all ages studied (Huggins et al., 2008). A person with an FASD may not appear to plan or execute a suicide attempt effectively; this is not indicative of the seriousness of the intent.

High Risk of Repeated Involvement with the Legal System

People with an FASD can have specific types of brain damage that may increase engagement in criminal activity (Kodituwakku et al., 1995; Page, 2001; Mattson, Schoenfeld, & Riley, 2001; Page, 2002; Moore & Green, 2004; Clark et al., 2004; Schonfeld, Mattson, & Riley, 2005; Schonfeld, Paley, Frankel, O'Connor, 2006; Brown, Gudjonsson, & Connor, 2011). These can include:

Suicide Intervention/Prevention for Individuals with an FASD

- Standard suicide assessment protocols need to be modified to accommodate neuropsychological deficits and communication impairments:
  - Instead of "How does the future look to you?" ask "What are you going to do tomorrow? Next week?" (Difficulties with abstract thought.)
  - The seriousness of the suicidal behavior does not necessarily equal the level of intent to die (lack of understanding of consequences).
- Obtain family/collateral input.
- Be careful about words used regarding other suicides or deaths.
- Intervene to reduce risk:
  - Address basic needs and increase stability.
  - Treat depression.
  - Teach distraction techniques.
  - Remove lethal means.
  - Increase social support.
- Do not use suicide contracts (impulsivity issues).
- Monitor risk closely.
- Reinforce and build reasons for living.
  - Be literal.
- Strengthen advocate-client relationship.

Source: Huggins, J. E., Grant, T., O'Malley, K., & Streissguth, A. (2008). Suicide attempts among adults with Fetal Alcohol Spectrum Disorders: Clinical considerations. *Mental Health Aspects of Developmental Disabilities, 11*(2), 33-42.

- Lack of impulse control and trouble understanding the future consequences of current behavior;
- Trouble understanding what constitutes criminal behavior (for example, a youth with an FASD may not see any problem with driving a car he knows was stolen if he wasn't the one who stole it);
- Difficulty planning, connecting cause and effect, empathizing (particularly if the experience is not explained in a very concrete way), taking responsibility, delaying gratification, and making good judgments;
- Tendency toward explosive episodes, often triggered by sensory overload, slower rates of processing the information around them, and/or feeling "stupid;"
- Vulnerability to peer pressure and influence (e.g., may commit a crime to please friends), and high levels of suggestibility; and
- Lower level of moral maturity (due in part to social information processing deficits).

The number of people in the criminal justice system with an FASD has not specifically been determined. Data are limited, and populations vary by state. In addition, few systems conduct any screening or can provide diagnosis. Streissguth and colleagues (2004) conducted an evaluation of 415 clinical patients with FASD at the University of Washington. Trouble with the law (including arrest, conviction, or otherwise) was reported in 14 percent of children and 60 percent of adolescents and adults with an FASD. In addition, Fast, Conry,

& Loock (1999) evaluated all youth referred to a forensic psychiatric assessment for FASD in Burnaby, British Columbia, Canada. Of 287 youths assessed, 67 (or 23 percent) were found to have an alcohol exposure-related diagnosis. Although this result should not be generalized to the entire prison population, it does reveal a possible disproportionate representation of individuals with an FASD in the juvenile justice system.

It is important for counseling professionals to consider a client's criminal history and any factors that place the client at risk for further criminal involvement. Because persons with an FASD have problems learning from experience, they may repeat crimes and cycle through the legal system multiple times.

Clinicians may encounter individuals with an FASD who are participating in court-ordered treatment. Such individuals need help navigating the legal system. The clinician can consult with the client's attorney and assist in educating him or her about FASD. In addition, the clinician can assist in finding resources to help the client understand any legal proceedings and requirements. The National Legal Aid & Defender Association (**http://www.nlada100years.org/**) or the American Bar Association (**www.americanbar.org**) may be able to identify resources at the local level.

Vulnerability of Individuals with an FASD
Individuals with an FASD are vulnerable not only to criminal activity but also to victimization (Freunscht & Feldman, 2011). Their poor judgment may lead them to associate with people who victimize them physically, emotionally, and financially. Their impulsivity may lead them into dangerous situations. Women with an FASD may get involved with negative associations for food, shelter, attention, or drugs (Page, 2003). In addition, their impaired sense of boundaries can lead to sexual victimization. Because of their unpredictable behavior, they may need 24-hour supervision (Streissguth, 1997).

Even with compensatory strategies, the person with an FASD may be less able to use judgment, consider consequences, or understand abstract situations (Kodituwakku, 2007; Astley, 2010; Freunscht & Feldman, 2011). Impulsivity is an ongoing issue. Social isolation and loneliness may drive the person to seek out any type of friendship and lead to victimization. A discussion or pursuit of safeguards for the person may be necessary:

- Recognize that victimization may occur, and keep vigilant for situations that may arise in the person's life.
- Role-play personal safety and specific scenarios that people face (e.g., who is a stranger vs. who is a friend) to allow the individual to practice taught skills and perhaps allow them to pursue safe activities (De Vos, 2003). Consider videotaping the client doing it right in the role-play, so he or she can watch it over and over, reinforcing the lesson. Watching the video also helps move the information from short-term memory to long-term memory. (In many cases, though certainly not all, long-term memory has been observed to function better than short-term memory for individuals with an FASD).
- Establish written routines and structured time charts, and have these where they are easily seen throughout the day.
- Provide a buddy system and supervision to help decrease opportunities for victimization.
- Consider a guardianship of funds to protect the individual. A trustee can ensure that the necessities of life are covered, including rent, food, clothing, and finding an advocate. The clinician may want to

include such provisions in the aftercare plan.
- Help the client find a healthy, structured environment in aftercare to help them avoid criminal activity.

Family Safety and Support

For all families caring for an individual with an FASD, or when parents themselves have an FASD, establishing family safety and support is vital. A crisis/safety plan should always be put in place (see Appendix F for an example *Crisis/Safety Plan* form). To stay safe and well-supported, it is important to help the client (and caregivers) identify available services, determine which ones are effective for them or their children, and understand how to work productively with service providers (Streissguth, 1997). (See Appendix G for a *Services and Supports Checklist* that can be reviewed with clients as a worksheet.)

For birth families in recovery, the counselor can help families cope with FASD during the recovery process. This is best done by building a protective environment for clients and their children. This may include helping them obtain safe, stable housing, assisting with daily living skills (such as bill paying and food shopping), and overseeing home situations. It is also important to establish a network of community service providers who will be available for aftercare to promote ongoing recovery and avoid relapse (Millon, Millon, & Davis, 1993).

For more information about this topic, see Step 6, *Transition and Connection to Community Supports*).

Modifying a Treatment Plan

Factors to Consider

When modifying a treatment plan for an individual who has or may have an FASD, the following should be considered:

- **Help the client adjust to a structured program or environment and develop trust in the staff**. Individuals with an FASD tend to be trusting (Freunscht & Feldman, 2011) and need a great deal of structure, but may have trouble adapting to changes in routine and to new people.
- **Share the rules early and often**. Put instructions in writing and remind the client often. Keep the rules simple and avoid punitive measures that most individuals with an FASD will not process. If a rule is broken, remind the client of the situation and help to strategize ways they can better follow the rule in the future.
- **Take a holistic approach**, focusing on all aspects of the client's life, not just the substance abuse or mental health issues. Include basic living and social skills, such as how to dress, groom, practice good hygiene, present a positive attitude, and practice good manners. Help the client develop appropriate goals within the context of his or her interests and abilities.
- **Provide opportunities to role-play or otherwise practice appropriate social behaviors**, such as helping others. Areas of focus may include impulse control skills, dealing with difficult situations such as being teased, and problem-solving.
- In an inpatient setting, **allow time** for the client to be stabilized and acquire the basic skills to cooperate with others before discussing his or her substance abuse or mental health issues. In an outpatient setting, it may help to develop a rapport with the client and establish trust and communication before addressing the primary treatment issue.
- **Assume the presence of co-occurring issues**. It is likely that a high percentage of people with an FASD have at least one co-occurring mental disorder (O'Connor

et al., 2002; Streissguth et al., 2004; Clark et al., 2004; Astley, 2010). In a study of 1,400 patients with FASD, Astley (2010) documented that 75 percent had one or more co-occurring disorders, with the most prevalent being ADHD (54 percent). In a study of 80 birth mothers of children with FAS, 96 percent had from one to nine mental disorders in addition to alcoholism (Astley et al., 2000b); the most common was phobia (76 percent). Forty-four percent of the women had mental disorders diagnosed by the age of 8 years.

- When possible, **include the family or caregivers in activities**, such as parent education about FASD and substance abuse and/or mental health, strategies for providing care for an individual with an FASD and a substance abuse or mental health problem (e.g., avoiding power struggles), and building the client's self-esteem. Help family and caregivers practice positive communication skills such as active listening, use of literal language, and avoiding "don't" (i.e., focusing on what *needs* to be done rather than what *should not* be done).
- **Include the client in treatment planning/modification**, and build family/caregiver meetings into the plan as well, with a clear purpose and agenda. Recognize that some family members may also have an FASD, and work with them accordingly.
- **Incorporate multiple approaches to learning**, such as auditory, visual, and tactile approaches. Avoid written exercises and instead focus on hands-on practice, role-playing, and using audio- or video-recording for playback/reinforcement of learning. Use multisensory strategies,

The Navigator

A person who has impaired vision is given a seeing eye dog. A person with impaired hearing is given an interpreter or a hearing aid. These external devices are necessary for the person with physical impairments to be able to function to maximum potential in life.

The person with an FASD has a physical impairment in the area of the brain, particularly the forebrain or frontal lobes, which regulate the executive functions. A navigator refers to the presence of another responsible person (parent, teacher, job coach, sibling) who can mentor, assist, guide, supervise, and/or support the affected person to maximize success (which may need to be redefined as the avoidance of addiction, arrest, unwanted pregnancy, homelessness, or accidental death).

Because some individuals with an FASD may appear to be bright and normal, the disability that is brain damage may only be apparent in test results, or in actions that place the person at serious risk. It is the risk of danger to the person and to others that makes a navigator such a useful and important concept. A navigator can seem like a form of enabling or an encouragement of co-dependency. More accurately, however, a navigator is an appropriate form of advocacy to ensure that the individual receives whatever assistive devices are needed for him or her to participate in life in as normal a capacity as reasonably possible.

For many individuals with an FASD, the navigator can be someone with whom they "check in" on a regular basis, or vice versa. For others, the navigator will play a more constant advocacy role, and may share the role with others. (See Vignette #9 for an example of a father playing the role of a navigator, and sharing the role with a coach and one of his son's relatives.)

Adapted from: Kellerman, T. (2003). External brain. Accessed June 5, 2012 at **http://come-over.to/FAS/externalbrain.htm**.

such as drawing, painting, or music, to assist the client in expressing feelings. These strategies take advantage of skills that many individuals with an FASD have. They can also help the client share difficult feelings that may be hard to talk about, such as fear and anger.

- **Consider sensory issues** around lighting, equipment sounds, and unfamiliar sensations and smells. Individuals with an FASD can be very sensitive to these environmental factors.
- **Arrange aftercare**, and encourage family/caregivers to participate in a support group to continue to learn parenting skills and to be encouraged in the recovery process (see Step 6, *Transition and Connection to Community Supports*).

Counseling Strategies

Due to the cognitive, social, and emotional deficits seen in FASD, counseling clients with these conditions requires adaptability and flexibility. Research data, clinical observation, and caregiver reports all suggest that it is crucial to tailor treatment approaches. Traditional approaches may not prove optimally effective, and more effort may be needed to convey basic concepts and promote a positive therapeutic relationship and environment. The following are recommendations designed to help providers:

- Set appropriate boundaries;
- Be aware of the client's strengths;
- Understand the impact of any abuse the client has experienced;
- Help the client cope with loss;
- Address any negative self-perception associated with an FASD;
- Focus on self-esteem and personal issues;
- Address resistance, denial, and acceptance;
- Weigh individual vs. group counseling;
- Consider a mentor approach; and
- Assess comprehension on an ongoing basis.

Boundaries

Establishing a trusting and honest relationship while maintaining boundaries is important with any client. Because persons with an FASD often lack social skills and have social communication problems (Kodituwakku, 2007; Greenbaum et al., 2009; Greenspan, 2009; Olson & Montague, 2011), they may breach boundaries by making inappropriate comments, asking inappropriate questions, or touching the counselor inappropriately. To set boundaries, it may help to have the client walk through the rules and expectations and demonstrate expected behavior. Frequent role-playing can help the client learn to apply concepts and figure out how to respond to various situations.

Persons with an FASD frequently experience difficulty with memory (Rasmussen, 2005; Riggins et al., 2012). Added to this, they may be able to repeat rules but not truly understand them or be able to operationalize them. Thus, it is important to review rules regularly. It is much more effective to limit the number of rules, review them repeatedly, and role-play different situations in which the person will need to recall the rules. Repetition is key.

Strengths

Many people focus on the deficits in persons with an FASD, but they also have many strengths. Some of these can be used in the treatment setting as part of counseling. Family may be a strength area: Parents report their children with FASD were engaged with their families and willing to receive—and even seek—help (Olson et al., 2009), as well as demonstrating a willingness to provide assistance with ordinary tasks (Jirikowic et al, 2008). Based on extensive clinical experience, Malbin (1993) identifies a number of other strength areas. For example, some people with

an FASD are quite creative. They can express themselves through art and music, which may prove more effective than traditional talk therapy. Other approaches may involve storytelling and writing. These techniques can also be used for practical matters, such as developing a poster with treatment goals. In addition, visual aids can assist by drawing on areas of relative strength, so drawn or pictured goals may aid recall better than a written or spoken list of instructions.

History of Abuse

Given the risk of abuse among persons with an FASD and among individuals with substance abuse and/or mental health issues, it is likely that a client with a combination of these will have some personal abuse history (Astley et al., 2000b). The counselor working with persons with an FASD needs to be sensitive to the possibility of childhood abuse and other forms of victimization, and their impact on the counselor–client relationship. A common theme that counselors need to be attentive to is *powerlessness*, a theme often reflected in the following types of client communications and behaviors:

- Clients undervaluing their own competencies.
- Clients viewing others' needs and goals as more important than their own.
- Clients' inability to obtain nurturance and support for themselves.
- Clients' feelings of depression, anger, and frustration about their lives.
- Clients' low expectations for their own success.

Loss and Grieving

All individuals with an FASD have experienced losses in their lives. The fact that they are not like their peers is a loss of the ability to be like everyone else. Some have lost the hopes and dreams of what they wanted to be. Others lose their family or a secure future. Some lose the opportunity for meaningful peer relationships and friendships. These losses can affect people in many ways and need to be addressed. The counselor can help to address these areas of loss through a number of strategies:

- Use active listening strategies, such as repeating what the person has said;
- Be honest;
- Raise awareness of experiences of separation and loss;
- Acknowledge and validate losses experienced;
- Acknowledge the client's feelings about loss;
- Avoid "good parent/bad parent" issues;
- Encourage communication; and
- Refer for further treatment (e.g., mental health) when necessary.

Self-Perception

Self-perception is a major issue with FASD. Despite the advent of the disease model, many people still view alcohol problems as a sign of moral weakness or a character flaw. This negative stereotype can be particularly severe in relation to pregnant women who drink, making the topic difficult to discuss (Salmon, 2008). Added to this, the negative judgment toward the mother may also be visited on the child. A counselor needs to be aware of this, and approach the issue carefully and sensitively if he or she suspects a client has an FASD.

Given their cognitive, social, and emotional deficits, persons with an FASD may think they are powerless to change. It is important to work through this issue with the client. They need to understand that they are not responsible for their disability and that they deserve respect. They also need to know that change is possible.

Self-Esteem and Personal Issues
The combination of abuse, loss, grief, and negative stereotypes can lead to self-esteem issues in any individual. Self-esteem is regularly an issue for individuals with an FASD (Olson, O'Connor, & Fitzgerald, 2001). Those who also have substance abuse or mental health problems face a double-edged sword: Their self-esteem can be damaged by their experience with an FASD and by their substance abuse or mental health issue. The clinician can use several strategies to help address self-esteem and personal issues:

- **Use person-first language**. An FASD may be part of who a person is, but it is not the person's entire identity. Someone can have an FASD, but nobody is an FASD.
- **Do not isolate the person**. Sending persons with an FASD out of the room to think about what they have done or responding to issues in a group session by simply ejecting them will often increase their sense of isolation and does not help them learn appropriate behaviors.
- **Do not blame people for what they cannot do**. Demanding that people repeatedly try to do things they cannot do is a lesson in frustration. It is important to have patience and understand individual limitations. People with an FASD may need something repeated several times because they have trouble remembering, not because they refuse to pay attention.
- **Set the person up to succeed**. Measures of success need to be different for different people. It is important to identify what would be a measure of success for the individual with an FASD and reinforce successes in concrete terms (e.g., "You did a great job of being on time for our session today. Thank you.") Training in social skills, anger management skills, and relaxation skills can help. In order for skills-building programs to be most successful for the person with an FASD, they need to be repeated periodically.

Resistance, Denial, and Acceptance
Individuals who have or may have an FASD may deny that they have a disability. Although some are relieved to know the cause of their difficulties, others may struggle to confront or accept their situation. The counselor needs to take time to help the person cope with the lack of understanding that often surrounds FASD. Women with an FASD, for instance, may fear becoming like their mothers and having a child with an FASD. An individual with an FASD may have difficulty with forgiveness of the birth mother, or may feel that it is inevitable that they will pass on FASD to their children. Counselors should reassure clients that they are not responsible for their disability, help them resolve their feelings about the birth mother, and educate them about the science of their condition (i.e., that it is not inevitable that they would pass on the condition). This process may take awhile, and the person may drift back and forth from accepting the disability to denying it. Exploring the reasons for the denial and understanding the client's fears can help.

Individual Counseling vs. Group Sessions
Individuals with an FASD may struggle to function in a group setting. Studies have shown increased levels of sensory sensitivities in this group, at least for children (Jirikowic et al., 2008). Clinical observations suggest individuals with an FASD can become overwhelmed by sensory input from large groups, noise, small spaces that cause crowding and touching of others, and visual distractions. Given the executive function deficits that are common in this clinical population, individuals with an FASD may not be able to process everything in the discussion and become lost. They may also 'talk too much,' and/or not be

able to effectively convey their feelings and ideas in group discussions.

Individual counseling may be needed to avoid some of the issues that arise in clients with an FASD who lack social skills and find group settings confusing or overwhelming. Talk therapy can be modified to incorporate role-playing, practice dialogues, play therapy, art therapy, and other methods that can draw on the strengths seen in individuals with an FASD. Printed material may be helpful, but should be written in simple language with a clear, non-distracting page layout.

If group work is necessary, the counselor can assist the client who has or may have an FASD by making some accommodations:

- Explain group expectations concretely and repeat these ideas often.
- If a person monopolizes conversation or interrupts, use a talking stick as a concrete visual reminder of who should be speaking. Hand the stick to the person whose turn it is to speak and pass the stick to others as appropriate.
- Give the person time to work through material concretely within the group time so he or she can ask questions or you can check understanding of material. The client may need extra time to process information. Listen for key themes to emerge slowly through the person's talk and behaviors.
- Allow the client to get up and walk around if he or she gets restless.
- Use concrete representations, such as marking the floor, to show the concept of boundaries.
- Make adaptations for the whole group to avoid singling out the client.

Use of a Mentor

Programs that work with individuals with an FASD have found that mentoring can be effective, as it provides a consistent, stable, one-to-one relationship and allows for the development of a personal bond with a trained individual who has knowledge and experience working with those who have an FASD (Malbin, 1993; Schmucker, 1997; Grant et al., 2004; Denys, Rasmussen, & Henneveld, 2011). A mentor can:

- Assist with the development of concrete and consistent rules and goals that will guide behaviors in specific situations;
- Improve comprehension in discussions with others (e.g., providers or other clients); and
- Assist with the development of personal scenarios for the adult to work out responses and practice through role-play.

Ongoing Assessment for Comprehension of Information

Extensive clinical observations reveal that individuals with an FASD may appear to understand when they do not. Parents often say their family member with an FASD "just doesn't get it." This means that individuals with an FASD may repeat information without actually understanding the content, and so will be unlikely to follow through. Because of this, it is important to provide consistency and re-check the retention of information often:

- Ask the client to summarize what you have said.
- Review written material, such as rules, at each session.
- Do not assume that the client is familiar with a concept or can apply it simply because you have reviewed it multiple times; have discussions that explore their understanding beyond simply being able to repeat the concept.

Clinical wisdom holds that the only consistent thing about FASD is that those who are affected behave inconsistently. This means, for example, that a client may demonstrate

that they know something on Monday, but have trouble recalling that same information on Tuesday. The clinician can benefit by following the rule to: REPEAT, REPEAT, REPEAT.

Sexual Abstinence, Contraception, and Pregnancy

Adolescents and adults with an FASD should be well informed and consulted about decisions regarding abstinence, contraception, and pregnancy. There are many ways to support pregnancy, delivery, and parenting by an individual with an FASD. The client may have questions about whether or not the FASD can be passed on to any offspring; caregivers must clarify that only prenatal exposure to alcohol can cause an FASD. If the client has children, the parenting skills taught to the client should account for the possible presence of an FASD in both parent and child; the skills learned must be appropriate to each of them and work for each of them.

Clinical experience reveals that women with an FASD can be vulnerable to exploitation and unintended pregnancy (Grant et al., 2004; Merrick, Merrick, Morad, & Kandel, 2006). It can be difficult for them to use contraception effectively due to memory lapses, problems following instructions, or difficulty negotiating contraceptive use with a partner. Counselors can help clients evaluate their family planning needs and assist in obtaining reliable, long-term birth control methods.

Although it may be unusual in a treatment setting, very practical and basic assistance may be important for a woman with an FASD. The counselor may need to accompany the client to a doctor's appointment to help her understand her options and choose the best one. One study found improved use of contraception among young women with an FASD by implementing a community intervention model of targeted education and collaboration with key service providers, and by using paraprofessional advocate case managers as facilitators (Grant et al., 2004).

Clinical consensus based on evaluation of common behavioral characteristics of FASD suggests that the causal relationship between HIV/STDs/viral hepatitis and substance use disorders may be heightened among those who also have an FASD. Care plans for individuals with an FASD entering substance abuse treatment should include communicable disease assessment.

Medication Assessment

In some cases, medication options may be appropriate to treat some of the functional or mental health components of FASD (Coe, Sidders, Riley, Waltermire, & Hagerman, 2001). The counselor may want to refer the client for an assessment to determine whether he or she can follow a regimen of taking a pill every day or getting a shot every few months. It is also important to consider the possible physical impact, since persons with an FASD may have health problems and be prone to side effects. Medications for individuals with an FASD may not work at rates similar to other populations and/or may require different dosages to work (O'Malley & Hagerman, 1999). Including a mentor or supportive family member in the discussion may help the individual with an FASD to be more comfortable asking questions and better understand what is being said.

Job Coaching

In a study of 90 adults with a diagnosed form of FASD, most had some work experience but the average duration was only 9 months (Streissguth et al., 1996). Some of the general barriers to successful work for people with disabilities are external; discrimination by employers, co-workers, and family, transportation issues, completing applications and job testing, social skills, and the lack of support

at interviews. Other barriers are internal, and need to be addressed early on in the vocational process; self-esteem and self-worth, fear of success, self-sabotage, and having a realistic view of strengths and career goals. All of these internal factors affect career choice, self-presentation at the interview and the job, and ultimate vocational success (Fabian, Ethridge, & Beveridge, 2009; Leon & Matthews, 2010). These issues should be addressed through counseling and skills-building prior to standard vocational tasks.

A job coach or vocational rehabilitation counselor may need to remain involved with an individual with an FASD beyond the time when he or she seems to "know" the job, and be understanding if the individual has days or situations in which he or she can't remember what to do or gets overwhelmed. Individuals with an FASD may do well enough on a job that a coach or counselor decides they "get it" and stops providing support, when in fact it was the support that enabled success.

Vocational Rehabilitation

Vocational Rehabilitation should be viewed as an interdisciplinary team process. It may be up to a parent or caregiver to coordinate information. The team may include a physician for medical and health issues, an occupational/physical therapist, a psychologist for counseling to address some of the above issues, teachers, case managers, and job placement agencies (Gobelet, Luthi, Al-Khodairy, & Chamberlain, 2007). Some adults and families will choose sheltered workshops because of concerns about safety, transportation, long-term placement, work hours, maintaining disability benefits, social environment, and work skills issues (Migliore, Grossi, Mank, & Rogan, 2008). At the same time, the majority of adults with an intellectual disability prefer integrated employment over sheltered workshops, regardless of disability severity (Migliore, Grossi, Mank, & Rogan, 2007).

Special Considerations for Adolescents Who Have or May Have an FASD

It is important to remember that adolescents are quite different from adults, and adolescents with an FASD differ from teens that develop in typical fashion. Adolescents with an FASD may function at social and emotional levels well below their chronological age, with an uneven cognitive and physical profile (some skills less impaired than others). The treatment process must incorporate the nuances of the adolescent's experience. In modifying treatment plans for adolescents with an FASD, it is important to consider cognitive, emotional, and social limitations, as well as risk factors that led to their substance abuse or mental health issue. Many youth with an FASD have grown up in less-than-ideal environments, facing parental substance abuse, economic deprivation, abuse, and multiple foster care placements. These situations can increase their risks for substance abuse and mental disorders.

A summary of clinical and empirical evidence shows that adolescents will commonly exhibit learning and behavior challenges, especially in adaptive function (getting along from day to day), and in remaining organized and regulated (Streissguth et al., 2004; Spohr, Willms, & Steinhausen, 2007). They often learn information slowly (especially what is said to them), tend to forget things they have recently learned, and make the same mistakes over and over. They can often have trouble shifting attention from one task to another. Like those with ADHD, they may be impulsive and find it hard to inhibit responses, and may be restless or even obviously hyperactive. In general, they may have trouble regulating their behavior. Even though adolescents with FASD may be talkative, they have social communication problems (such as leaving out important details or explaining things in a vague way). Adolescents with FASD tend to show poor judgment, are suggestible (and therefore easily

Treatment Tips From the Field

In addition to the guidance provided in this chapter, providers in British Columbia provided the following anecdotal suggestions for effective programming for individuals who have or may have an FASD.

Treatment Planning	• If medication is used, simplify medication schedules and provide support.
	• Avoid using students as therapists.
	  • May reinforce loss issues related to childhood/youth.
	  • May not be skilled with FASD.
	• Reassess concepts of dependency and enabling.
	• Use reminders.
	  • Use texting to provide reminders and stay connected.
	• Find something that the person likes to do and does well (that is safe and legal) and arrange to have the person do that regardless of behavior.
	• Create "chill-out" spaces in each setting.
	• Be creative about finding ways for the individual to succeed.
	  • Establish achievable, short-term goals.
	  • Reconsider zero-tolerance policies.
	• Be consistent in appointment days and times.
	  • Consider shorter, more frequent meetings or sessions.
	  • Arrange for someone to get the person to appointments for at least 6 months.
	  • Have the meetings on the same days each week.
	  • Discuss each meeting with the person.
	  • Use open meeting times, if necessary.

Assisting Navigation and Success	• Have pictures of the counselors on their office doors. • Identify possible buddies (e.g., family, friends, church or other organizations) to ensure the client gets to appointments, etc. • Identify persons who are appropriate supports for the client, as well as persons who are not helpful. • Program important numbers and reminders into their cell phone for them.

Language	• Do not use metaphors or similes.
	• Do not use idiomatic expressions and proverbs.
	  • "A day late and a dollar short."
	  • "People in glass houses shouldn't throw stones."
	• Don't use sarcasm, and be careful about joking with the person.

Source: Rutman, D. (2011). *Substance using women with FASD and FASD prevention: Service providers' perspectives on promising approaches in substance use treatment and care for women with FASD.* Victoria, British Columbia: University of Victoria.

influenced by others), and show immature social skills. Because of this, they may be too friendly with people they do not know well, too trusting, and have difficulty recognizing dangerous situations.

Treatment Plan Modification

It is generally believed that traditional forms of therapy, such as "talk therapy," are not the most effective choice when working with adolescents with an FASD. Their cognitive

Adolescent Development Issues in FASD

The following table outlines some of the more common developmental delays and deficits experienced by individuals with an FASD through the adolescent years (ages 12–21), and useful treatment approaches. This table is based on an expert clinical consensus.

Normal Development		FASD	Intervention
Age Range: 12-21	Ability to evaluate own behavior in relationship to the future	Lack of connection between thoughts, feelings, and actions	Repeated skills training with role-playing and videotaping; videotaping of person's behavior
	Understanding consequences of behavior		
	Importance of peer group	Difficulty resisting negative peer influences	Connect person with pro-social peers, mentors, and coaches
	Development of intimate relationships	Difficulty with accurately interpreting social cues (e.g., words, actions, nonverbal cues)	Social skills training; repeated discussions of sexuality and intimacy as appropriate

deficits prevent them from developing insight or applying lessons to their real lives. However, with creativity and flexibility, a treatment plan can be developed that includes techniques counselors are familiar with and comfortable with, adapted to fit the needs of the client (Baxter, 2000).

Addressing Peer Influences

Clinical observations indicate that adolescents with FASD are socially immature, and research documents that adults with FASD are more suggestible (Brown et al., 2011). Developmental literature makes clear that peer influences are important in the adolescent stage, and that deviant peer influences can lead to antisocial behavior. The counselor should address issues such as peer pressure in treatment to set the stage for less risky behavior outside treatment. Linking an adolescent with an FASD with a mentor is a sound treatment strategy.

Ongoing Assessment for Comprehension of Information

As with adults, it is important to check often to make sure the adolescent client understands what has been said. Ask the client to summarize what you have said. Review written material, such as rules, at each session. *Repeat, repeat, repeat*, even if the client says, "You've told me this a hundred times."

For adolescents, applying concepts can be difficult. Cognitive deficits, the frustration of having an FASD, and typical teen rebellion can make communication especially hard. Role-playing different situations, providing opportunities to share and process feelings, and giving the client time to process information is important. It also may help to use alternative methods of expression, such as drawing, to assist the client in sharing his or her understanding.

Educational Support (IDEA and FAPE)
The Individuals With Disabilities Education Act (IDEA) entitles every young person to a *f*ree and *a*ppropriate *p*ublic *e*ducation (FAPE) in the least restrictive environment. If the client is eligible, this can continue until age 21. If you have a client who has or may have an FASD and is in school, it is important to consult with the school regarding any provisions in that client's individualized education plan (IEP), either those identified by the school that should be carried over to treatment or vice versa. In a study of 120 children undergoing FASD diagnosis at a Washington State FAS DPN clinic, Jirikowic and colleagues (2010) found that over 90 percent did require intervention recommendations associated with their educational plan.

In the outpatient setting and during aftercare, it is a good idea for the psychologist to consult with the school counselor or case manager (if the client has one) regarding educational needs. Areas such as social skills may be addressed in the IEP, and are important to address during treatment and as part of aftercare. It also helps to be aware of any academic issues that may affect the client's treatment, such as stress about academic performance or difficulties with classmates.

Parents may not be aware of the laws regarding education of children with disabilities and may feel overwhelmed. They may be having problems dealing with their child's school and wonder what to do. The counselor can help by informing the client and family about IDEA and FAPE requirements and helping outline possible interventions to suggest to the school.

The U.S. Department of Education provides an online overview (**http://www2.ed.gov/about/offices/list/ocr/docs/edlite-FAPE504.html**) of the stipulations of FAPE and who qualifies for educational support under its terms.

In addition, vignette #10 in Part 1, Chapter 3 of this TIP discusses some of the key aspects of developing an IEP for an individual who has an FASD.

Psychosexual Development
Early and ongoing social experiences play a key role in psychosexual development. Adolescent tasks include having and maintaining intimate relationships, managing complex emotions and social situations, and developing independent thinking. The adolescent with an FASD may not achieve these milestones all at the same time, at the usual age range, or at all. Many adolescents with disabilities are delayed or prevented from achieving these goals by social isolation or a variety of functional limitations. Social skills may be broken down into manageable tasks, just as in every other area of instruction. This includes the basics first, such as mastering appropriate greetings, eye contact, body language, personal space, self-advocacy skills, and telephone and computer skills. A foundation in some or all of these basic skills will allow for the development of more complex skills. Mentors and peers may be very effective in this regard.

Vocational Coaching
Young adults with a disability need advocacy and support with a variety of new agencies and support services throughout the transition and adult years. A life skills curriculum should include how to use the internet to search for employment and employment enhancement services, awareness of issues associated with safe work environments, interviewing strategies, appropriate use of medication, managing finances, dealing with workplace routines and expectations, being cautious about at-risk situations, and knowing when to ask for help (Winn & Hay, 2009). Role-playing each of these skills with the client will be beneficial.

Counselor Self-Assessment

Working with clients with an FASD can raise issues for you, the counselor. You might feel resentment about being "stuck" with such challenging clients, or harbor negative attitudes toward women who drink while pregnant. The client with an FASD can trigger feelings of guilt and shame in a counselor who drank while pregnant or has a child with an FASD.

Understanding how to cope with clients with an FASD can help the counseling professional serve such clients more effectively. Olson and colleagues (2009) have underlined the importance of the need to **Reframe**, **Accommodate**, and **Have Hope** for caregivers raising those with FASD. These same strategies can help counselors, and are combined with the recommendations of Malbin (1993) and Schmucker (1997) to create the following recommendations for counselors providing FASD-related services.

REFRAME

Reframe your perception of the person's behavior. He or she is not trying to make you mad or cause trouble. He or she has brain damage and may have a history of abuse or other family dysfunction. You need to explore behaviors, stay patient, and tolerate ambiguity.

- Understand that FASD involves permanent brain changes.
- The client is not refusing to do things. He or she can't do them or does not understand what you are asking him or her to do.
- Clients often are not lying purposely. They are trying to fill in gaps in memory with their own information.
- Perseverating behaviors are an attempt to control or make sense of their own world.
- Transition and change are very difficult for the person with an FASD. Acting out when things change may be a reaction to fear of transitions or difficulty processing change.

ACCOMMODATE

- **Expect to repeat things many times in many ways**. Clients with an FASD may ask the same question every time you see them. Remember that these clients have cognitive deficits. They are not asking just to test your patience. Be patient and avoid looking bored going over the same information multiple times.
- **Use a written journal or goal sheets** to remind people how far they've come and where they are headed. Due to their memory difficulties, clients with an FASD will not always remember what supports or programs have been developed with them or their goals. Keep a positive attitude and focus on what the person has accomplished, rather than on goals yet to be met.
- **Realize that there is no set approach**; what works one time may not work the next. As part of the dysfunction of FASD, the client may experience things differently day to day or even hour to hour, and variability is the norm. Keep an open mind and be flexible. Avoid statements such as "But it worked last time."

HAVE HOPE

- **Be good to yourself**. Even with a realistic plan and an established routine, nothing is perfect. Things change and setbacks occur. By expecting bumps in the road of a person's journey through life, we can learn to not take these dips personally. By offering the person with an FASD nonjudgmental and informed support, we offer hope.
- **Know yourself**, and **take the time to reflect on your comfort level in dealing with issues surrounding FASD**. Gain knowledge if needed. Gain comfort in tackling the subject by role-playing with colleagues. Know your limits and get outside help or referrals as required. Plan to connect to appropriate community resources.

Thinking Ahead and Planning for the Future
It is important to think ahead and plan for the future with adolescents and young adults with FASD. If they are able to build an independent life, counselors can help the client learn how to self-advocate and self-monitor, and should communicate these skills to the client's caregivers, as well. It is important to think ahead about education on topics such as (1) safe sex; (2) communicating clearly with partners about consensual activity; (3) use of cigarettes and alcohol; (4) use of illicit substances, such as marijuana and drugs; (5) the consequences of criminal activity; and (6) ideas of what to safely do when the individuals goes through times of feeling irritable and negative (calming strategies).

5. Working with the Family

Introduction

Multiple studies have spoken to the value of involving the family in the treatment of an individual who has or may have an FASD, if possible (Schmucker, 1997; Grant, Ernst, Streissguth, & Porter, 1997; Olson et al., 2009; Olson, Rudo-Stern, & Gendler, 2011). Involving the family in planning, choosing, and shaping services for the client has become a key intervention concept in the field of developmental disabilities, as greater family involvement has been linked to better outcomes (Neely-Barnes, Graff, Marcenko, & Weber, 2008). Family-centered care is also strongly advocated for individuals with co-occurring mental health issues and a developmental disability like an FASD (McGinty, Worthington, & Dennison, 2008).

As with many clients in substance abuse and mental health settings, it is advisable to take a broad view of family. Many individuals with an FASD will have resided with foster parents and/or in kinship care (foster and adoptive scenarios being the most common), and care scenarios may extend well beyond the more typical ages of independence, like 18 or 21. Ultimately, who the client chooses to see as family or as the important caregiver in their life should be incorporated into the process, if possible.

As the table on the next page makes clear, involving the family can be as much about meeting their needs as the client's. The most frequently unmet family needs can be met with emotional support and, later in the counseling relationship, offering opportunities to "look forward" to the future and discuss both hopes and worries. Other frequently unmet needs can be met by helping caregivers find methods for self-care and respite. FASD education and appropriate intervention will meet other common needs, but may be less important (at the start) than support and direct assistance to help understand and meet caregivers' own needs.

Approaching the Family
It is imperative to obtain permission to approach family on the topic of an FASD. If the birth mother is still involved in the individual's care and is not aware of the possibility of an FASD, it is vitally important not to make her feel shamed or judged. The counselor should be prepared to address feelings of guilt. The family may also experience many of the feelings of anger, grief, and loss that the client experiences. All members of the family should be made to feel as comfortable as possible expressing these feelings.

If the family agrees to be involved, there are a number of ways that the counselor can support both them and the client. It is vital to use "reframing" to help the family better understand the client's behaviors as being at least partly caused by brain-based disabilities (Olson et al., 2009). A positive view of the affected individual, of the relationship between the caregiver and the individual, and of the caregiver process has been associated with

Top Unmet Needs for Caregivers Raising Children who have FASD and Behavior Problems

Percentage Indicating Need is Unmet	Type of Family Need
69.2%	Discuss feelings about my child with someone who has gone through the same experience.
61.7%	Have help in preparing for the worst.
60.8%	Have enough resources for myself or the family.
58.8%	Have help in remaining hopeful about my child's future.
58.0%	Get a break from my problems and responsibilities.
55.8%	Be reassured that it is usual to have negative feelings about changes in my child's behavior.
52.9%	Have complete information on my child's thinking problems.
51.0%	Be shown what to do when my child is upset or acting strange.
48.1%	Be told why my child acts in ways that are different, difficult or strange.
47.1%	Have different professionals agree on the best way to help my child.
47.1%	Pay attention to my own needs.

'Important' is defined as parent report that a need was 'important' or 'very important' (where there were two other levels indicating less importance). 'Unmet' was defined as parent report that a need was met 'not at all' or 'a little' (where there were two other levels indicating that a need was met more completely). Items shown here were the most frequently endorsed items; the remaining items (of 20) received far less frequent endorsements.

Source: Olson, H. C., Oti, R., Gelo, J., & Beck, S. (2009). "Family Matters:" Fetal Alcohol Spectrum Disorders and the family. *Developmental Disabilities Research Reviews, 15*, 235-249.

more positive outcomes for the individual and family (Blacher & Baker, 2007). The counselor can then help the family reach out to extended family and friends to help them reframe the situation. Reframing can help everyone more positively understand the client's behavior, and appropriately adjust the home and school environments. Treatment approaches that stress problem-focused management and stress reduction may be a useful addition to parent training (Olson et al., 2009). Other suggestions include:

- As with the client, review the diagnostic report thoroughly with the family (if it is available). Chapter 3 of Part 1, *Clinical Vignettes*, contains a vignette illustrating this process.
- Help the family arrange for respite care or a community support worker: Caregivers may feel stressed or burned out by the responsibilities of caring for someone with an FASD.
- Assist family in coming up with ways to educate extended family and friends about FASD to help them understand the client's behaviors and adjust the home environment accordingly.
- Connect family and friends with support groups or other community resources (see Step 6).
- Help find long-term mentors for clients. Family members or friends who have become exhausted or burned out dealing with an FASD may be willing to help

after a mentor has stepped in for awhile and the client has made progress.

- Encourage parents and caregivers to maximize independence, even if they are used to "helping" or completing tasks for the client.
- Help the family access needed services and supports (see Appendix G, *Services and Supports Checklist*, for a list that can be used as a worksheet).

The *Families Moving Forward Program* intervention is a scientifically-validated behavioral consultation program tailored for families raising preschool and school-aged individuals with FASD or confirmed prenatal alcohol exposure. The intervention includes methods and materials that appropriately trained counselors can use when working with families of a client who has an FASD, even if the client is older (**http://depts.washington.edu/fmffasd**). See Appendix F, *Sample Crisis/Safety Plan*, and Appendix G, *Services and Supports Checklist*, for materials that have been adapted from the *Families Moving Forward Program* for this TIP.

If the client had an existing diagnosis of an FASD before presenting in your setting, involving the family is still valuable. Caregivers are probably already well-versed in FASD and the difficulties of obtaining effective services, and can be as much of a resource of information for the counselor as the counselor is for the family.

6. Transition and Connection to Community Supports

Transitional Services

Part of the counselor's role is to prepare for discharge of the client. This involves working to establish a network of community resources and providers of service who will continue to provide support and advocacy when your role is complete. Providing these supports with education about FASD and the client's unique patterns of behavior is an important part of successful transitioning. See Appendix G, *Services and Supports Checklist*, for a worksheet that can be used to quickly identify linkages the counselor and client may want to explore.

Network of Providers

Counselors need to be familiar with available resources in the community, such as psychiatrists, social workers, developmental disability providers, and physicians. Counselors can include referrals to these resources in the transition plan and work with case managers at their facility as appropriate. For clients who are still in school, it is also important to consider the transition to school, and to work with school administrators and/or the school counselor to determine how best to address the client's ongoing needs within the school setting.

It may also be necessary to consult an advocate or legal representative if the client has had any legal problems. Adolescents with an FASD can get pulled into illegal activity or manipulated into relapses.

Mentorship

Locating a long-term mentor within the person's sphere of relationships can be another way to support the transition process. Providing tips and strategies for things that have worked well with the client during treatment can enable the mentor to provide support in the future (Schmucker, 1997). There are also organized programs that can help to identify mentors, though these resources are scarce and differ by community.

If the family is involved in treatment and the client had an existing diagnosis of an FASD before treatment, it is likely that they will have developed relationships with a variety of providers and can thus potentially be a useful

resource for information on services available in the community. There are a number of things that should happen during transition planning that a parent or caregiver could help to facilitate, such as introduction to the relevant service providers and transfer of information to those agencies.

Assessment of Living Skills/Planning for Safety

Even if taught as part of treatment, basic functional living and social skills will need to be re-assessed before transition to help the client function more effectively and safely in the community. The provider should work with the client to:

- Assess ability to handle money, pay bills and rent, buy groceries, etc. The clinician can consider a representative payee, if necessary.
- Anticipate housing needs: Will the client live alone? With caregivers? With others in structured housing or a group setting? An individual with an FASD is likely to need dedicated, long-term caregiver support in any setting, but this is particularly vital if they will be living alone. Assistance is likely to be needed with negotiating public transportation, handling interpersonal relationships, grocery shopping, and structuring leisure time (Streissguth et al., 1996).
- Identify job desires and possibilities, as well as what is needed for job success.
- Review appropriate social interaction.
- Review processes for checking whenever the client is unsure of a situation or response, or is in trouble.
- Ensure that learned skills are practiced in the new environment.
- Continue supports at least until the client adjusts to the new environment.

If a mentor, family member, or other caregiver is identified for the client, Vignette #9 in Part 1, Chapter 3 of this TIP walks through the process of working with that person or persons to develop a personalized Safety Plan on behalf of an individual with an FASD.

Connection to Community Supports

Both the client and the client's family and caregivers (if involved) can benefit from connection to support systems in their community. As with referral for assessment or diagnosis, it is vital that the counselor actively assist the client through transition to other providers and follow up regularly to ensure client satisfaction and full and open communication between agencies and with the client (and the client's family, if they are involved in the treatment process).

Appendix C, *Public and Professional Resources on FASD*, provides links to a number of support organizations for individuals with an FASD, including NOFAS (**www.nofas.org**), the Birth Mothers Network (also known as the Circle of Hope; visit the NOFAS Web site and the FAS Community Resource Center (**http://www.come-over.to/FASCRC/**).

NOFAS can be a particularly valuable resource, as it houses not only the Birth Mothers Network but also an extensive affiliate network whose members provide a broad range of FASD-related services to individuals and their families. In addition, NOFAS's "Living With FASD" page (**http://www.nofas.org/living/**) contains links to financial assistance programs such as Supplemental Security Income (SSI), Social Security Disability Insurance (SSDI), and Medicaid, as well as family and mother support programs such as Women, Infants and Children (WIC).

An emerging community resource for individuals with an FASD is the Self-Advocates with FASD in Action (SAFA) Network. Members

include individuals with an FASD and their support persons. The SAFA Network provides speakers and training on living with an FASD, and also peer support for other individuals and families coping with these disorders. The SAFA Network can be contacted through SAMHSA's FASD Center for Excellence (**www.fasdcenter.samhsa.gov**, or toll-free at 1-866-STOP-FAS).

Job Support

Your local One-Stop Center (**www.careeronestop.org**) may provide links to your state Department of Labor and Workforce Development, the local division for vocational rehabilitation services, and/or specific state initiatives for development of customized employment for people with disabilities. For individuals with an FASD, customized employment should include a protocol that addresses their special needs.

Self-Help Participation

The person with an FASD will need support to participate successfully in a 12-Step program. Many areas of the country have "Double Trouble" meetings; these are 12-Step self-help groups designed to meet the special needs of people with addiction and mental health issues (Vogel, Knight, Lauded, & Maura, 1998). Double Trouble meetings may be more flexible about impulsive behaviors than routine meetings. The counselor should be cautious about referring a client who has or may have an FASD into a self-help group, due to issues of victimization as well as the possibility that the individual's special needs will not be met.

Another significant resource for people with an FASD and co-occurring issues is the recovery movement in the mental health field. Recovery centers (also known as "drop-in" centers) offer a variety of supports, groups, and meetings in some areas.

For more information on treatment approaches with individuals who have or may have an FASD...

Vignettes 5–10 in Part 1, Chapter 3 of this TIP illustrate scenarios where a counselor works with a client who has or may have an FASD, or provides assistance to family members/caregivers. In addition, Part 3, the online Literature Review, also contains further discussion of interventions, protective factors, and co-occurring issues.

3 Clinical Vignettes

IN THIS CHAPTER

Introduction

This chapter presents vignettes of counseling/intervention sessions between various service professionals and either 1) women of childbearing age where FASD prevention is warranted, and/or 2) individuals who have or may have an FASD or their family members. The vignettes are intended to provide real-world examples and overviews of approaches best suited (and not suited to) FASD prevention and intervention.

The Culturally Competent Counselor

This TIP, like all others in the TIP series, recognizes the importance of delivering culturally competent care. Cultural competency, as defined by HHS, is…

"A set of values, behaviors, attitudes, and practices within a system, organization, program, or among individuals that enables people to work effectively across cultures. It refers to the ability to honor and respect the beliefs, language, interpersonal styles, and behaviors of individuals and families receiving services, as well as staff who are providing such services. Cultural competence is a dynamic, ongoing, developmental process that requires a long-term commitment and is achieved over time" (U.S. Department of Health and Human Services, 2003, p. 12).

A critical element of this definition is the connection between attitude and behavior, as shown in the table on the next page.

Areas of Clinical Focus

In this chapter, you are invited to consider different methods and approaches to practicing prevention of an AEP and/or interventions and modifications for individuals who have or may have an FASD. The ten scenarios are common situations for behavioral health professionals and focus on:

Attitude	Behavior
Respect	• Acknowledging and validating the client's opinions and worldview • Approaching the client as a partner in treatment • Communicating with clients in their primary language, either directly or through an interpreter • Respecting the client's self-determination
Acceptance	• Maintaining a nonjudgmental attitude toward the client • Considering what is important to the client
Sensitivity	• Understanding the client's experiences of racism, stereotyping, racial profiling, and discrimination • Understanding the life circumstances, daily realities, and financial constraints of the client
Commitment to Equity	• Intervening on behalf of clients when a problem stems from racism or bias • Actively involving oneself with minority individuals outside the counseling setting to foster a perspective that is more than academic or work-related
Openness	• Recognizing the value of indigenous helping practices and intrinsic help giving networks in minority communities • Building ongoing collaborative alliances with indigenous caregivers • Seeking consultation with traditional healers and religious and spiritual leaders and practitioners in treatment of culturally different clients, when appropriate
Humility	• Acknowledging the limits of one's competencies and expertise and a willingness to refer clients to a more appropriate counselor when necessary • Seeking consultation and pursuing further training or education, or a combination of these • Constantly seeking to understand oneself as being influenced by ethnicity and culture and actively seeking a nonracist identity • Being sensitive to the power differentials between the client and the counselor
Flexibility	• Using a variety of verbal and nonverbal responses, approaches, or styles to suit the cultural context of the client • Using cultural, socioeconomic, and political contextual factors in conducting evaluations and providing interventions

This table originally appeared in TIP 48, *Managing Depressive Symptoms in Substance Abuse Clients During Early Recovery* ((SMA) 08-4353). The authors of this TIP gratefully acknowledge the authors of TIP 48.

1. Intervention with a woman of childbearing age who has depression, is consuming alcohol, and may become pregnant (AEP Prevention)
2. Examining alcohol history with a woman of childbearing age in substance abuse treatment for a drug other than alcohol (AEP Prevention)
3. Intervention with a woman who is pregnant (AEP Prevention)
4. Intervention with a woman who is pregnant and consuming alcohol, and who is exhibiting certain triggers for alcohol consumption, including her partner (AEP Prevention)
5. Interviewing a client for the possible presence of an FASD (FASD Intervention)

6. Interviewing a birth mother about a son who may have an FASD and is having trouble in school (FASD Intervention)
7. Reviewing an FASD diagnostic report with the family (FASD Intervention)
8. Making modifications to treatment for an individual with an FASD (FASD Intervention)
9. Working with an adoptive parent to create a safety plan for an adult male with an FASD who is seeking living independence (FASD Intervention)
10. Working with a birth mother to develop strategies for communicating with a school about an Individualized Education Plan for her daughter, who has an FASD (FASD Intervention)

Organization of the Vignettes

To better organize the learning experience, each vignette contains an **Overview** of the general learning intent of the vignette, **Background** on the client and the setting, **Learning Objectives**, and **Master Clinician Notes** from an "experienced counselor or supervisor" about the strategies used, possible alternative techniques, timing of interventions, and areas for improvement. The Master Clinician is meant to represent the combined experience and expertise of the TIP's consensus panel members, providing insights into each case and suggesting possible approaches. It should be kept in mind, however, that some techniques suggested in these vignettes may not be appropriate for use by all clinicians, depending on that professional's level of training, certification, and licensure. It is the responsibility of the counselor to determine what services he or she can legally/ethically provide.

1. INTERVENTION WITH A WOMAN OF CHILDBEARING AGE WHO HAS DEPRESSION, IS CONSUMING ALCOHOL, AND MAY BECOME PREGANT (AEP PREVENTION)

Overview: This vignette illustrates how and why a counselor would address prevention of an AEP with a young woman who is being seen for depression.

Background: This vignette takes place in a college counseling center where Serena, 20, is receiving outpatient services for the depression that she's been feeling for about 4 months. In her intake interview, Serena has indicated that she consumes alcohol, is not pregnant, and is sexually active. She has had two prior sessions with the counselor, during which they have discussed Serena's general background, family interactions, social supports, and her outlook on school.

In today's session, they have been discussing her boyfriend, Rob. A therapeutic relationship has begun to form between Serena and the counselor, and the counselor would now like to explore Serena's alcohol use and whether it is a possible contributing factor in her depression. While doing this, the counselor will identify an opportunity to deliver an informal selective intervention to prevent a possible AEP.

Learning Objectives:

1. To illustrate that clients often have multiple issues that need to be addressed besides their primary reason for seeking counseling.
2. To demonstrate a selective intervention ("FLO") for preventing an alcohol-exposed unplanned pregnancy.
3. To recognize that prevention of an AEP can be accomplished by eliminating alcohol use during pregnancy or preventing a pregnancy during alcohol use; often the most effective route is to prevent the pregnancy.

Vignette Start

The session is already in progress. Serena has been discussing how she and her boyfriend Rob tend to fight a lot, but she continues to spend time with him because they have fun at parties.

COUNSELOR: So, how long have you and Rob been together?

SERENA: About 7 months.

COUNSELOR: And you've said that the two of you are sexually active.

SERENA: Yeah, I usually sleep over on the weekend, after the parties.

COUNSELOR: Do these fights occur at any particular time?

SERENA: Not really. When we're stressed, mostly, over school or work or whatever. Then I feel more depressed cuz we're fighting, and he gets upset because I'm depressed. It's like a circle. That's why we go to the parties, to unwind and forget about stuff.

COUNSELOR: And then you tend to end up spending the night with him.

SERENA: Usually.

COUNSELOR: Are you using any protection, or birth control?

SERENA: No.

COUNSELOR: And during these parties, are you drinking?

SERENA: Sure.

COUNSELOR: About how many drinks do you have?

SERENA: I don't really know. My cup's never empty, it just gets refilled at the keg.

COUNSELOR: Are there other times when you drink alcohol?

SERENA: No, it's really just at the parties.

Master Clinician Note: Serena is presenting high-risk behavior by combining alcohol use and unprotected sex. The counselor seeks to identify the link between alcohol, unprotected sex, and pregnancy.

COUNSELOR: I know you're not expecting this, but if you were to find out right now that you were pregnant, how would that change things for you?

SERENA: Oh lord, that would *totally* turn my life upside down. And Rob's. God, he'd freak.

COUNSELOR: So, you do *not* want to get pregnant.

SERENA: No, I definitely do not wanna get pregnant.

Master Clinician Note: Serena has made it clear that she does not want to become pregnant, so the counselor shifts to addressing the gap between Serena's behaviors (being sexually active but not practicing safe sex) and her stated desire (to not get pregnant).

COUNSELOR: I understand, and I'm concerned about your health and what you want for your future. So, if you plan to keep attending these parties and being sexually active, then maybe we can talk about contraception. Did you know that half of all pregnancies in the U.S. are unplanned?

SERENA: Wow. No, I didn't know that.

COUNSELOR: It's true. It's possible that you could get pregnant, and the drinking could impact the health of that baby. Let's talk about how we can avoid those things.

SERENA: Okay.

The counselor gives Serena a pamphlet that describes effective contraception.

COUNSELOR: Would you be willing to read this? It's short, but it has good information. Perhaps we can go over it when we meet next week.

SERENA: Okay. I thought I was here to talk about depression, though.

COUNSELOR: Yes, absolutely, our first goal is to help you stop feeling depressed. And as you've said, you definitely don't want to have a baby, so I think it's important for us to discuss ways to avoid getting pregnant, so that that's not something that adds to your worries.

SERENA: Oh, okay. I see what you mean.

COUNSELOR: So next week I can answer any questions you have about that material, and then we can talk about some positive goals you want to lay out, like feeling less depressed, or fighting with Rob less, or not getting pregnant. Does that sound okay?

SERENA: Yeah, thanks.

Master Clinician Note: This vignette does not "solve" the issue of Serena's depression. However, as part of examining the possible causes, Serena has talked about a pattern of regular at-risk drinking, combined with unprotected sex. Because of this, the counselor—who by now has established a good rapport with Serena—has taken the opportunity to carefully include a selective intervention for preventing an AEP.

In an informal way, the counselor has used the steps of the "FLO" intervention discussed in Part 1, Chapter 1 of this TIP. During intake and again at this visit, Serena has indicated that she consumes alcohol and is sexually active. The counselor provides **F**eedback on these responses (by discussing the possibility of an AEP), then **L**istens as Serena indicates that she does not want to become pregnant. The counselor thus shifts the focus of medical advice to the **O**ption of contraception and provides Serena with educational material.

At the same time, the counselor has not lost sight of depression as Serena's primary treatment issue. In this session, the counselor has laid the groundwork for continuing to discuss Serena's at-risk drinking and her problematic relationship with Rob as possible components of the depression, but in the context of positive goals that Serena can aim for (i.e., finding ways to feel less depressed, fight with Rob less, and avoid an unwanted pregnancy).

2. EXAMINING THE ALCOHOL HISTORY WITH A WOMAN OF CHILDBEARING AGE IN SUBSTANCE ABUSE TREATMENT FOR A DRUG OTHER THAN ALCOHOL (AEP PREVENTION)

Overview: This vignette illustrates the value of asking about alcohol use in a female substance abuse treatment client of childbearing age, even though her primary drug is not alcohol.

Background: Chloe is being seen at an outpatient treatment center for methamphetamine abuse. The counselor has the health history that was provided during intake. It indicates that Chloe reports as non-pregnant, but is 28 (of childbearing age) and is sexually active.

The counselor wants to explore whether Chloe is using other substances, as well as screening for a possible mental health problem. Given that the client is sexually active, there is a risk of an unplanned pregnancy, therefore the counselor begins with alcohol.

Learning Objectives:

1. To emphasize the importance of probing for alcohol use even if it is not the primary drug.
2. To recognize that quantity of use is subjective. The use of a visual helps the client understand what a one-drink equivalent is.
3. To recognize that if a mental health issue presents itself, it will need to be addressed concurrently.

Vignette Start

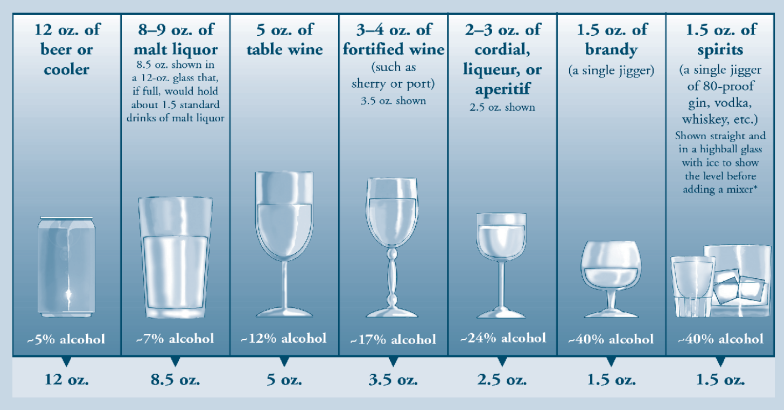
COUNSELOR:	Hi, Chloe.
CHLOE:	Hey.
COUNSELOR:	Please have a seat. I have some questions that I would like to ask you, Chloe. You're in treatment for methamphetamines, correct?
CHLOE:	Yes.
COUNSELOR:	If it is okay with you, I would like to ask you first about your use of some other drugs. I would like to start with alcohol. Do you know how much alcohol you drink?
CHLOE:	You mean, altogether? I don't know.
COUNSELOR:	Okay, in an average week, how much alcohol would you say you drink?
CHLOE:	Well, usually I just drink enough to wash down my pills.
COUNSELOR:	What pills are those?
CHLOE:	The, whatayacallit, desoxyn.
COUNSELOR:	And what do you wash these pills down with? What kind of alcohol?
CHLOE:	Usually vodka. With some orange juice in it.
COUNSELOR:	And do you do this every time you take the pills?
CHLOE:	Not every time, but most times.

COUNSELOR: Okay. And how much vodka do you drink to wash down the pills?

CHLOE: One drink.

COUNSELOR: Here, let me show you something real quick. This is a picture of different glasses that people tend to use for drinking alcohol. Which one do you use?

Master Clinician Note: The counselor uses the visual below to help Chloe more concretely understand her level of consumption. However, this visual does not reflect every available drinking size or container, so any discussion of a standard drink should incorporate the client's personal experience (i.e., "If you don't see your glass on here, what do you use?").



CHLOE: None of them. Well (*Chloe indicates the 8.5 ounce drinking glass*), that looks like what I use, but it's not all vodka.

COUNSELOR: How much do you fill with vodka, and how much orange juice?

CHLOE: About half and half.

COUNSELOR: All the way to the top?

CHLOE: Yeah, but with ice in it.

COUNSELOR: Okay, so that's going to be about three to four ounces of vodka, and an ounce and a half of hard liquor is equal to one drink. So, it looks like you're having the equivalent of two to three drinks every time you wash down the pills.

CHLOE: Hmm. I didn't know that.

COUNSELOR: Is there any other time when you use alcohol?

CHLOE: I may have some when I'm feeling bad. It takes the edge off.

COUNSELOR: Can you tell me more about how you feel when you "need to take the edge off?"

CHLOE: I just feel very upset, worried. Sometimes sad.

COUNSELOR: That must be hard for you. About how often do you feel worried and/or sad?

Master Clinician Note: The counselor expresses empathy for the client and how sad/worried she is feeling. This expression of empathy assists in establishing more of a caring relationship, so that further questions around alcohol use can be explored in a helpful manner. The counselor also explores more with the client about how she is feeling when she talks about "taking the edge off" to see what might be the result of her drug use and to see if she needs a mental health evaluation. A mental health evaluation might explore whether medication is indicated that could assist Chloe in reducing her alcohol use.

CHLOE (*laughs*): A lot.

COUNSELOR: It must be difficult to feel so sad and worried a lot. Can I ask you a few more questions about this?

CHLOE: Okay.

COUNSELOR: Did you feel very sad or worried this week?

CHLOE: Yeah.

COUNSELOR: So, when you felt this way this week, did you need to use alcohol to feel better? Or, as you said, to take the edge off?

CHLOE: (*shrugs*) Yeah, I had three or four drinks.

Master Clinician Note: The counselor does not assume that the client is deliberately underestimating, but keeps in mind that clients may minimize when self-reporting alcohol use (Taylor et al., 2009).

COUNSELOR: Did you also feel like this *last* week?

CHLOE: Probably.

COUNSELOR: How about last month? Did you need to use alcohol to try to feel better then also? That would have been August.

CHLOE: I'm sure I did.

COUNSELOR: So Chloe, you would say that you're feeling sad and worried, and using alcohol to help you feel better, has been going on for quite a while, is that right?

CHLOE: Yeah, most of this year.

Master Clinician Note: Given the frequency of poly-drug use among clients in substance abuse treatment, this counselor did not assume that methamphetamine was the only substance that Chloe was using. Through some simple probing, the counselor has identified that not only has Chloe been drinking, she has been doing so at a high-risk rate. At a future time when dealing more specifically with the amount Chloe is drinking, the counselor might show her a chart with drinking frequencies to help Chloe see what level of drinking is defined as heavy and/or problematic for women.

Chloe has also talked about a pattern of self-medication. The reason or trigger for this may be depression; Chloe has said only that she drinks when she is "feeling like s&@*." This will require further exploration. For now, the counselor knows that a potential co-occurring mental health issue, a co-occurring substance abuse issue, and prevention of a possible AEP should all be factored into the treatment plan.

3. INTERVENTION WITH A WOMAN WHO IS PREGNANT (AEP PREVENTION)

Overview: This vignette illustrates that screening for alcohol use should be done at every visit with women who are—or are at an indicated likelihood for becoming—pregnant. Alcohol-exposed pregnancies occur in all demographics, regardless of socio-economic status, age, ethnicity, or marital status.

Background: April, 27, works full-time. She recently found out she is pregnant with her first child. She and her husband have relocated to a new city, and she is being seen at a private OBGYN office for the first time.

Learning Objectives:

1. To recognize that asking about alcohol use during the first visit only is not enough; screening should occur at every visit.
2. To identify that a woman could begin drinking during the pregnancy if she is experiencing a relapse.
3. To highlight there is no known safe amount of alcohol use during pregnancy.

Vignette Start

1st Office Visit

PRACTITIONER: Hello, I'm Dr. Johnson. I see on the chart that you are pregnant. Congratulations!

APRIL: Thank you.

PRACTITIONER: I have a number of questions that I need to ask you before the exam.

Practitioner inquires about health history and eating habits, recommending an increase in fruit consumption.

PRACTITIONER: A few other quick questions. How much do you smoke per day?

APRIL: I don't smoke.

PRACTITIONER: That's good! How much coffee and water do you drink?

APRIL: I have a cup of coffee in the morning, that's about it. I try to drink water all the time. I don't know how much I have per day. Probably a few glasses worth.

PRACTITIONER: Okay, how often do you drink alcohol?

Master Clinician Note: The practitioner has included alcohol as part of a general health exploration rather than asking the question by itself, which can make some clients nervous. Still, April looks a little concerned.

APRIL: I don't drink any alcohol.

PRACTITIONER: Okay, that's good to hear. Not to worry, that's just a general question that I will be asking during all of our visits. There's no safe time, amount, or kind of alcohol to drink during pregnancy, so we recommend women not drink during their pregnancy.

2nd Office Visit: *We pick up the conversation after the practitioner has again gone over the general health questions about smoking and level of intake of water and coffee.*

APRIL: I'm actually trying to drink more water now, and less coffee. I carry a water bottle around with me all the time.

PRACTITIONER: Okay, that's good. How much alcohol have you had?

APRIL: None, really.

PRACTITIONER: Have you had *any* alcohol?

APRIL: One glass. We were having dinner with some friends.

Master Clinician Note: This interaction demonstrates the value of re-screening in relation to alcohol. April stated in the first visit that she does not drink. However, during this second visit, she has revealed that she does drink on occasion. It will be important for the practitioner to repeat the benefits of abstinence during pregnancy and probe for level of alcohol use, while remaining supportive and nonjudgmental.

PRACTITIONER: I see. Well, as we discussed at your last visit, no alcohol use during the pregnancy is the best policy. We just want to take the best possible care of your baby. About what size was that glass, would you say?

Master Clinician Note: The practitioner can use a visual aid, as in the previous vignette, to help April understand how much really equals one drink. The practitioner has also repeated the importance of abstinence during the pregnancy, and tied the guideline specifically to the health of April's baby.

3rd Office Visit: *At this visit, April again indicates alcohol consumption, this time "a couple of drinks" at a dinner party. The practitioner explores further.*

PRACTITIONER: How many drinks did you have?

APRIL: Well, my friend handed me a glass of cabernet when I arrived, because she said I would love it. I reminded her that I was pregnant, but she said a couple wouldn't hurt and that she had a few when she was pregnant and her kids were fine.

PRACTITIONER: So, you drank the cabernet. Did you have any others?

APRIL: Well, then I had some with dinner, too. I felt like I had been really good during the pregnancy, so I just decided to have a few drinks this one night.

PRACTITIONER: So, you ended up having a few drinks that night.

APRIL: Yes, but just that one time. And it was only wine.

PRACTITIONER: I know that the temptation to have some drinks at a party or a celebration can be great, but there are a couple things to keep in mind. One is that science has shown that alcohol can harm the baby. We don't know yet how much alcohol consumption is too much, so it's very important to avoid all alcohol during the pregnancy.

The practitioner pauses for the client to process what has been said.

APRIL: Okay.

PRACTITIONER: Also, it's important to understand that *any type* of alcohol you drink can hurt the baby, not just certain kinds. Wine, hard liquor, beer…any beverage with alcohol in it. So it's important to avoid all of them during the pregnancy.

APRIL: Gotcha.

Master Clinician Note: Given that April has continued to drink even after her first couple of visits, the practitioner takes the educational process a step further this time, clearly noting that science has established a risk and that there is no "acceptable" form or amount of alcohol. A counselor or practitioner may also want to discuss the possibility of equipping April with some tools to help her abstain during the pregnancy (e.g., relaxation techniques, recreation, avoiding trigger situations such as parties). The need to continue to monitor April's alcohol consumption should be clearly noted in the medical record.

4. INTERVENTION WITH A WOMAN WHO IS PREGNANT AND CONSUMING ALCOHOL, AND WHO IS EXHIBITING CERTAIN TRIGGERS FOR ALCOHOL CONSUMPTION, INCLUDING HER PARTNER (AEP PREVENTION)

Overview: This vignette illustrates a method for obtaining the alcohol history of a pregnant woman.

Background: Isabel, 30, has been referred to an outpatient mental health treatment center for feelings of depression. She is Hispanic, married, and pregnant (in her third trimester), and has one other child. The counselor and client have completed the intake process and Isabel has participated in the development of her comprehensive treatment plan. This is their third meeting. The counselor and Isabel agreed at the end of their last session that this would be about potential health risks with the pregnancy.

Learning Objectives:

1. To learn how to use a practical visual tool (a calendar) to more accurately and effectively identify client drinking patterns and possible triggers for alcohol consumption.
2. To identify verbal cues that can indicate that a topic is becoming uncomfortable for a client, and apply effective techniques when a client becomes upset.

Vignette Start

COUNSELOR: Hi, Isabel. How are you?

ISABEL: Fine, how you doing?

COUNSELOR: I'm fine, thanks. When we met last, we finished working on your treatment plan. You have had a little bit of time to think about the plan now. Do you have any thoughts or concerns about what we developed?

ISABEL: No, not really.

COUNSELOR: How are you doing with the pregnancy?

ISABEL: Pretty good. Things are going pretty well.

COUNSELOR: Great. Now, at the end of your last visit here, we said we would spend part of today's session talking about alcohol use during pregnancy. You indicated during your intake that you drink socially, so let's talk about that a little more. Knowing about when and how much you drink will help us to see if there is any need to be concerned about any health issues for you or the baby. Is that okay with you?

ISABEL: *[Sounding a little concerned.]* What do you mean "concerned about health issues?" I am not an alcoholic.

Master Clinician Note: The counselor wants to reassure Isabel that she has not formed a negative opinion of her. The counselor now also needs to be aware that Isabel may try to minimize the frequency and amount of alcohol consumed so that she is not viewed as an alcoholic.

COUNSELOR: *[Calmly and reassuringly.]* I am sorry, Isabel. I wasn't trying to say that you have an alcohol problem. Nothing you have told me during our previous sessions would lead me to believe that you are an alcoholic or have a drinking problem. You said you only drink socially, correct?

ISABEL: Yes. I don't drink every day or even every weekend.

COUNSELOR: Good. That's just what I thought. I know, just from the short time we have been seeing each other, that you would never do anything to hurt your child. But, would you agree that drinking socially for one person might be different than drinking socially for another?

ISABEL Of course.

COUNSELOR: Alcohol can have an influence on individuals who are anxious, depressed, and even on women who are pregnant, and possibly their unborn child. That influence can depend on the frequency and amount of alcohol consumed. So knowing the social situations and how much you drink at those occasions will help us determine if you need to make any changes between now and when the baby is born. If it is okay with you, let's see if we can identify those situations.

ISABEL: Okay, I'll give it a try.

COUNSELOR: Thanks. That's great. So first let me ask you this: Normally, when you aren't pregnant, how often would you say you drink alcohol?

ISABEL: Well, most of the time I'm not normally a drinker.

COUNSELOR: Okay, that's good. When you *do* drink, about how much do you have?

ISABEL: I can't really say. It depends.

Master Clinician Note: The counselor wants to get an accurate picture of Isabel's drinking during pregnancy, so she brings out a calendar. The visual is helpful as it allows both client and counselor to put their eye contact elsewhere, which can contribute to the ease of discussion. The counselor explains that it also helps to trigger memory by looking at dates.

COUNSELOR: Okay, so let's start by figuring out when you first found out that you were pregnant.

ISABEL: I went to Dr. Murphy's office and they did a pregnancy test. I had not had my period. I can look at the calendar, but I am pretty sure it was sometime in May.

COUNSELOR: Do you think it was the beginning of May or the middle?

ISABEL: It was the middle, and then I went home and told Marco.

COUNSELOR: Ok, so you found out you were pregnant in the middle of May. *[Counselor marks the calendar.]* When did Dr. Murphy tell you your due date would be?

ISABEL: Around December 22.

COUNSELOR: Great, so we know you're in your third trimester now. *[The counselor circles the third trimester with a colored pencil, then circles the other trimesters with different colors.]* It looks like you probably got pregnant somewhere around the beginning of April. *[The counselor also marks this on calendar.]* Did your alcohol drinking change after you found out you were pregnant in mid-May?

ISABEL: Yes, I pretty much quit drinking after that. But right before, around the beginning of May *[points to calendar]*, Marco had just gotten a job and we went out with some friends. We went to party that one time, and I drank a little, but I don't think that would harm the baby. It wasn't a lot.

COUNSELOR: You're doing great. Do you remember what you were drinking?

ISABEL: I had one rum and Coke. Mostly Coke, with a little rum.

COUNSELOR: Was that all?

ISABEL: I had one wine cooler which I sipped for the rest of night. That wasn't too much, was it?

Master Clinician Note: The counselor senses that Isabel is getting a little anxious about this line of questioning and tries to be reassuring and non-judgmental.

COUNSELOR: Two drinks in one night don't sound like a lot to me. I'm only asking because I want to help you do the best for the baby between now and the time you deliver. So let's see: It seems like you are saying that you mostly drink on special occasions. Is that right?

ISABEL: Yes, those are the times I usually drink, and sometimes when Marco has friends over to watch a game I might have a beer or two.

COUNSELOR: Okay. Can you remember any other occasions when you might have been drinking during your pregnancy?

ISABEL: I drank a little on my birthday in July.

COUNSELOR: Did you go out for your birthday?

ISABEL: No. Marco surprised me when I got home. He made me dinner with flowers and wine and everything.

COUNSELOR: He sounds very thoughtful.

ISABEL: *[Smiling, shrugs a little.]* He can be.

COUNSELOR: So, do you remember how much wine you had that night?

ISABEL: I had maybe two or three glasses. I have read that drinking a little wine would not hurt the baby. I try to be aware not to do anything that would hurt my baby. I drank a little with my first child and he is healthy.

COUNSELOR: I know that, Isabel. No mother would do anything on purpose to hurt her baby. I know how hard you're working to take care of yourself during the pregnancy, and that's really important. Did Marco drink with you on your birthday?

ISABEL: Marco drinks all the time. He drinks beer every day. I'm sure that I'm okay, because you know I'm not like Marco. I don't come home and a have a six pack.

COUNSELOR: Okay. So, you drank these two times before you got pregnant. And right about here is when you would have found out you were pregnant. *[The counselor points to circled first trimester on calendar.]* Are there any other days in these months that you can think of, or any events?

ISABEL: *[Pauses, squirms a little in her chair.]* Well, there was one time Marco and I had an argument about the amount of time he spends with his friends. He goes out on Friday nights and drinks with his friends, doesn't come home sometimes until the next morning. He went out and I had some of my girlfriends over and I wound up getting drunk. I was so bad I was throwing up. I was embarrassed. I had to go to the bedroom and they had a bucket and they were saying "Isabel, are you okay?" But that's the only time I can think of.

COUNSELOR: And what were you drinking then?

ISABEL: We were drinking rum and Coke.

COUNSELOR: Okay, do you know how many drinks you had?

ISABEL: We were drinking and playing cards. I must have had three or four, at least.

COUNSELOR: How many drinks does it take to make you feel high?

ISABEL: It depends. A couple glasses of wine, or one rum and Coke, if it is strong.

Master Clinician Note: The counselor is gradually asking more detailed questions about Isabel's alcohol use. Although Isabel claims not to be a drinker, a pattern of usage is emerging through the use of the calendar. Isabel is bringing up Marco often, so the counselor takes this cue and probes further about her husband.

COUNSELOR: It sounds like whenever you drink it has something to do with Marco. Are there times that you drink by yourself?

ISABEL: No.

COUNSELOR: Okay, so tell me about drinking with Marco.

ISABEL: *[Sighs.]* It's just mostly because we're with friends and I like to do what everyone else is doing. I want to be social. I don't drink every day with him. He'll come home with a six pack and drink beer while he is watching TV or sports. He loves baseball and basketball.

COUNSELOR: So he drinks when he comes home from work. Does he want you to drink with him?

ISABEL: He'll offer me a beer now and then, ya know, but that's his thing. That's what men do. I have too many other things going on. I really drink just a little. I really don't think that I am doing anything that is going to hurt the baby. I don't want to fight with Marco about his drinking or his friends. I have to come here to deal with my other problems.

COUNSELOR: Is Marco excited about the baby?

ISABEL: *[Relaxing a little at the change in subject.]* Oh yeah. Very. I'm excited, too. We're looking forward to this.

COUNSELOR: How do you think it's going to be with his drinking after the baby is born?

ISABEL: I don't know. I doubt he will change.

COUNSELOR: Are you worried about that?

ISABEL: No, he's a good guy. *[She sniffles and wipes her nose.]* He really is. I know you probably think he's an alcoholic or something. That's not how it is. We're not like that. *[She starts crying.]* I love this baby. So does he. We're trying to take care of it. *[Her crying continues, and she gets an anxious expression on her face.]*

Master Clinician Note: Isabel is becoming anxious, and is shifting the topic away from alcohol. This is a signal, or cue, to the counselor that the client is uncomfortable. The counselor needs to acknowledge what Isabel is feeling and be careful about how much further she probes on this issue during this visit.

COUNSELOR: I know you have a lot on your plate and I think you are handling it quite well. You did quite a bit in today's session, and you did very well. I would like to end this session and talk a little about our next session. Would that be alright with you?

ISABEL: Sure.

COUNSELOR: I heard you say you had read something that drinking small amounts of alcohol was okay for a pregnant woman. Is that correct?

ISABEL: Yes, I read it on poster, I don't remember where.

COUNSELOR: I would like to give you something to read. It's short. It's about what can happen when babies are exposed to alcohol before being born. I would like you to read it so we can discuss it in our next session. Is that okay with you?

ISABEL: Sure. The more I know, the more I can protect the baby, right?

COUNSELOR: Absolutely.

Master Clinician Note: The mental health counselor is in a difficult position. Her use of the calendar helped to reveal a pattern of alcohol use by Isabel and her husband that exceeds what Isabel first admitted and is unsafe for the baby. It also helped to establish some of Isabel's triggers for drinking alcohol, which include her husband and being angry.

At the same time, discussing alcohol use and how it can hurt a baby can be an emotional topic for the mother. She is working hard to take care of her baby, and the topic of alcohol may have gone further than she is comfortable with. At the same time, it has been useful, as Isabel seems to be reaching a point where she has begun to question her use of alcohol during pregnancy.

This is a learning moment for the counselor. She can see the value of exploring alcohol use with her pregnant patients, but she also knows that, in the future, she can pay closer attention to verbal cues that indicate a client's discomfort; in Isabel's case, the changing of the topic and the repeated assertions that she doesn't think she has hurt her baby. The counselor should continue the session long enough to bring closure to the topic of alcohol use, while supporting the positive things that Isabel has done to take care of her baby. The door should be left open to come back to the topic of alcohol in future sessions.

If Isabel continues to show a pattern of alcohol use during the pregnancy, the counselor can help her identify other ways to deal with her anger besides drinking (stress management), and help her identify or find support systems in her life other than her husband if he is not being supportive of her abstinence during pregnancy (e.g., a pregnancy peer support group). If a mental health counselor does not feel comfortable addressing these issues, referral to a qualified substance abuse treatment counselor is advisable.

5. INTERVIEWING A CLIENT FOR THE POSSIBLE PRESENCE OF AN FASD (FASD INTERVENTION)

Overview: This vignette illustrates the clues the health care worker is receiving that suggest an impairment and possible FASD. A client with an FASD, with brain damage, will not receive the information from the worker the same way someone without FASD will receive it. The client may not have a diagnosis and may not immediately present as someone with a disability. There are a number of questions the worker could ask to determine whether they need to operate in a different kind of therapeutic environment with the client. The main goal of this vignette is for the health care worker to consider the *possibility* of an FASD, not to diagnose an FASD, which can only be done by qualified professionals. A woman who has an FASD is at high risk for having a child with an FASD.

Background: Marta is a single woman, 19, who recently had a baby, and is being seen at a Healthy Start center by a health care worker. This is the first time they are meeting. The health care worker's colleague asked her to meet with Marta as she knew that the health care worker was knowledgeable about FASD and was known as the office "FASD champion." The colleague has begun to suspect that Marta may need an evaluation for FASD, as she has repeatedly missed appointments or been late, gotten lost on the way to the center, failed to follow instructions, spoken at inappropriate times, and has repeated foster placement and criminal justice involvement in her case history. The only information in the history about Marta's biological mother is that she is dead. The colleague wants the health care worker to conduct an informal interview to assess the possibility of an FASD.

Learning Objectives:

1. To learn how to identify behavioral and verbal cues in conversation with a client that may indicate that the client has an FASD.
2. To learn how to apply knowledge of FASD and its related behavioral problems, in order to reassess clients with troublesome behaviors or concerns for factors other than knowing noncompliance.

Vignette Start

HEALTH CARE WORKER:	Hi Marta, how are you?
MARTA:	Good.
HEALTH CARE WORKER:	Your regular counselor has asked me to meet with you today for a few minutes to ask you a few questions, if that's okay. *[Marta nods in agreement.]* Okay, so tell me how you got here today.
MARTA:	*[Shrugs.]* I took the #10 bus, then I got off and walked.
HEALTH CARE WORKER:	Where did you get off the bus?
MARTA:	Madison Avenue.
HEALTH CARE WORKER:	Did you know you could have taken the bus to Washington Street instead of Madison Avenue? Then you would have been six blocks closer.
MARTA:	*[Shaking her head.]* I didn't know that.
HEALTH CARE WORKER:	Do you want me to write that down for you?
MARTA:	Okay.
HEALTH CARE WORKER:	*[Writes down the information.]* Here, you can keep this in your purse. *[Hands Marta the piece of paper.]*

Master Clinician Note: Individuals with an FASD sometimes exhibit poor working memory. The health care worker is not assuming that Marta has an FASD at this point. However, if she does, it is unlikely that she will remember the information about the bus route, so the health care worker writes it down.

HEALTH CARE WORKER:	Did you pay for your bus ride with cash or a bus card?
MARTA:	Today I paid with cash, but I don't always have it.
HEALTH CARE WORKER:	When are the times when you don't have money?
MARTA:	Sometimes friends borrow it, or other people.
HEALTH CARE WORKER:	What other people?
MARTA:	Well, like last time, a man on the corner asked me for money, so I gave it to him. Then I didn't have any for the bus.

Master Clinician Note: Marta has exhibited a double "red flag" for an individual with an FASD; poor money management skills, and a lack of understanding of consequence (i.e., giving away the money without understanding that she then wouldn't be able to pay for the bus).

HEALTH CARE WORKER: Marta, I'd like to ask you a little more about some of the questions that you were asked when you first came here.

MARTA: Okay, go ahead.

HEALTH CARE WORKER: You told us that your mother is not alive. How old was she when she died?

MARTA: Twenty-five, I think.

HEALTH CARE WORKER: How old were *you* when she died?

MARTA: Four.

HEALTH CARE WORKER: I'm very sorry to hear that you've lost your mother.

MARTA: *[Very matter-of-factly.]* I didn't lose her. She died.

Master Clinician Note: Marta is exhibiting very literal interpretation of language, which is common among individuals with an FASD.

HEALTH CARE WORKER: You're right, that's what I should have said. That was probably a hard time for you. *[Marta nods.]* Did you know much about her?

MARTA: *[Shakes her head and shrugs.]* Not really.

HEALTH CARE WORKER: Do you know if she ever had any kind of problem with alcohol?

MARTA: Like, being an alcoholic?

HEALTH CARE WORKER: Yes.

MARTA: *[Shrugs.]* I heard she drank, yeah.

HEALTH CARE WORKER: Do you know if she drank alcohol while she was pregnant with you?

MARTA: I don't know. *[Pauses for a moment.]* That's a weird question. Why are you asking that?

HEALTH CARE WORKER: Did the question make you uncomfortable? Sometimes when women drink during pregnancy their kids end up having extra challenges. Do you know what I mean when I say challenges?

MARTA: Sure.

HEALTH CARE WORKER: Can you give me an example?

MARTA: *[Shrugs].* I don't know.

Master Clinician Note: Marta has stated that she understands when really she doesn't. Any young person might do this, but it is especially common for individuals with an FASD. Checking for cognition is important with clients that have or may have an FASD.

HEALTH CARE WORKER: Needing extra help in school is an example of a challenge.

MARTA: Right, okay.

HEALTH CARE WORKER: Is it okay to ask a few more questions?

MARTA: Yeah.

HEALTH CARE WORKER: Thanks. This will only take a couple more minutes, I promise. How about you? Do you drink alcohol at all?

Master Clinician Note: Because this is an interview to see if there is reason to believe that Marta has an FASD, the counselor is probing to see if perhaps Marta's baby was also exposed to alcohol before birth.

MARTA: No, I don't like the taste of it.

HEALTH CARE WORKER: Me neither. So, you didn't have any alcohol while you were pregnant?

MARTA: No, my foster mom and dad told me not to drink or smoke while I was pregnant.

HEALTH CARE WORKER: That was very good advice. Tell me, where did you live when you were growing up?

MARTA: First with my aunt, then lots of places. I was in foster care.

Master Clinician Note: It is not unusual for individuals with an FASD to no longer be in the care of their parents, and to have been placed multiple times in foster care.

HEALTH CARE WORKER: Did you like school when you were growing up?

MARTA: *[Looking down.]* Umm… I guess it was okay.

HEALTH CARE WORKER: What classes did you like?

MARTA: I liked art. And I liked Ms. Norton.

HEALTH CARE WORKER: Who was Ms. Norton?

MARTA: Ms. Norton was in the resource room.

Master Clinician Note: Time spent in the "resource room," while not a clear-cut clue, is certainly a strong indicator that the child was identified in school as having special needs. This is often the case with children who have an FASD. The counselor could further explore by asking a follow-up question like "Did you ever have extra help with your school work?" or "Did you ever have special classes or tutoring in school?"

HEALTH CARE WORKER: How many students were in the class with you?

MARTA: Five, including Eddie.

HEALTH CARE WORKER: Who's Eddie?

MARTA:	*[Laughing a little to herself as she remembers.]* Eddie is the kid that I used to get in trouble with all the time. He was always coming up with ideas.
HEALTH CARE WORKER:	What do you mean when you say Eddie "came up with ideas?" Can you give me an example?
MARTA:	Well, like, one time we were walking home from school, and he saw a bike in someone's yard that he really wanted. So he told me to go get it for him. I did, but the man who lived there caught me and called the cops.
HEALTH CARE WORKER:	Did you realize that taking the bike could get you into trouble?
MARTA:	I had a feeling. I wasn't sure, but I wanted Eddie to keep liking me.

Master Clinician Note: Involvement in "trouble" or crime as an unintentional secondary participant is an FASD "red flag," particularly when the motivation is social (i.e., to make friends).

Master Clinician Note: Marta's case/vignette is oversimplified. In a matter of minutes, she has exhibited a handful of behavioral clues that suggest that she may have a disability. Not all individuals who may have an FASD will be this easy to 'spot.' This conversation is provided simply as a way to learn how such "red flags" might come up in conversation with a client. By identifying these red flags, which are particularly common in individuals with an FASD, the health care worker will be able to manage the case in a way that better suits the needs of the client, and can make a better-informed decision regarding the need for a more complete FASD diagnostic evaluation. Additional probing questions that could be asked include the following:

- How much alcohol did your mom drink when she was pregnant?
- Think about when you were a child. How did you do in school?
- Do you ever have trouble keeping appointments? How do you do with telling time?

Refer to Part 1, Chapter 2 for guidance on referring a client for a formal FASD diagnostic evaluation, and for strategies and treatment modifications that will improve treatment success with an individual who may have an FASD.

6. INTERVIEWING A BIRTH MOTHER ABOUT A SON WHO MAY HAVE AN FASD AND IS HAVING TROUBLE IN SCHOOL (FASD INTERVENTION)

Overview: Counseling professionals in mental health or substance abuse treatment may avoid talking to a female client or family member about their alcohol use during pregnancy, either to avoid communicating any shame or judgment to that individual, or out of a lack of knowledge about FASD. This case illustrates a scenario where such a discussion may prove fruitful, and the sensitivity required when starting the discussion.

Background: The vignette begins with a community mental health professional talking to Dixie Wagner, 35, about the behavior of Dixie's 7-year-old biological son, Jarrod. (Jarrod is not present at this session.) Jarrod is in trouble again for hitting another child, and this is causing distress for the mother that the mental health professional wants to address, which leads into a discussion of FASD.

Learning Objectives:

1. Cite methods to help the caregiver clarify the child's issues and discover why the child is having problems.
2. Specify skills needed to follow the caregiver's lead in asking probing questions.
3. Explore the negative perceptions surrounding prenatal alcohol exposure, and examine how lack of knowledge or fear of shaming may interfere with asking the right questions.

Vignette Start

MENTAL HEALTH PROFESSIONAL:	Dixie, we talked briefly on the phone about Jarrod's school issues. It sounds to me like you are concerned for him. Today I'd like to hear more about your concerns, and then we can work from there. How does that sound?
DIXIE:	Yes, that's fine. You're right, I'm very concerned about him.
MENTAL HEALTH PROFESSIONAL:	Is it okay that we talk about the kinds of behaviors that led to Jarrod hitting a fellow student? Was the student a friend of Jarrod's?
DIXIE:	That is exactly what's so disturbing about this situation; it was someone I thought was a good friend, a kid named Garrett. Jarrod looks up to Garrett and talks about him all the time. I was excited that he wanted to be friends with Garrett. I was very surprised to get a call from the principal.
MENTAL HEALTH PROFESSIONAL:	You're right. Friends are so important for all children this age. Has Jarrod been having problems with his peers?
DIXIE:	*[Sighs].* He's always had a hard time getting along with kids his own age. He starts off happy and friendly. He wants everyone to like him. Sometimes I think his enthusiasm might be too much for some kids. Sometimes he says such crazy things. I don't know if he thinks the kids will laugh at what he says or if he is really being serious. Slowly I can see the kids moving away from him. It breaks my heart. He ends up playing by himself. He really wants everyone to like him. He'll talk to anyone! We always say Jarrod has never met a stranger he didn't like. I worry a little that he'll listen to the wrong person when he gets older. Most of the time he's just so sweet and loveable.
MENTAL HEALTH PROFESSIONAL:	Okay, so what I'm hearing is that Jarrod has been having problems making and keeping friends his own age, although he really wants to have a friend. Is that right? *[Dixie nods.]* How about in the school setting? How do you think he is doing in class and with his school work?
DIXIE:	Well, he's been labeled a "talker" in class, and we've gotten plenty of notes from the teacher because Jarrod likes to chat with his neighbors and that annoys them sometimes, and the teacher. He has a lot of energy, and sometimes loses focus on his work. He can get frustrated, and may have a hissy fit

	at school when he doesn't want to do his work. He likes to do a good job. Sometimes he just won't finish his work. So the teacher will send it home for us to do with him. Every night we sit down and spend a lot of time on homework, but that usually ends up in Jarrod fighting and yelling at us.
MENTAL HEALTH PROFESSIONAL:	So, Jarrod generally has a hard time focusing and sitting still. These hissy fits, as you call them, how many of these will he have in a typical school day? Can you tell me a little more about that? Are you noticing any consistent struggles?
DIXIE:	I guess he's had several since starting school this year. The hissy fits are like toddler temper tantrums. I can't believe he is still having tantrums. We never really know why he has them, especially at school. I know he leaves every day happy to be going to school, but when he gets home he's tired and cranky, and very angry. He doesn't know where his homework is in his backpack. This leads to raised voices, either me or my husband. The teacher always tells us Jarrod was given the homework, so he must be deliberately misplacing it. If we do find the homework assignment, Jarrod will sit and work really hard for awhile, but then he starts to whine and cry that he is tired and doesn't remember what the teacher told him that day. My husband and I review his spelling words with him every day. He sits and really tries hard to remember them. But he never passes the test on Friday. We spend lots of time with him on his homework. It's like we have to re-teach him everything he learned from the day. Many times it ends in a hissy fit. It's not like we don't help him. We've done this with him since he was in first grade.
MENTAL HEALTH PROFESSIONAL:	Jarrod sounds like he is facing some challenges with his school work. Are there other times or activities when he struggles?
DIXIE:	Well, when he gets off the bus in the afternoon, he is out of control. He runs around, bumping into furniture and screaming. Sometimes he will knock down the dog. I am sure he doesn't mean to hurt the dog, though, because he really loves it. The teacher says he has trouble standing in line for lunch, and pushes the other students next to him. She also says he has a hard time on the playground for recess. He prefers to stay inside with her. And about 2pm every day, Jarrod gets very sleepy.
MENTAL HEALTH PROFESSIONAL:	I see. Is he getting enough sleep?
DIXIE:	We start the bedtime routine about 7:30, right after dinner. The kids will take showers, brush their teeth, and then we'll read a book together. We struggle to get Jarrod to brush his teeth. He hates taking a shower, but once the water is in the tub, he loves taking a bath. Everyone gets a chance to pick a book when it's their turn. Jarrod always picks a picture book

	about Kermit the frog. But when it is time to go to bed, Jarrod is wide awake, talking or playing his video games. We've had to put him in his own room so my other children can go to sleep. Jarrod is up before my husband, usually before 5am, because he's never needed much sleep.
MENTAL HEALTH PROFESSIONAL:	So what I am hearing is that you and your husband have set up a nighttime routine for all the children, but Jarrod has a hard time with the routine. It sounds like Jarrod is only getting a few hours of sleep at night. This may be a reason why Jarrod is having problems in school, since he is tired, but I would like to hear more from you. What else is worrying you?
DIXIE:	This isn't school-related, but that boy can't keep his room clean! I run a tight ship, and an unmade bed is not welcome. He can never find anything. I raise my voice, and still no results. My other kids listen to me. I have no idea why Jarrod disobeys me all the time.
MENTAL HEALTH PROFESSIONAL:	Can you describe a typical room-cleaning episode?
DIXIE:	I'll say "Did you clean your room?" and he says "Yes" and then I'll go and check and nothing is put away. There are clothes on the floor. Dirty and clean clothes will be in his dresser drawers. The bed is unmade. He'll leave wet bath towels on the floor. And there he sits playing a video game. Nothing is done and he still says "Yup, it's clean!" He just doesn't listen. Sometimes I punish him. That doesn't work, either.
MENTAL HEALTH PROFESSIONAL:	That can't be easy, and I can see where that could be frustrating for you and your husband. Do you think it's a case of Jarrod not having the organizational skills needed to keep his room clean, or that he doesn't understand what you're asking him to do?
DIXIE:	I think he understands, he's just resisting. I know he can do it, but usually not until I stand over him and make him do it, one thing at a time. It's exhausting.
MENTAL HEALTH PROFESSIONAL:	Well, That sounds like a lot of kids Jarrod's age. But what I'm getting at is when you break down the specific tasks for Jarrod—one thing at a time, like you say—he does what he's told and does it correctly. Is that right?
DIXIE:	Yes, we have found that there isn't a better kid when you work with him one-on-one.
MENTAL HEALTH PROFESSIONAL:	You're providing me with a lot of needed detail. Thank you. Knowing his behaviors out of school really does help me understand how we might be able to help him *in* school. I'd also like to follow up on something you mentioned earlier,

	about Jarrod's friends. How is he with kids his own age, besides Garrett?
DIXIE:	Besides the kindergarten twins who live next door, Jarrod has no one to play with. We tried to get him into soccer, but he ran after the soccer ball no matter what side had it and the kids made fun of him. We tried cub scouts with my husband helping out as den leader, but Jarrod would be very bouncy and talkative, grabbing the other kids' project, sometimes breaking them. The kids would be polite, but eventually started to shun him. Eventually he would go off by himself and play with a toy.
MENTAL HEALTH PROFESSIONAL:	This must be hard for you and your husband.
DIXIE:	We were told last year that Jarrod was immature for his age, but the teacher said boys tend to mature later than girls. The teacher wanted to wait and see if Jarrod matured over the year before we did any official school testing.
MENTAL HEALTH PROFESSIONAL:	So, let's recap what we have talked about. Jarrod tries to be social and verbal, is trusting, and wants to be a good friend. He also has trouble cleaning his room, staying on task, and doing his school work, but when he does sit down for homework, he can be very diligent in getting his work done. Then there may be some sensory issues, like brushing his teeth or taking a shower, and the bus tends to be a problem. Of course, we cannot forget the fight with Garrett. Out of all these things, I don't see a child with an aggressive nature. What I am concerned about, though, is that Jarrod might be facing some difficulties that will lead him to get into another fight.
DIXIE:	This isn't making sense to me.
MENTAL HEALTH PROFESSIONAL:	Well, I don't have a real clear picture yet. However, one of things that could be at work is that Jarrod could have some cognitive issues that are creating differences in the way he processes information. These deficits can occur for a whole range of reasons. Sometimes children are born with them, and as they grow, their brains are different from most kids.
DIXIE:	You mean like ADHD? We've had people suggest ADHD before.
MENTAL HEALTH PROFESSIONAL:	ADHD may be one issue, but other things could be at work, too. Is it okay that we talk about before Jarrod was born? This is something that I've asked some of my clients before, and it may be helpful here, as well. I'd like to ask about Jarrod's birth, and when you were pregnant with him. It will help us understand Jarrod's environmental background. Were there any complications during your pregnancy with Jarrod?

DIXIE:	No, everything was fine. In fact it was a pretty easy pregnancy. I didn't have much morning sickness.
MENTAL HEALTH PROFESSIONAL:	Would you say that you planned your pregnancy with Jarrod?
DIXIE:	No, not really. He's our third, and we weren't really planning on a third.
MENTAL HEALTH PROFESSIONAL:	Now, many pregnancies are unplanned. About half in this country, in fact. Were you pregnant for awhile before you knew?
DIXIE:	Yeah, I found out kind of late. *[Starts to become defensive.]* But I had a good doctor, and good prenatal care.
MENTAL HEALTH PROFESSIONAL:	What did your doctor tell you about the use of alcohol during your pregnancy?
DIXIE:	My husband and I are social drinkers, but we always have been. I don't smoke. I drank during my other pregnancies. My doctor even told me to do it sometimes, because I get really stressed out and it's how I used to relax. I really think you're way off here.
MENTAL HEALTH PROFESSIONAL:	Your doctor told you that the occasional drink was okay? That it would relax you?
DIXIE:	Yes, he did, and why would he say that if it wasn't true? He's a pediatrician, for god's sake. Where is this going? Are you saying I did something wrong to hurt Jarrod?
MENTAL HEALTH PROFESSIONAL:	No I do not think you would do anything to hurt Jarrod. Some doctors still give that advice, even though the evidence now suggests that alcohol can harm a fetus. It won't necessarily harm *every* fetus, but it can hurt some. I recognize that this is hard to talk about. I only want to explore the possibility. We both have the same goal, to help Jarrod. He has exhibited a pattern of behavior that makes an FASD something worth examining, even if it's just to rule it out. Do you know about FASD?
DIXIE:	*[Sits forward in her chair, holding up her hands in a defensive manner.]* So, wait. What you're saying is that I drank alcohol and hurt Jarrod while I was pregnant. Is that it?
MENTAL HEALTH PROFESSIONAL:	Only experts can determine whether a person has an FASD. Changes in the brain due to alcohol can only be identified by certain professionals, but what I do suggest is that we start to look at why Jarrod might be experiencing some of the problems that you and his teacher have identified. I am seeing a pattern of behavior that may suggest an FASD. We all want the best for Jarrod, and knowing what is happening in his head may help all of us meet his needs.

DIXIE: *[Leans back, crossing her arms, more relaxed but still wary.]* What is this stuff, FASD?

MENTAL HEALTH PROFESSIONAL: It stands for Fetal Alcohol Spectrum Disorders. See, alcohol is an environmental factor that can affect a developing fetus. I mentioned alcohol because some women are unaware of the effects that alcohol can have on an unborn baby. Scientists refer to the effects of alcohol on the fetus as FASD.

DIXIE: I've never heard of it. Are you saying you think Jarrod has that? *[Sits forward in her chair; tears well up in her eyes.]* What you're saying is that I drank alcohol and changed Jarrod's brain while I was pregnant. Is that it? This is my fault?

MENTAL HEALTH PROFESSIONAL: I'm not leaping to that conclusion. If Jarrod does have an FASD, there is no blame here. I just think it's worthwhile to discuss the possibility, because it may help your son, which is what we both want.

DIXIE: *[Sits back in her chair and slumps a little.]* Yeah, I wanna help him. I want nothing more. My husband and I have done everything we can. *[She sniffles some more and shakes her head, considering; the counselor offers a box of tissues.]* This has been so hard. It's been going on so long. We've seen so many doctors, and heard so many diagnoses, and no one's ever right. Nothing works. But no one's said anything like this before. And when you sit there and tell me that this might all be because I had some drinks while I was pregnant… *[She sniffles some more.]*

Master Clinician Note: It's important at this point for the mental health professional to respond to the fact that the client is feeling blamed and becoming agitated.

MENTAL HEALTH PROFESSIONAL: Then I have to apologize to you. If that's what you're feeling, then I'm to blame, not you. I haven't done my job properly. It's incredibly important to me that you understand that my only goal is to work with you to identify a potential root cause for the problems that Jarrod having, because it's clear that his situation is causing *you* distress. That's all I want to do. There are many cases of FASD. Jarrod would not be the first or the only one. No mother on earth does anything to intentionally hurt her baby. I know you certainly didn't. I have a child of my own. I know the feeling of being a mother, and it's very, very clear to me how much you love your son.

DIXIE: I just… I don't even know what to say. I feel like you're pointing a finger at me. *[She is angry, beginning to cry.]* You're in *mental* health. No offense, but what do you know about *medicine*? Or about my son? About how much I love him? Or about what we've been through? I can't even understand that you're sitting there saying I did this to him.

	I mean, I hear your "no blame" crap, but I'm feelin' real blamed right about now!
MENTAL HEALTH PROFESSIONAL:	Well, like I said, I do apologize if that is how you feel. Maybe we just need to rule out FASD. If it happened, you were going on the advice of your doctor. Would it be alright if we focused on what you want to do next for Jarrod?
DIXIE:	*[Waving her hand to stop the counselor.]* What's it called again?
MENTAL HEALTH PROFESSIONAL:	Fetal Alcohol Spectrum Disorders. FASD. I can give you a pamphlet that talks about the basics of it.

Master Clinician Note: It is advisable to provide FASD information that does not include pictures, particularly of children with prominent facial dysmorphology (e.g., thin upper lip, smooth philtrum). These facial characteristics are present in only a small percentage of children who have an FASD, and if the client's child does not resemble the children in the pictures, this may enable the client's desire to believe that their child can't possibly have an FASD.

DIXIE:	*[Taking the pamphlet.]* So I should read this?
MENTAL HEALTH PROFESSIONAL:	Yes, it would be good if you and your husband both read it and discussed whether you think it describes Jarrod's situation.
DIXIE:	I still say you're wrong. But, what if it does? What happens then?
MENTAL HEALTH PROFESSIONAL:	To start, I think you could begin the process for the school to start testing Jarrod for a learning disability. There are several tests that could help them understand the best way to teach Jarrod so that he doesn't get so frustrated. There are a few pieces of the testing that you will have to complete, like his developmental history, when he walked and talked, things like that. I think you should also look at doing another test for ADHD. In the meantime, we can set up another appointment to talk about FASD, possibly with your husband, as well. And if the two of you are okay with it, I can help you access a more complete evaluation.
DIXIE:	Where does that happen?
MENTAL HEALTH PROFESSIONAL:	It may be best to complete the assessment with a developmental pediatrician at the local hospital. I am sure that doctor will want to see the test results from school. If you like, there is a support group for families called the Circle of Hope. I could give you the phone number or e-mail address for them if you need someone else to talk to who has been through this. How would that be?

Master Clinician Note: Although the mental health professional makes repeated attempts to assure Dixie that she does not need to feel blame about the possibility that Jarrod has an FASD, Dixie has still become upset. This is a very natural response, and counselors should be prepared for birth mothers to feel as though they are being 'blamed' for their child's condition when FASD is discussed. However, many pregnancies are unplanned, some doctors do still recommend a glass of wine as a way for a pregnant woman to relax, and many women do not realize until well into their first trimester that they are pregnant. The mental health professional utilizes these realities as a way to reassure Dixie and disconnect her from a sense of guilt and consistently reiterates their shared goal, to find the best way to help Jarrod. She also effectively coordinates care by putting Dixie in touch with additional testing and offering a support group number.

7. REVIEWING AN FASD DIAGNOSTIC REPORT WITH THE FAMILY (FASD INTERVENTION)

Overview: The purpose of this vignette is to provide counselors with guidance on how to review a diagnostic report (or Medical Summary Report) with family members of a child who has been just diagnosed with FAS.

Background: The client, Jenine, is the caregiver of her grandson, Brice. Jenine is meeting with a counselor from the Indian Health Service to review Brice's Medical Summary Report for the first time. In a prior session, Jenine confided that she felt overwhelmed. Knowing how detailed a Medical Summary Report can be, the counselor suggested that Jenine bring trusted family members and elders to this session. Together they arranged for Jenine's sister, aunt, and an elder to attend.

Learning Objectives:

1. To recognize that clients will need support after an FASD-related diagnosis.
2. To identify how to help the client prioritize the child's and the caregiver's needs.
3. To recognize that the client will need to be educated to understand that the child's behavior problems are due to damage to brain caused by prenatal alcohol exposure.

Vignette Start

COUNSELOR: Welcome, everyone. It is so good for Brice that you could be here. I am very happy to try to answer all of your questions today. We'll go through the basics, so that we can work on what is best for Brice. Does that sound good?

JENINE: Yes.

AUNT: Yes.

ELDER: Yes.

Master Clinician Note: The counselor is listening to everyone in order to validate the feelings and concerns of all individuals attending the session.

COUNSELOR: As I mentioned when you arrived, I am so glad that each of you are here today to support Jenine through this diagnostic process. Together, we can come up with a plan and move forward from there. The plan will build on Brice's strengths, as well as the diagnosis. We'll get started today, but it will take more meetings and community support to understand this diagnosis. A lot of detailed information can be overwhelming, but again, together, we will work through this process.

JENINE: Okay.

COUNSELOR: Before we review the report, let's talk about FAS. What kinds of things have you learned about FAS?

JENINE: I have been reading a lot on the internet.

Master Clinician Note: It is advisable for the counselor to caution the client and all attending the session that the quality and reliability of online information about all forms of FASD varies. She should provide the client with a reading list of up-to-date sources, but advise them to put it down when they need a break to avoid feeling overwhelmed.

COUNSELOR: Okay, I like the internet as a source of information because there can be some helpful sites. At the same time, not all internet information is up-to-date. Here is a list of three Web sites that I recommend. They are updated all the time. They're really the best place to start. The first site publishes some basic facts and I'd like to review that with you all for a few minutes.

Master Clinician Note: The counselor can now review the report with Jenine and her support persons. The counselor can use the review to assess the knowledge level of the client and her sister and elder, in order to determine how much education and support will be needed throughout the process. It is also advisable to inquire about other family members (grandparents, brothers, sisters, aunts and uncles, extended family) to assess how they will feel about the child's disability and to gain insight into cultural differences.

A sample Medical Summary Report can be viewed at the Web site of the Washington State FAS Diagnostic & Prevention Network (FAS DPN): **http://depts.washington.edu/fasdpn/pdfs/4-digit-medsum-web-2006.pdf**.

After completing the review, the counselor should focus on Brice's priority problem area, as well as the most significant need(s) of the caregiver.

COUNSELOR: Okay, now that we've worked our way through the report, we need to focus on the number one area where Brice is having problems. Is that in school or at home?

JENINE: Both, but I can handle home. School is getting out of control. I hope that this diagnosis gets him the help he needs.

COUNSELOR: Well, I know that a diagnosis is not always the pathway to services that we expect. But what I did see in the report was a clear description of Brice's speech and language difficulties, so I think that we can get him the speech therapy services that will help in school.

JENINE: That would be wonderful. Brice stutters, and really has a hard time coming up with the right word on the spot.

COUNSELOR: Okay, then let's make the top priority for Brice to get services and therapy for speech. Does that sound like the best place to start?

JENINE: Yes, let's do that.

AUNT: I will help.

ELDER: We will help, too.

COUNSELOR: Now let's discuss a top priority for you, Jenine. I want to check in with your stress level. If you are stressed, then it will be hard to be truly supportive for Brice. And it is my experience that parents and caregivers of children who have special needs do deal with burn-out.

JENINE: Yeah, that sounds like me.

COUNSELOR: Then since that's the case, let's use a couple of sessions to make a plan. If we have any medical questions, I can consult with a pediatrician to try to get those answered for you. Next, we'll get the speech therapy going for Brice.

JENINE: Okay. How am I going to pay for all of this? All of these services?

COUNSELOR: I know some of that is being paid through your insurance company. I'm more or less the case manager for Brice, so anything not covered, we'll work together to address how those things will get paid for.

JENINE: Okay. Now, what's going to happen in school now, with this diagnosis?

Master Clinician Note: Even though answers to these questions cannot all be provided immediately, the counselor assures the client that they will work together to establish plans to address them.

COUNSELOR: I think that it will be a process, and that will be the focus of our time next week. We'll want to think about how you can best approach the school to get Brice's special needs met. We'll also discuss how to talk to your family and friends as well as his teachers about FAS.

JENINE: Okay.

COUNSELOR: One thing we can definitely do today is make a list of Brice's strengths. It's very important that our plan for helping him focuses not just on his diagnosis but also on his positive abilities. Can you all help me with that?

JENINE: Sure. He has a lot of wonderful qualities, he really does.

COUNSELOR: I know he does. We're going to build on those. So, let's recap. Our first priority is to get the process started on Brice's speech therapy. We also need a plan to help you, Jenine, when you're feeling burned out. We want to talk about payment for services. And we want to address what this diagnosis means in terms of special needs at school. Does that sound right?

JENINE: Yes.

AUNT: Yes.

ELDER: Yes, it does.

COUNSELOR: Good. I'm writing all this down, and I'll give everyone a copy. And we'll set up a time for our next meeting. Let's pick a time that works for everyone.

Master Clinician Note: A diagnosis of any form of FASD can be overwhelming for a family. Although this vignette lacks specifics, the overarching theme of importance is that the counselor is positive, is willing to work with the family to make a plan to address any areas of concern, and is available to help them through the process. For families and caregivers of an individual with an FASD, having this navigational assistance can be tremendously helpful and relieve much of the stress that can go along with caring for such an individual. In addition to addressing the areas identified by the family as priorities, it will be important in future sessions for the counselor to:

- Consistently point out the child's positive attributes;
- Recommend a specific support group for the family, if available;
- Emphasize the need for respite care; and
- Ask the client about ways to involve the child in an area of interest, like music or sports or art. This can provide a 'break' for both the child and the caregiver.

8. MAKING MODIFICATIONS TO TREATMENT FOR AN INDIVIDUAL WITH AN FASD (FASD INTERVENTION)

Overview: The purpose of this vignette is to demonstrate how to modify treatment plans for a client with an FASD.

Background: The client, Yvonne, is an adolescent female with a history of truancy and fighting. She has been mandated to counseling for anger management, and has missed her last two appointments. When the counselor phoned her about the missed appointment, Yvonne's mother suggested that Yvonne may not be taking her medication, and hinted that Yvonne may be depressed.

Learning Objectives:

1. To adjust expectations regarding age-appropriate behavior, since individuals with an FASD may be adult-aged by calendar years, but are much younger developmentally and cognitively.
2. To demonstrate the value of collateral information and how to ask an individual for consent.
3. To demonstrate the importance of seeking involvement from parents and caregivers.
4. To identify how concrete thinking plays a role in comprehension for clients with an FASD.
5. To cite the value of time spent developing rapport and establishing trust.

Vignette Start

COUNSELOR: Hi, Yvonne. We've missed a couple sessions, so I haven't talked to you in awhile. How has everything been going? *[Yvonne does not respond.]* Are you taking your medicine?

YVONNE: Yep.

COUNSELOR: I understand that you are not coming home at night. I'm concerned that on those nights you're not able to take your medicine.

YVONNE: I take my medicine! Can I go?

COUNSELOR: Well, we have more time today, so let's keep talking. You know, I need a break. Do you?

YVONNE: Yes, I want to leave.

COUNSELOR: Well, I don't want you to leave yet, but we can go for a walk. Would you like to walk around the courtyard, or go to the cafeteria?

YVONNE: Outside. I want to walk in the courtyard.

COUNSELOR: Yeah, let's do that. It'll get us out of this stuffy office.

They exit to the courtyard.

Master Clinician Note: Yvonne is clearly confrontational. The counselor is navigating around the resistance by not repeating questions and insisting on answers, and changing the physical environment to one that Yvonne chooses. The counselor then begins a rapport-building process by holding off on treatment talk in favor of getting to know Yvonne personally.

COUNSELOR: So, tell me a little bit about things that you like to do. We've only seen each other one time, and that was a few weeks ago. I'd like to know more about the kinds of hobbies and things you like to do.

YVONNE: I love being outside. I love being with animals. My pets are the best.

COUNSELOR: Mine, too. I have three dogs, all Dalmatians. What kinds of pets do you have?

YVONNE: We have a dog named Scooter, he's a chocolate lab, and we have a cat, Cory. I don't know what kind of cat he is. My brother also has a little lizard, but I think it's pretty gross.

This continues for several minutes. At an appropriate time, the counselor begins to shift the conversation back to treatment issues.

COUNSELOR: Let's talk a little about your treatment plan, what is working and not working for you.

YVONNE: Okay.

COUNSELOR: Sometimes clients do not like to take medication, or they don't remember to take their pills. Do you ever forget to take your medication?

YVONNE: Sometimes.

COUNSELOR: Okay. Well, that's not surprising. Taking medication is hard to remember for a lot of people. Sometimes there are bad side effects, or sometimes it's just a bother.

YVONNE: Yeah, it's annoying.

COUNSELOR: What annoys you about your medication?

YVONNE: I don't know.

Master Clinician Note: The counselor should not leave it at "I don't know," but probe further. With a client who has an FASD, the probes should be very specific.

COUNSELOR: Does the medication make you feel bad?

YVONNE: No, not really.

COUNSELOR: Is it hard to remember to take it?

YVONNE: Yeah. I have a lot of stuff to do, ya know.

COUNSELOR: Yeah, I know what you mean. Ya know, I take a vitamin each day with my lunch. That way, whenever I eat lunch, I know to take the vitamin. They go together. Since I go home for lunch, I keep my vitamins at home on the counter, next to the 'frig. I also put a reminder in my phone so that at noon, my phone says "Take vitamin." I think we could work out a system like that for you, something easy that reminds you to take your medication that won't be annoying.

YVONNE: Okay.

COUNSELOR: Let's start by writing this down.

The counselor works with Yvonne to develop a few simple, concrete steps to help her remember to take her medication. Once back in the office, the steps are written down and then reviewed with Yvonne to make sure she comprehends them.

COUNSELOR: Does that look okay?

YVONNE: Yeah.

COUNSELOR: When did we say you should start using that plan?

YVONNE: Right away.

COUNSELOR: That's right.

Master Clinician Note: The counselor does not merely ask "Does that look okay?" but also asks a follow-up question to make sure Yvonne understands. Since this is a client that has been noncompliant with medication, the counselor also schedules another session at an early date to reinforce the new plan, rather than waiting a week or longer.

COUNSELOR: Okay, let's try this treatment plan for the next few days. I'd like to see you in three days so that we can see how it worked.

YVONNE: Okay.

COUNSELOR: I'll write all this down for you. Also, I'd like to ask that your mom help you with taking the medication. Would it be okay if I talked to your mom after today's session? The three of us could spend a few minutes discussing how she can help you remember to take your medication.

YVONNE: Yeah, that'd be okay.

COUNSELOR: I know she's picking you up today, so let's also ask if she can drop you off for your next appointment.

YVONNE: Okay.

COUNSELOR: *[Reinforcement of rapport-building].* Will you bring me a picture of Scooter and Cory? I'd like to see what they look like.

YVONNE: Sure. I'd like to see your Dalmatians.

COUNSELOR: I'll bring a picture, too. Let's program a reminder into our phones for our next appointment, with a special note to bring pictures.

Master Clinician Note: The counselor has employed a number of steps to build rapport, avoid confrontation, and simplify processes for a client that has an FASD:

- Although clinicians are trained to ask open-ended questions, this counselor made the questions quite specific. For example, when the question "How has everything been going?" got no response (it's a fairly abstract question to someone with an FASD), the counselor avoided confrontation and switched to something specific: "Have you been taking your medication?"
- The counselor never used the word "why." A person with an FASD will most likely struggle with understanding or communicating their motivations.
- The counselor limited choices to avoid overload; for example, instead of "What would you like to do?" the counselor offered a specific choice: "Would you like to walk around the courtyard, or go to the cafeteria?" This simplified the choice for Yvonne, and also changed the environment to one she likes, allowing her to share a little more easily.
- The counselor broke down the medication plan into small chunks, wrote them down, and reviewed the steps one at a time with Yvonne. If Yvonne had not seemed to be grasping the plan, the counselor could have considered reviewing it several more times, or even role-playing to solidify each step.
- The counselor scheduled a quick-turnaround follow-up visit so as not to lose valuable time if the plan isn't working, and is bringing the mother into the process as reinforcement.
- Lastly, the counselor built rapport and found a common ground around something that Yvonne really enjoys, her pets.

9. WORKING WITH AN ADOPTIVE PARENT TO CREATE A SAFETY PLAN FOR AN ADULT MALE WITH AN FASD WHO IS SEEKING LIVING INDEPENDENCE (FASD INTERVENTION)

Overview: The purpose of this vignette is to demonstrate how counselors can help develop a safety plan for clients with an FASD. This vignette focuses on creating a safety plan with a caregiver, as many individuals with FASD have someone in their life who provides advocacy and support. If there is no such person in the life of the client with FASD, an important treatment goal will be to identify persons who can fill that role.

Background: In this vignette, Mike's son, Desmond, is 21 years old, and has been diagnosed with an FASD. Mike adopted Desmond when he was five years old. Since Desmond turned 16, and Mike's wife left him (partly due to the difficulties of parenting Desmond), Mike has been Desmond's sole caregiver. Lately, Mike has become increasingly distressed about his son and life in general, and has sought counseling from a mental health provider.

We are picking up this session after Mike has mentioned that Desmond is excitedly preparing to live on his own, with the move-in date just a month away. Mike is sure his son can't handle all the responsibilities of independent living. He has tried to talk to Desmond about this, his son doesn't seem to listen or agree. Mike is realizing that there is a lot he has not talked about with his son.

The counselor took time to gather a good deal of background information. Mike is here on his own in this visit, but the counselor has met Desmond. Desmond has intellectual abilities in what is called the borderline range (just below average). Like many individuals with an FASD, he acts like someone who is younger. In the first session, when the counselor asked Mike to estimate Desmond's "acts-like" (i.e., functional) age, Mike said that Desmond still acts like someone who might be in 10th grade. As the counselor has gotten to know Desmond, this estimate seems accurate. The counselor has also carefully reviewed Desmond's Medical Summary Report (from age 11) and his latest school testing (age 20, when he graduated from high school). She now better understands his unique learning profile.

Master Clinician Note: Clinical wisdom in the field of FASD, and now some scientifically validated treatments, hold that knowing the unique cognitive/learning and behavioral profile of the affected individual is crucial to understanding the reasons for their actions. This helps to reframe caregiver understanding in light of the individual's brain-based disability.

Mike also told the counselor that Desmond was diagnosed with ADHD at age 8, which helped with an accommodations plan at school and a medication regimen. When Mike tried to transfer responsibility for taking the medication to Desmond 3 years ago, he couldn't remember to take it on his own. When Mike and Desmond's doctor realized Desmond showed no decline in function off the medications, they decided to stop the regimen. Without a clear benefit, and because Desmond could be pressured to give away his stimulants to peers, stopping the medication seemed wise.

Learning Objectives:

1. To show how to identify and validate caregiver concerns, and how to integrate common issues for individuals with FASD in safety planning.
2. To show that safety for a client with an FASD requires a plan that decreases risk, increases protective factors, and focuses on comprehensive life skills planning.
3. To illustrate how to assist caregivers as they proactively develop strategies to ensure their child's safety.
4. To demonstrate that individuals with FASD need a plan that is practical, useful, developmentally appropriate, uses concrete language and visual aids, uses role-play, and takes into account their unique cognitive/learning and behavioral profile.

Vignette Start

[The dialogue starts with the counselor meeting with Mike in an individual counseling session. The counselor requested that Mike come in on his own for this session, but expects to meet with Mike and Desmond together in at least some future visits.]

COUNSELOR: What are your greatest concerns about Desmond living on his own?

MIKE: Well, I've always been there for him, and I'm really concerned that he could get into trouble out there in the real world. He has a lot of good points, and I know Desmond's tough. We got through it when his mom left a few years back. I know he turned 21 and he's *feeling* independent, but I know that he can't *be* totally independent. There's too much stuff I help him with, all the time. But I do need some time of my own. Some days…well…there are those days that

I'm zapped—done. The truth is: I'm at my wit's end. I work my butt off. Besides that, I don't take vacations from being a parent. I've sacrificed. Don't get me wrong, I love him, but there are days…. Well, you know. I'm sorry, my head's somewhere else today.

COUNSELOR: I know how much stress parents of a young person with an FASD can be under, and how much strength it takes to parent a child with a disability, especially alone. Take all the time you need to explain what's on your mind. Sounds like there are many sides to this situation.

Master Clinician Note: Mike's thoughts are somewhat discursive due to stress, and perhaps due to grief about the challenges of his son's upcoming life transition. Creating safety protection for Desmond is an important way to help Mike, but the counselor should remain aware that Mike also has his own needs. Research shows that caregivers have many unmet family needs, often focusing on dealing with the emotional aspects of caregiving. The counselor is allowing Mike to express all sides of the situation. This includes negative feelings, but the counselor is also listening for signs of positive "expressed emotion," deemed to be a protective factor. The counselor is also thinking about how to promote caregiver self-care.

[Mike expresses his concerns for several more minutes. The counselor listens and normalizes, validates and reflects Mike's emotions and thoughts, and also makes clarifying summary comments. Providing Mike with time to express his emotions and thoughts and to have his perspective heard allows the counselor to move ahead with more skills-based techniques. These include problem-solving, identifying social supports, identifying and clarifying treatment goals, and cognitive restructuring.]

COUNSELOR: Okay, thank you. I think I have a sense of your concerns, both for Desmond and for your own situation.

MIKE: Yeah. I mean, this is one tough gig.

COUNSELOR: It is, and feeling "burned out" is natural. At the same time, if Desmond is going to be on his own to some degree, as he moves into his life as a young adult, that means a huge transition for both of you.

MIKE: That's an understatement.

COUNSELOR: The good news is that I can provide you with some strategies to help you cope, in the short-term and the long-term. The key here is that the definition of independence and safety is different for a person with an FASD or other developmental disabilities. I think it's important that we start by identifying one or more advocates or "champions" for Desmond. These can be professionals or family members; people who are willing to help him—and help you—manage various parts of his life. So, who can act as an advocate for Desmond? Who are his supports?

MIKE: I can be an advocate, first and foremost. And so can my aunt. Desmond gets along with her really well and sometimes she has him help at her law office doing filing, that kind of stuff. Also, she is one of the few people he'll talk to when he gets upset or angry, and she's good at calming him down. He also helps out with the middle school football team, so Coach Gray looks out for him, but they don't see each other much in the off-season. But…I think he would still be willing to help Des out. Yeah, I think they can help when I can't. And maybe Des can reconnect with his mom.

COUNSELOR: It sounds like Desmond has a number of advocates and supports, but that he mayneed help with both identifying *when* he needs help and, then, *how* to best communicate to get that help. I am so impressed and pleased that Desmond is involved with your aunt and Coach Gray. That gives Desmond's days and weeks more structure and meaning and more opportunities to connect socially. Everyone likes to feel useful! I bet there are more folks who can act as support persons or advocates. We'll try to figure out all those folks in our next session, and what each support person can do. To help move us along, here is the first page of a worksheet to do at home, to make a list of people you think of, their contact info, and what kinds of things they can help with.

[Shows Mike the first part of the Crisis/Safety Plan Worksheet.]

Think about family friends, any providers that work with Desmond, people who know him in his circles, like other people that help with the football team or friends from the community, kids from his high school youth group, church, anything like that. If possible, it is especially important to find someone in their 20's—more Desmond's age, who has good problem-solving skills, to be a kind of "mentor." Can you bring that back next time?

MIKE: *[Nods, takes the first part of the Crisis/Safety Plan Worksheet.]* I'll try to get it done. I don't know about that mentor idea; can't think of anyone right away. But it does help to write things down. If I don't have time for the worksheet… well, you know.

COUNSELOR: Sounds good. This may be a chance to ask your aunt and Coach Gray for ideas, too, as there may be someone that Desmond already knows that could be a good mentor. In terms of the worksheet, I will leave that to you.

Master Clinician Note: Clinical wisdom, and now some new interventions for caregivers of adolescents and young adults with FASD, such as the *Partners for Success Program* (information available through the CDC-funded FASD Regional Training Centers), hold that mentors can be very useful in intervention. Mentors can be community college students, aides who work in developmental disabilities services, younger relatives or family friends, or students studying to work in social services. A mentor is someone who can act as a very competent peer or a caregiver closer in age to the affected individual. They can build an ongoing and positive relationship, be available for check-ins to provide input and guidance on solving problems with peer relationships and lifestyle problems, and work toward helping the affected individual become more self-aware. They may also be able to connect the individual to pro-social and competent peers, and help find appropriate, positive recreational activities for leisure time.

COUNSELOR: Okay, let me ask you: Have you worked much with developmental disability services to help Desmond with life skills, how to live as independently?

MIKE: No, hardly at all. Desmond doesn't qualify for those kinds of services because of his FASD, and his ADHD diagnosis doesn't help, either. He doesn't have really low scores on his IQ test. And, you know, even though he struggles sometimes, he really tries to be friendly and sociable, and he talks a good game. Sometimes I think his good points actually keep him from getting all the help he needs.

COUNSELOR: It must be hard that others don't always see that he struggles with a lot of things. At that same time, it's good to know that he has so many strengths. Alright then, I think you and I will need to work together to identify the most

important things to think about as Desmond becomes as independent as he can safely be.

MIKE: I think my biggest concern is that others will take advantage of Des. Especially if he has a place of his own and people want to stay with him. He tends to do things like steal to be someone's friend, or fall in with wrong crowds, then it's always him that gets caught. I'm not going to be there to prevent that if he's on his own. I mean, Des is willing to accept help, and that's good, but he may not always realize he needs to ask, especially when he gets worked up.

COUNSELOR: I hear you. That sounds like a really big worry for you, so let's talk about some way to provide safety and structure for Des as he moves into having this new freedom. This will be a safety plan, basically. We'll have to find what works and doesn't work for him, and this will be an ongoing process. We can come up with an initial plan, then when he gets into his own place, we can meet together with Des a few times to modify the plan. We'll kind of be testing it out. Adjusting a plan is always a good idea.

MIKE: I've done a lot on my own, talking with Des about what is an appropriate situation and what's not. Appropriate money use. Appropriate touching. This has been all from me. No doctor or therapist helped me out. I should write a book on it. At least I got through to him about drinking, because he just tells people he's allergic, and so far, so good. But now…well, that's another worry.

Master Clinician Note: For parents of individuals with developmental disabilities, it is very helpful to be proactive. At the same time, "looking forward" is an emotional process. The clinician will have to judge how far ahead the caregiver really wants (and needs) to plan. The clinician also needs to use reflective listening and summary statements to help the caregiver process their own emotional reactions as they do future planning. Beyond this, the clinician can help caregivers plan ahead in a practical way. Because Desmond is a young adult (though functionally an adolescent), and is starting to build an independent life, the clinician can coach Mike on how to help Desmond self-advocate and self-monitor.

One important direction is to coach Mike in creating concrete, behavioral "benchmarks" for his son, so Desmond can show daily or weekly progress and also show his father that he is ready for this life transition. This could include practicing things such as buying groceries as if he were already living on his own, and/or troubleshooting, such as thinking out loud about what to do in real-life situations—e.g., if he gets sick, the toilet starts overflowing, etc. If Desmond resists doing this (which would not be unlikely given his functional age), the counselor can work with father and son to integrate rewards for Desmond after he shows certain behaviors or masters specified tasks. An age-appropriate reward for someone functioning at an adolescent level could be more 'space,' i.e., increased time between check-ins from his father after Desmond demonstrates mastery.

Mike has educated his son carefully about drinking, which is good, but he should think about other areas he needs to talk about with Desmond, as well, including 1) safe sex; 2) communicating clearly with partners about consensual activity; 3) use of cigarettes; 4) use of illicit substances, such as marijuana and other drugs; 5) the consequences of criminal activity; and 6) ideas on what to safely do when Desmond has times of feeling irritable and negative (calming strategies).

COUNSELOR: I'm glad you already laid the groundwork! For now, let's write down some of the ideas you already figured out. We'll make cards. Two kinds, actually. First,

when Des comes in we can make an identity card that says "I have an FASD" for Desmond to give to caregivers, police, co-workers, etc. Then we can make Safety Cards that he can use as reminders in his new routine. The Safety Cards can be one thing to talk to Desmond about when he comes with you to see me. We will also plan to talk about specific behavior benchmarks or things you want to see him doing before he moves out. We can talk to Des about how having him do this will let you be more comfortable giving him space and independence. *[The counselor and Mike work together to identify areas of safety concern for Desmond.]*

Master Clinician Note: Choice and level of language used on Safety Cards will differ depending on the intellectual level of the individual with an FASD. Areas of safety concern may include:

- Household reminders (buying groceries, paying bills, cleaning the apartment, taking out the trash, maintaining personal cleanliness, etc.)
- Useful phone numbers (advocates, police, hospital, primary providers, etc.)
- Transportation (routes, times, and costs)
- Work and school schedules
- Personal and household safety reminders (turning off appliances, locking doors and windows, etc.)
- High-risk behavior warnings (e.g., unsafe sex, alcohol or drug use, getting really irritable and upset)

There are programs for caregivers raising affected youth that have other useful ideas for ways to plan ahead (e.g., the *Families Moving Forward Program and Partners for Success Program*).

COUNSELOR: What else could help you with keeping Desmond safe?

MIKE: Well, I think, as long as he applies these things we're writing down for him and I check in on him regularly, things may go okay. For awhile, anyway. Then I just need to get organized with my aunt and Coach, so they're helping to keep an eye on him. Like I said, he's pretty good about accepting help and listening to us when we give him advice. That's one of the most important things I taught him—*accepting* help. But he really has trouble *asking* for help, or watching for signals that he's getting into trouble.

Master Clinician Note: Research on FASD and, more generally, on developmental disabilities has uncovered important protective factors. Many of these are well-known, such as positive family and peer relationships, appropriate social services and freedom from substance abuse by the individual, peers, or family members. Other protective factors may be less obvious but are no less important. For the caregiver, these include decreased stress and depression, a sense of parenting efficacy, positive expressed emotion and a viewpoint on the affected individual, and adequate caregiver support and self-care. For the affected individual, these include a willingness to ask for (and value) help from others, positive, time-filling extracurricular activities, adequate and refreshing sleep, connections to pro-social and competent peers, a positive self-perception, a sense of meaningfulness through activities such as a job, talents that others recognize and value, spirituality, and more.

COUNSELOR: Will Des be working?

MIKE: He's going to continue as an assistant with the football team as a volunteer. And he can keep helping my aunt. When he gets done with his training, we think he'll be able to do inventory and stocking at the grocery store.

COUNSELOR: Okay. Let's start figuring out how all this is going to work. So, I think it may make sense for you to manage Des's budget, at first anyway, by doing his shopping and grocery list-making until new routines are established.

MIKE: Yeah, I expected that. I'm gonna be checking in on him every day for as long as I need to, then less often if I'm sure he's doing okay. I made sure the apartment isn't far away, even though we have to pay a bit more. He isn't showing a real interest or understanding of all the little things required to live on your own; budgeting, or don't buy all your groceries at the gas station just because that's where you get gas, stuff like that. He can use my car if he asks permission, and tells me where he's going and when he'll be back. Mostly, he's going to be taking the bus. I can't imagine him knowing how to take care of his own car, even though he's a pretty good driver.

COUNSELOR: Clearly, you've already thought a lot of things through! Okay, so, why don't you bring Des next time? That will give me a chance to see if I think he needs the support of his own mental health counselor. With his ADHD, and times he gets irritated, that might be a good idea down the road. He has lots of supports, but we should think about this angle, too.

MIKE: That sounds like a plan. I appreciate your help, Doc. I feel like the load is a little lighter.

COUNSELOR: I'm glad. Remember—if you bring that worksheet back next time we can move forward more quickly with our plan.

Master Clinician Note: This session shows what it is like to work with the caregiver of someone with FASD. A possible future session could include Desmond's aunt and the coach, to create advocacy or "look-out" tasks they could all divide up to help Desmond stay organized while Desmond first starts living on his own. In sessions that include Desmond, the clinician will need to change pace and style. Specific ideas that would help Desmond, and can be used with most other affected individuals:

- Work with the affected individual to identify his or her goals, including how to generate an effective goal, "mini-steps" to achieve the goal, and needed supports.
- Discuss warning signs that they need help.
- Discuss and practice through role-play how to ask for help.
- Create a written Crisis/Safety Plan.

This vignette would play out differently depending on the culture and ethnicity of the caregiver and youth. Research shows there are different expectations for independence and type of family relationships in different cultures. This interacts with the impact of developmental disabilities. In some cultures, for instance, adult children are not expected to move out of the family home, though they will still increasingly assume more leadership and adult responsibilities within the family. In cultures where the extended family tends to be closer, affected individuals may have more resources and support from relatives, or a greater likelihood of available peer models to serve as caregivers or mentors. Research also shows that some protective factors may differ by culture: Attachment to and identification with the values of one's culture of origin is a protective factor for immigrant youth. Yet this can also be a risk: Data suggest that these youths may also be at higher risk for marginalization and discrimination. Recommending involvement in culturally relevant and pro-social leisure time activities can be a productive way for an individual with an FASD to learn about their own culture.

10. WORKING WITH A BIRTH MOTHER TO DEVELOP STRATEGIES FOR COMMUNICATING WITH A SCHOOL ABOUT AN INDIVIDUALIZED EDUCATION PLAN FOR HER DAUGHTER WHO HAS AN FASD (FASD INTERVENTION)

Overview: This vignette illustrates how a social worker can make useful suggestions for a parent or caregiver's first meeting with educators at the beginning a new school year.

Background: The start of the school year is 2 weeks away. Denise is a birth mother who is meeting with a social worker to get some advice on how to educate the school staff about working with her daughter, Elise, who is 11. Elise has recently been identified as having an FASD, although she has been tested as having a "normal" IQ and is in a mainstream learning setting. This social worker was part of the diagnostic team that assessed Elise for FASD, but this is her first time helping with Elise's school issues. Denise is hoping to develop learning strategies that she can discuss with the school staff in an Individualized Education Plan (IEP) meeting.

Learning Objectives:

1. To describe typical challenges that children with an FASD may face in the classroom.
2. To demonstrate how collaboration and creativity can lead to accommodations that result in improved outcomes for a child with an FASD.

Vignette Start

DENISE:	Now that we're gearing up for a new school year, with a new teacher who is also new to the school, I need some tips on talking to her. I want to avoid last year's fiasco with the parent aide who complained that Elise was disrespectful and "the worst."
SOCIAL WORKER:	This will be 6th grade for Elise this year, correct?
DENISE:	Correct.
SOCIAL WORKER:	And what happened last year?
DENISE:	The parent aide was a nightmare from the get-go. I had heard it all before: "Your kid won't listen" or "Your kid isn't motivated" or "Your kid *never* does her homework." I knew this aide was gonna be a problem, but I couldn't be in the classroom because I was working full-time. Poor Elise got in trouble day after day for the same stuff; homework not completed, late to class, missing class, getting in fights. Honestly, I think the parent aide did not get any insight into FASD from the teacher at all.
SOCIAL WORKER:	That's unfortunate, but not uncommon, as you know. Educators will sometimes relate differently to a birth mother than they do to adoptive or foster parents. We've talked about those issues before, and it is something that may come up again.

Master Clinician Note: Whether intentional or not, the birth mother of a child with an FASD can be perceived negatively by others, including educators, for having "caused" her child's disorder. The social worker is gently preparing Denise for this possibility and reinforcing the positive nature of how she advocates for her child.

DENISE: I know. I've been there.

SOCIAL WORKER: Well, it's important to remember that you're a fantastic mom, dealing with issues that not many people would have the courage to handle. You're open and willing to learn, to educate yourself about what will work best for Elise, and she is successful because of all the love and support you give her.

DENISE: Thank you, I appreciate that. When I set up the meeting, do you think you can attend with me?

Master Clinician Note: If the social worker cannot attend an IEP meeting with the client, they should still encourage them to have a support person with them, if at all possible; someone else who is familiar with the caregiving situation.

SOCIAL WORKER: I won't be able to attend with you, unfortunately, but I absolutely suggest that you bring someone with you to all meetings. I recall that your sister-in-law has helped out a lot. Is she available, or a good friend?

DENISE: My sister-in-law is the best, yeah. She'd be a great support. She knows the questions to ask.

SOCIAL WORKER: Great. We'll come up with the suggestions and strategies, and you and Elise and your sister-in-law can talk and jot down any additional key issues that you think of. Definitely include Elise. It's her education, after all. Will she be part of the meeting with the school?

DENISE: We weren't planning to include her in the actual meeting, no. She wasn't in it last year. We do talk to her about the issues, though.

SOCIAL WORKER: Well, she's at an age now where it might be worthwhile to consider including her. She's in middle school now, and at this age it might be beneficial to her to see how caring people are planning her supports. Plus, it teaches her to self-advocate, and she can offer specific information and suggestions about problems she's having, or environmental issue that are bothering her; lighting, noise, etc.

DENISE: Okay, we'll talk to her about joining us.

SOCIAL WORKER: Great. And you're meeting with her teacher only? Are there any volunteers in the class this year?

DENISE: I'm not sure.

SOCIAL WORKER: You might wanna ask. If there are volunteers, it would be great if they can attend, as well.

DENISE: Okay.

SOCIAL WORKER: And be sure to allow enough time in the meeting to discuss concrete solutions. Accommodations can take a lot of time to work out. It shouldn't be left to the end of the session.

DENISE: I'll try to address them right up front. What suggestions do you have?

SOCIAL WORKER: I have a couple suggestions for the meeting itself, and then some examples of free, simple accommodations that can improve Elise's school experience. These go beyond the stuff on a standard IEP form. You did a plan last year, correct?

DENISE: Yes, we did.

SOCIAL WORKER: And she'll be in the same school?

DENISE: Yes.

SOCIAL WORKER: Okay, good. So there's already a record with the school of an accommodation history.

DENISE: Right. And it really is just frustrating to have to do this every year. I'm always surprised that one teacher can be great and the next is like a blank slate.

SOCIAL WORKER: I find that, as well. Many families have to start over every year with the school, transferring information, as school personnel changes each September. At the same time, the child is growing and changing, too. Elise is growing older, and what worked for her last year might need to be revised this year. Also, the accommodations in last year's plan might not have been implemented, at least not fully. Elise can speak to that if she's in the meeting. So, let's go through a few simple things that I've found have worked for other clients and their children.

Master Clinician Note: Denise is clearly frustrated with the educational process, and this is understandable. At the same time, the social worker is tempering this frustration and laying the groundwork for a more successful IEP meeting by helping Denise remember the reasons why annual meetings are worthwhile even if difficult. For the meeting itself, the counselor makes the following suggestions:

- To spotlight the child's aptitudes and hobbies, bring pictures of the child enjoying these activities and/or examples of things they've done or created (e.g., artwork, crafts).
- Parent should be encouraged to "catch more flies with honey than with vinegar." The parent's frustration with the system as a whole should not be targeted at the individuals on the other side of the table.
- Parent should approach the meeting with a mindset of using statements such as "My child needs…" rather than "I want my child to..." The federal law is for educators to meet the child's needs, not the parent's wishes.

DENISE: I like those ideas, thanks. What accommodations were you thinking of?

Master Clinician Note:

- Example 1: Federal law limits schools in terms of sanctioning children who act out as a result of a disabling condition, such as an FASD. If the child is acting out, a Behavioral Modification Plan should be considered instead.

SOCIAL WORKER: This first example is really important because I see so many kids with FASD who get into trouble when they're revved up. As a parent, you probably see this often with Elise, and you know her triggers, but educators won't. I worked with a middle-school-aged child, a boy, and his caregiver. The boy was acting out, hitting the bus driver. The school threatened to get the police involved, and the boy was kicked off the bus. I suggested that he be given time at end of each day to relax. It turned out that one of his favorite places was the library, because he could listen to music, so he ended up being able to use last period to go there and sit with headphones on, and we arranged with the librarian to keep an eye on him and monitor the time for him. We called it his "chill zone." After that, he was always cool for the bus ride home.

DENISE: I like that. Elise gets antsy very easily, especially with headphones on, but she'll sit still to read and draw. The library might work.

Master Clinician Note:

- Example 2: Watch for cases when bad behavior is a result of modeling other children with behavioral issues.

SOCIAL WORKER: Another student I worked with, a girl, was getting out of control during the day. She sat in the front row of her classroom, but the teachers and classroom volunteers still reported that even on a good day she was fidgety, and on bad ones she was practically climbing the walls. I explained that sitting in the front row typically helps children focus, but a child with an FASD can also get distracted by kids nearby. In the girl's class, the rest of the kids in the front row were working on behavioral issues, including ADHD. In this case, the girl was modeling the behavior of these classmates in an effort to make friends. I suggested we move the girl next to a model student who could maybe be her buddy or mentor, and that worked well.

DENISE: That could prove useful, as well. Elise does tend to model other children's behavior.

Master Clinician Note:

- Example 3: Work with the educational staff to think "outside the box" when it comes to accommodations.

SOCIAL WORKER: Educators are generally working from a menu of options when it comes to accommodations; such-and-such is suggested based on what the child's condition is. Now, this menu is fairly long, as you know, but it's still an Individualized Education Plan. It should still be geared to Elise's specific needs. Don't be afraid to suggest ideas that you've found work for her, even if they aren't "on the form." Think about what you've done with her in other environments, like at church or in other social activities.

DENISE: Okay. Thanks for your suggestions.

SOCIAL WORKER: You're welcome. Please call me after the meeting and let me know how it goes.

DENISE: I will, thank you.

Refer to Part 1, Chapter 2 for additional guidance on educational accommodations for individuals with an FASD who are still in school.

Part 2: Administrator's Guide to Implementing FASD Prevention and Intervention

Introduction

This Treatment Improvement Protocol (TIP) is designed to assist not only substance abuse treatment and mental health counselors in providing FASD-informed services, but also the clinical supervisors and administrators who support the work of these professionals. The need for a TIP that addresses FASD prevention and intervention for these settings is clear:

- Individuals with an FASD experience higher rates of substance abuse and mental health issues than the general population (Streissguth et al., 1996; Streissguth & O'Malley, 2000; Astley, 2010). In addition, individuals with an FASD exhibit higher rates of life problems commonly encountered in substance abuse and mental health treatment populations, including higher risk of suicide (Huggins et al., 2008), exposure to multiple traumas throughout the lifespan (Henry, Sloane, & Black-Pond, 2007; Greenbaum et al., 2009), homelessness (Fryer, McGee, Matt, Riley, & Mattson, 2007), and increased interaction with the criminal justice system (Streissguth et al., 1996).
- According to the 2009 *National Survey on Drug Use and Health* (NSDUH), 17.1 percent of women age 18 or over in the U.S. received mental health treatment or counseling in 2009, compared to only 9.2 of men in the same age group (Center for Behavioral Health Statistics and Quality [CBHSQ], 2010), while the *Treatment Episode Data Set* (TEDS) indicates that 33.0 percent of admissions to substance abuse treatment facilities in 2011 were female, more than half of whom (50.5 percent) indicated alcohol as a primary, secondary, or tertiary substance of abuse (CBHSQ, 2013). In addition, an in-depth study of 80 birth mothers of children with FAS revealed that 97 percent had from 1 to 9 mental disorders, and the subset that successfully achieved abstinence was significantly more likely to have received treatment for their mental disorders than the subset who did not achieve abstinence (Astley et al., 2000b).

Thus, these settings are 1) likely to see a high prevalence of individuals with an FASD (and/or their parents/caregivers), and 2) provide an ideal environment for conducting interventions with women of childbearing age to prevent additional incidences of FASD.

The methods and techniques presented in this TIP are appropriate for clients in all stages of recovery and treatment. However, this TIP is not meant to create a 'one-stop shop' for FASD-informed services. An FASD is not a simple category that can be addressed with a simple, categorical response; the disorders in this spectrum cannot be cured, and clients

with an FASD need specialized treatment from a variety of healthcare professionals to function at their maximum potential. At the same time, when treating a substance abuse or mental health issue with a client, the counselors' role is to:

1. Be able to recognize when a client is exhibiting a co-occurring issue (such as an FASD) that can impede treatment success;
2. Address how the physical, cognitive, and behavioral manifestations of that issue interact with treatment; and
3. Develop a collaborative treatment relationship with the other healthcare and social service professionals who do—or potentially can—provide assistance to the client to maximize that person's potential for success, both in and outside treatment.

Like any other co-occurring issue in treatment—trauma, homelessness, etc.—addressing FASD is a fundamental step toward helping the *whole* person and ensuring that he or she does not encounter treatment barriers.

Note: This Implementation Guide follows two tracks; FASD prevention, and FASD intervention. This is because this TIP promotes 1) the screening of all women of childbearing age (whether pregnant or not) in all behavioral health settings for alcohol consumption, to help prevent future incidences of FASD [FASD prevention], and 2) the development of staff skills in recognizing individuals who have or may have an FASD, to be able to more effectively tailor treatment to their needs [FASD intervention]. In Part 1 of this TIP, these topics are treated separately. In the Implementation Guide, they are discussed together, since they each represent organizational change and the core processes involved in making such changes within a program overlap significantly.

1 The Administrative Response to FASD in Behavioral Health Settings

IN THIS CHAPTER

Why SAMHSA Created an Implementation Guide as Part of This TIP

Part 1 of *Addressing Fetal Alcohol Spectrum Disorders (FASD)* provides the tools your clinicians need to begin addressing FASD prevention and intervention with clients. However, an extensive literature review suggests that without specific attention to implementation issues, these tools are likely to go unused or to be used ineffectively (Fixsen, Naoom, Blase, Friedman, & Wallace, 2005). This Implementation Guide will help you ensure that the ideas in Part 1 are put into practice in your program or agency in a way that creates value, both for your agency and your clients. Implementation will require the active support of executive administration and the expertise of clinical supervisors.

Much of the guidance provided in this Implementation Guide will be familiar to readers of TIP 48, *Managing Depressive Symptoms in Substance Abuse Clients During Early Recovery* (Center for Substance Abuse Treatment [CSAT], 2008). TIP 48 provides a useful framework for approaching organizational change, and a significant portion of that framework is reiterated here, but with some important modifications and "tweaks" that are essential to providing FASD-informed services. Another useful resource is SAMHSA's Technical Assistance Publication (TAP) 31, *Implementing Change in Substance Abuse Treatment Programs* (CSAT, 2009).

Why Address FASD Prevention and Intervention?

The value of screening women of childbearing age in behavioral health settings is clear-cut. For any woman who is or may

become pregnant, protecting the health of that pregnancy (or potential pregnancy) is a fundamental health issue for the woman herself. Added to this, alcohol consumption questions are built into most forms of health screening, making exploration of this issue a professional commitment. If pregnant women are part of your client base, ignoring this issue means not fully serving the client.

The case for providing services tailored to individuals who have or may have an FASD may not be as simple, but is equally compelling. The historical perception that an FASD represents permanent brain damage, and thus these people cannot be helped in a mental health or substance abuse treatment setting is only half true: Yes, an FASD *does* represent permanent brain damage; no, it *does not* mean that these people cannot be helped, any more than being homeless or involved with the criminal justice system means an individual cannot be helped in these settings.

An FASD is a co-occurring disorder, and needs to be approached from that perspective. Families are seeking this expertise, even if they don't yet know to call it 'FASD,' and clients in need of FASD-informed services will continue to appear in your settings. There is an active movement in the mental health field toward a recovery focus and a strengths-based focus, toward meeting clients "where they are." This movement is growing in the substance abuse treatment field, as well, as are the trauma-informed and family-centered care movements. An individual who has or may have an FASD fits perfectly into any of these paradigms. Individuals with an FASD *do* want to recover, whether in substance abuse or mental health treatment; they *do* have strengths; they *do* experience trauma (at higher rates than the general population); they *do* have families; and, as with any other client, they *are* capable of responding positively when treatment is tailored to their unique needs.

The Effects of FASD on Recovery

At the same time, it cannot be ignored that clients with an FASD are likely to experience challenges to successful treatment above and beyond those experienced by clients who do not have one of these disorders. The client with an FASD may have difficulty in any or all of the following areas:

- Remembering program rules or following multiple instructions.
- Remembering and keeping appointments.
- Making appropriate decisions by themselves about treatment needs and goals.
- Appropriately interpreting social cues from treatment professionals or other clients.
- Attending (and not disrupting) group activities.
- For those accessing substance abuse treatment, staying substance-free after treatment.
- Interpreting or understanding complex meanings of language or information.

The combination of some or all of these factors may lead a counselor to assume that an individual with an FASD is resistant to treatment (and this assumption is often made). It is essential that staff be able to discriminate between a symptom of an FASD and actual treatment resistance. Clients with an FASD may fully intend to be compliant with treatment and want to do well in recovery, but lack the skills and understanding from the provider to help them meet their unique challenges while participating in a recovery program.

The Benefits to Your Program of Addressing FASD Prevention and Intervention

A growing body of evidence is demonstrating that interventions with individuals with an FASD can be effective, that this population can and does succeed in treatment when approaches are properly modified, and that

these modifications can lead to reduced stress on family/caregivers as well as providers (Bertrand, 2009). Moreover, in a study of 1,400 patients with prenatal alcohol exposure, Astley (2010) found that 9.3 percent presented with no central nervous system (CNS) dysfunction, despite alcohol exposure levels as high as the 10 percent that did receive a diagnosis of FAS. The one factor that significantly differentiated the children with no CNS dysfunction (no evidence of learning or behavior problems) from those with full FAS was a stable, nurturing home environment *with intervention services*.

Addressing FASD also has the potential to enhance the treatment experience for both the individual with an FASD and those around him or her, increase retention, lead to improved outcomes, reduce the probability of relapse, increase engagement rates in aftercare services (alternately referred to as recovery support services), and reduce overall societal costs. In addition to the benefits for the client, addressing FASD as part of your program can potentially lead to increased clinical competence of your staff, an increase in appropriate referrals, increased staff retention, higher levels of staff satisfaction, reduced risk of burnout, and reduced turnover.

Addressing co-occurring disorders is also a key priority for the federal government, state governments, insurance companies, credentialing boards, and accrediting organizations. By starting now to address FASD, you will be better positioned to compete in the future treatment marketplace. Ideally, your agency can become part of the larger community of research practitioners who seek the best ways to help clients more quickly experience a higher quality of recovery. By joining with other agencies in your network, you can coordinate treatment practices and perhaps collaboratively obtain research grants. Many effective treatment practices in both the substance abuse and mental health fields, as in the field of approaches to FASD, are not yet validated through research because agencies do not fully realize the value to the greater treatment community of their unique approaches. However, the body of research around FASD is growing rapidly, and addressing FASD now positions your agency at the front end of an emerging skill area.

Most importantly, addressing FASD provides another possible route to success with a client. Individuals with an FASD are a largely hidden population, yet one that is at an increased risk of presenting in your treatment setting. For every client that did not return for additional appointments, or seemed noncompliant or resistant with no clear explanation of why, or just didn't seem to 'get it,' **a knowledge of FASD on the part of your staff can be the one additional clue that solves that puzzle and enables success for both the client and the program**.

Thinking About Organizational Change

If you have decided to implement some or all of the recommendations in *Addressing Fetal Alcohol Spectrum Disorders (FASD), Part 1*, you, your staff, your clients, and the other agencies and organizations with which you interact may require the development of new treatment protocols and policies, as well as new clinical knowledge, attitudes, and skills. These changes can be rewarding and/or frustrating. Any change in services or approaches to clients will call for a significant change in organizational culture, but will be beneficial to client well-being in the long run.

The box "Key Elements of Assessment and Planning" summarizes the key elements of organizational assessment and planning for change, topics that are discussed in greater detail in Chapter 2 of this Guide.

Key Elements of Assessment and Planning

The following five areas are critical to organizational assessment and change planning.

Current status of the organization relative to targeted change goals	Current practices, staff and administrator competencies, policies and procedures, facilities, etc., will need to be evaluated. These are similar to client assessments that determine the nature and scope of a client's issues and challenges as well as their strengths and assets.
Past experiences with change initiatives	Just as a bad experience in a previous treatment program may color a client's perception of a new program, old experiences with organizational change may affect attitudes toward new efforts. A thorough review of organizational history of change is critical to planning new organizational change.
Ongoing assessment	As in treatment, assessment is not a one-time activity, but rather an ongoing process that includes regular feedback and adjustment of your plans for organizational change and your approaches to facilitating change.
Stakeholders of all kinds	Involve as many clients, stakeholders, and community resources as possible (e.g., boards, staff, funders, clients, community representatives, 12-Step groups). These groups function best when they feel involved, and have a key role in determining how to make the recommended changes work best in daily practice (particularly staff). In addition, the plan should speak to what these groups want and what motivates them for the change: If your staff desires professional growth opportunities, change aimed at providing FASD-informed services can be linked to expanding staff capabilities. Similarly, your board's concern with expansion might be tied to the need for increased capacity if the organization is to address FASD among clients.
Clinical supervision	No stakeholder is more important than the clinical supervisor commissioned to implement the clinical mission and vision of the administrators. This individual's challenge is to help clinicians maintain a high level of best practices, to oversee the application of these practices, and to conduct process and program evaluation for quality control. Supervision should be more instructive and less crisis-driven—proactive rather than reactive—by using such strategies and resources as: • Innovative methods including live, in-session supervision, role-playing, taping, and group and peer supervision; • Regularly scheduled, ongoing clinical supervision; • Checklists and fidelity scales; • Quality skills training; and • Counselor mentoring.

An excellent resource for organizational assessment for change is the Program Change Model discussed by Lehman, Greener, & Simpson (2002; **http://forces4quality.org/sites/default/files/Tool2.1Lehman_Assessing_Agency_Readiness_for_change.pdf**), and its accompanying survey, Organizational Readiness for Change (**http://www.ibr.tcu.edu/pubs/datacoll/Forms/orc-s.pdf**). Their model addresses strategies and tools for assessing institutional and personal readiness and outlines the stages of the transfer process.

Ultimately, the application of these elements may suggest that the best decision is to delay attempting a change and focus instead on organizational climate and readiness. Introducing organizational change before the groundwork has been laid—much like introducing change to a client when they are not at the right stage of readiness—can hinder later change opportunities. However, if you decide to move forward with a change plan, the box "Key Principles of Implementation" provides information on implementation.

Key Principles of Implementation

Principles for implementing the change plan are directly analogous to principles of treatment and recovery in that both are achieved in steps, making it a process rather than an outcome. The following principles of managing change are directly adapted from principles of care that are relevant to providing effective FASD-informed services.

There is no single model or approach to providing FASD-informed services, or for implementing a program of organizational change.	A preconception about how change should occur or inflexibility during the change process is likely to be counterproductive to meeting a client's treatment goals or a program's change goals. Constant vigilance and course corrections will be needed, and should be made in consultation with the same stakeholders who developed the original change plan. Periodic focus groups or meetings with staff, clients, and administration provide excellent opportunities for feedback and give all those involved a voice in the process.
A belief in your organization's ability to accomplish the change plan is fundamental.	As with counselors, an administrator's belief that change can happen (and the ability to communicate that belief) is a central component of the change process.
The change program for an organization should be individualized to accommodate the specific needs, goals, culture, and readiness-for-change of that organization.	Like any treatment plan for an individual who has or may have an FASD, it is critical to adapt and 'personalize' the plan to fit specific organizational needs and culture.
It's about maintenance.	After implementing an organizational change plan, maintenance of the changes is essential, particularly in the first year or two. Flexibility around incorporating staff and client recommendations is critical to buy-in of the change. Newly learned practices and procedures are fragile and will tend to drift. In addition, organizational change almost always brings about some degree of personnel change, which requires up-front planning for the selection and integration of new employees. Equally important, unforeseen barriers may arise. Regular supervision and training boosters are the best insurance that behavior change will last over time. Even when the changes are institutionalized, however, a commitment to continuous quality improvement will help ensure your program's ability to respond to ongoing changes in the needs of your client population and community.

The Challenges of Implementation

Any approach to organizational change should assume that resistance may challenge the process. Specific to FASD, some of the usual forms of staff resistance you may encounter are included below, along with suggested responses that may help staff members to see the change process in a more positive light.

It is also useful to remember that resistance can be valuable to a change effort, as it often springs from legitimate needs and/or concerns. By rolling with resistance, you can identify aspects of your change plan that warrant revisiting or revising.

At the same time, failure to implement new clinical practices often has little to do with resistance to change on the part of staff.

> ***Addressing resistance directly will lessen the likelihood that opposition will spread and influence others.***
>
> - ATTC *Change Book,* 2nd Edition, p. 27

Failure to implement can be a result of issues such as inadequate modeling from administration, lack of follow-through, inadequate training, and many others. Even the best

Resistance	Response
I haven't learned this. When will I have time to do the training?	All changes in programming require new learning, and FASD will be no exception. However, new learning means new and expanded skill sets, which can positively impact professional development and advancement. I will work with you to adjust your caseload so that the training is possible.
How can I tell a pregnant mother not to drink? Her OBGYN/doctor says it's okay.	It is true that some doctors still suggest that the occasional drink is okay. However, the SAMHSA FASD Center for Excellence Web site (**www.fasdcenter.samhsa.gov**) contains evidence-based materials that we can use to communicate the "no safe level" message with clients.
The mother is choosing to harm her baby.	Many women are unaware of the risk of alcohol consumption during pregnancy (see previous statement). In addition, half of all U.S. pregnancies are unplanned, so the mother may not realize the potential harm she's doing. Lastly, if the mother has a problem with alcohol, her 'choice' to drink is no more a choice than it is for any other individual in substance abuse treatment.
How do I adjust this cognitive abstract program for someone who does not have the ability to understand abstract concepts?	You don't have to abandon the techniques you generally use. The FASD training will show you how to modify treatment for these individuals within the framework of your usual treatment approaches.
Why am I making exceptions for this client and not for others? This will require ongoing modification of the treatment plan.	It is better to see modifications to the treatment plan as tailoring rather than 'making exceptions,' as tailoring and ongoing modification are a necessary part of meeting clients where they are.

counselors and administrators are highly constrained by the contexts in which they work. Accordingly, implementation success requires administrators to 1) be proactive in making the new practice fit the context, and 2) create an organizational climate that encourages and supports implementation.

These two tasks are intertwining: Fitting new practices to your context requires a thorough review of your agency's current operations. Such self-examination, in turn, helps create an organizational climate of openness to new ideas and experimentation. Before implementation begins, it is important to create positive expectations among staff. Investing the time to educate staff, express support for the specific implementations, and explore potential barriers and concerns with staff can go a long way toward creating an environment of operational transparency and ensuring staff acceptance of change, especially in the early stages.

Often, the executive staff faces more immediate resistance or ambivalence because the initial groundwork was not done. Moreover, administrators have likely considered the change ideas for some time and expect staff to be at a similar level of enthusiasm and commitment to the proposal. Change is easier to make when those involved:

- Understand why the change is needed and the benefits they will realize;
- See how the new ways will integrate into and honor what has been done previously; and
- Are given motivation strategies for providing ideas and offers of assistance in implementation.

Maximizing the Fit

For a clinical innovation to take hold, it must fit with:

(1) Key characteristics of your target population and community (e.g., values, expectations);
(2) The skills, licensures, certifications, and team structures of your staff;
(3) Your program or agency's facilities and resources;
(4) Your policies and practices;
(5) Local, state, and federal regulations;
(6) Available interagency networks (e.g., needed outside resources, memoranda of understanding); and
(7) Your reimbursement procedures.

Certain kinds of mismatches will impede change. For example, no one would expect successful implementation of an innovation when staff lacks the skills to perform it. However, something as seemingly trivial as a lack of appropriate space or needed audiovisual equipment can also stall an innovation. As with many endeavors, the details are critical.

It is likely that adjustments will be needed both in your agency or program's context and in the ways that the recommendations presented in Part 1 are implemented. Part 2, Chapter 2 of this TIP provides procedures, checklists, and other tools for assessing the fit between the recommendations provided in Part 1 and your program or agency's current context, procedures, and so on. Useful though these materials are, your ultimate success in "maximizing the fit" will depend on creativity, problem-solving skills, and determination and patience in applying them.

The Stages of Organizational Change

Change in a program, just like change for a client, occurs in stages. In the early stages of implementing the recommendations in Part 1, organizations will profit from a climate that promotes:

- A willingness to take risks and try unconventional approaches;
- A willingness to tolerate some ambiguity as the fit between new practices and context evolves;

- An ability to recognize false starts and to abandon approaches that are not working;
- Transparency and inclusion when pursuing change; and
- Appreciation and reward for ideas and implementation.

As noted earlier, the later stages of implementation will be facilitated by:

- A commitment to continuous quality improvement;
- The development of structures that support and reinforce the change (e.g., standardized training for new staff, and continuing education and supervision for all staff);
- Expressions of organizational pride in accomplishment; and
- Institutionalization (in which new practices become everyday practices).

The Role of the Administrator in Introducing and Supporting New Clinical Practices

Chapter 2 of this Implementation Guide presents the tasks you will need to accomplish to implement the changes elaborated in Part 1. Important as these tasks are, successful implementation will ultimately depend on the leadership you provide as they are carried out. The box, "Key Elements of Leadership," provides a summary and leads directly into the more detailed discussions of Chapter 2 of this Implementation Guide.

Key Elements of Leadership

Commitment	If you and your administrative colleagues are not fully committed to making your agency's services more FASD-informed, meaningful change is unlikely to occur. In many ways, attempting change without the commitment of organizational leaders can be worse than no attempt to change at all. Staff will eventually "figure it out" if leaders are only giving lip-service to a new idea. This perception will undermine the current attempts at innovation and may lead to a staff that is reluctant to try new ideas.
Vision	Leadership means having a vision of how the organization will change. This vision should include explicit goals and a clear statement of how conflicts with other organizational goals will be resolved. However, a vision is more than a list of goals. It is a picture of how the organization will look when change has been accomplished—a picture you must paint with words. Developing this vision and the means to communicate it throughout an agency requires effort.
Knowledge	Leadership should include skilled and competent clinicians trained in mental health and/or substance abuse treatment who can direct and supervise services for clients with FASD-related issues. These clinicians should know and appreciate the specific roles that can be played by speech-language pathologists, occupational therapists, licensed social workers, psychologists, physicians, and other behavioral health professionals that are part of a comprehensive network of care for individuals who have or may have an FASD. They should also have an appreciation for the role that FASD can play in interfering with treatment.

Inspiration	Inspirational leaders communicate confidence in the organization's ability to change, enthusiasm and optimism about the change process, and an unwillingness to accept failure. This must be communicated to all stakeholders including current and potential clients, funders, board members, staff, community leaders, community 12-Step participants and programs, and sister agencies. Inspiration not only is a process of oral and written communication, but also involves modeling the attitudes and values you want staff and other stakeholders to adopt. Inspiration also involves getting your hands "dirty;" struggling alongside staff in the day-to-day tasks of making new ideas work.
Appraisal	Finally, leadership means an ongoing and honest appraisal of progress. As noted above and discussed further in Chapter 2, implementing the recommendations from Part 1 of this TIP will require ongoing assessments of progress, including regular formative evaluation of process and outcomes. Periodic reports on how the organization is doing can and should be developed from the assessments and evaluations. These reports should be shared with staff, as should plans for corrective action (when needed). The most effective leaders frame both good and bad news in a positive light; e.g., emphasizing the learning value of challenges and setbacks and reminding staff that it is the organization as a whole, rather than any individual, that is responsible for making change happen. This means that "we still have room to improve" is preferable to "you still have room to improve."

2 Building an FASD Prevention- and Intervention-Capable Agency

IN THIS CHAPTER

Introduction

The resources presented in this chapter have been organized into those related to organizational assessment and those related to planning and implementing organizational change. The change process in your agency or program will require creative and thoughtful adaptation and application of these resources to your specific circumstances. They should be viewed as points of departure only. You should revise or otherwise modify the materials as needed for your organization.

You may also wish to consult with colleagues who have managed organizational change in organizations similar to yours. At this point in the development of implementation strategies for human services, many excellent ideas are still to be found outside the published literature. Your colleagues may have insights or ideas that are equal to or more applicable than those presented in this Implementation Guide.

The *Change* Book, produced by the Addiction Technology Transfer Center (ATTC) Network, provides the basis for the organizational change process presented in TIP 48 and in this TIP. The page numbers referenced in this chapter refer to the Second Edition, 2010, which can be downloaded for free from the ATTC Network (**www.attcnetwork.org**) in English or Spanish (**http://www.attcnetwork.org/explore/priorityareas/techtrans/tools/changebook.asp**).

Additionally, you may wish to consult *Implementation Research: A Synthesis of the Literature* (Fixsen et al., 2005; **http://cfs.cbcs.usf.edu/_docs/publications/NIRN_Monograph_Full.pdf**). This monograph provides a valuable summary of the scientific basis for various implementation practices.

Another resource is SAMHSA's TAP 31, *Implementing Change in Substance Abuse Treatment Programs* (CSAT, 2009).

Assessment and Planning Before Implementation

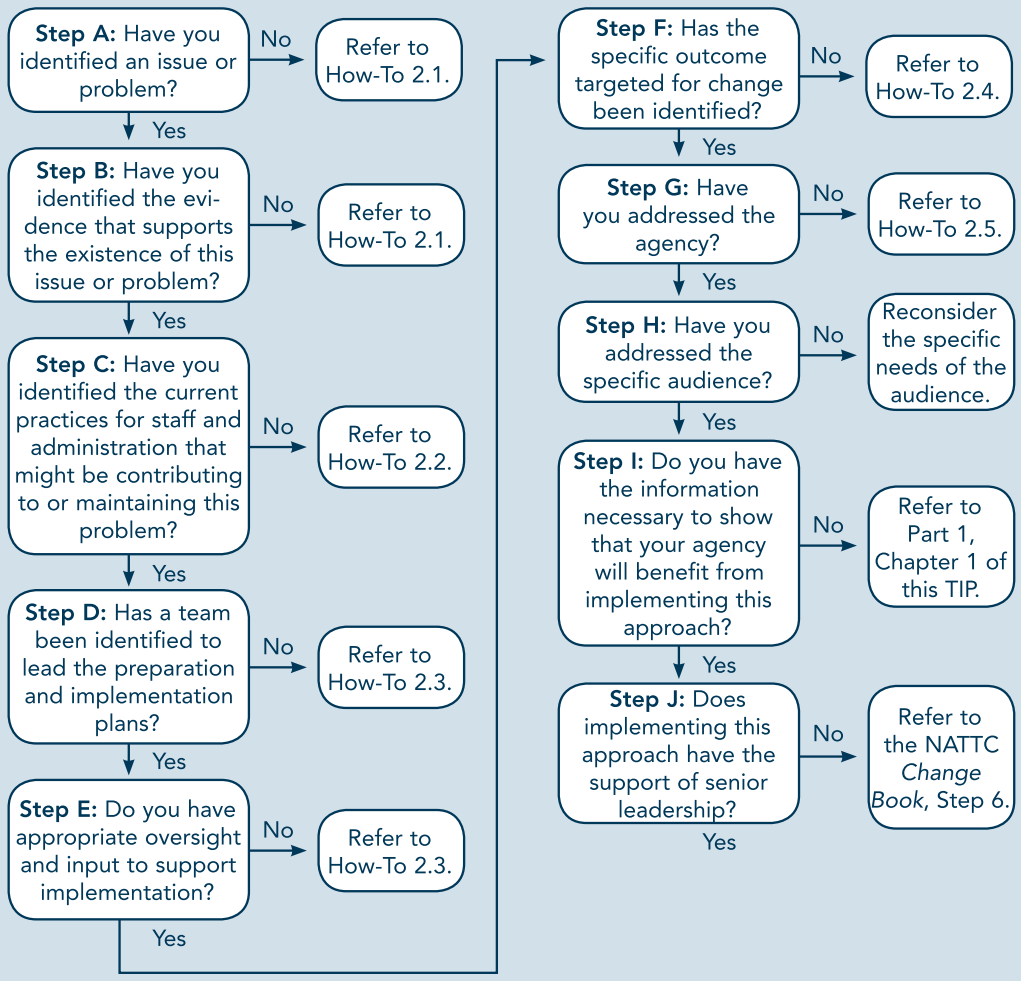
How Do You Decide Whether to Implement a Policy for Addressing FASD?

To determine whether it makes sense for your agency to implement the recommendations made in Part 1 of this TIP, refer to Figure 2.1.

How Do You Identify the Issue or Need?

The How-To components on the following pages provide ways to operationalize the steps presented in Figure 2.1.

Figure 2.1: Decision Tree
How to Decide Whether to Implement a Policy for Addressing FASD



Each of the steps in this figure tie to the How-To's throughout this chapter. (For instance, Steps A and B tie to How-To 2.1, below.)

How-To 2.1: How to Identify the Issue or Need (Figure 2.1, Steps A and B)

Research suggests that the following issues or problems may be relevant to your agency's treatment outcomes. Think about the three levels where change can occur (i.e., program/organizational, practitioner/counselor, and client/patient) when considering the following steps. Also, begin thinking about the part of the agency where you may want to implement changes first (for more information, see also the section *How Do You Decide Where To Start?* later in this chapter).

1. Individuals with an FASD are at higher risk for substance abuse and mental health issues. Determine whether clients who have or may have an FASD are being identified and effectively treated in your agency (see How-To 2.2).
2. People who present with FASD symptoms may take longer and/or require different guidelines and rules to benefit from treatment. Determine whether this is an issue for your agency. Does your program offer the option of longer treatment stays to clients who may have an FASD? Does it offer alternatives to standard policies (e.g., zero tolerance rules) for such clients? If not, how is this need addressed? What practices may need to be changed?
3. Unrecognized symptoms of an FASD result in poorer substance abuse treatment outcomes. Determine whether a goal for your agency is to improve retention rates of clients with an FASD. Determine whether a goal for your agency is to more effectively reduce the number of barriers experienced by these clients.

One aspect of the identification process is to assess the organizational capability of the agency to implement or augment a program for services to clients with an FASD.

How Do You Assess the Capacity of the Agency to Provide FASD Prevention and Intervention?

Individuals with an FASD may see themselves as not fitting in, may be hostile or act out, and may struggle with multiple directions and tasks. Is this addressed in your treatment program? For example, are people failing to make appointments with no clear explanation of why? Speaking at the wrong time during group sessions? Or consistently completing only a portion of the treatment tasks they're given? In terms of prevention, is your program serving pregnant women and/or women of childbearing age? Are these women being asked about their alcohol consumption? Are they being made aware of the risk of FASD? Assess the current capacity of your agency

How-To 2.2: How To Assess Current Capacity to Address FASD (Figure 2.1, Step C)

For each program setting consider the following questions:

1. Has a needs assessment been done to determine the needs of both the clients and the agency?
2. If FASD prevention and intervention have been identified as areas of need, are they adequately addressed in treatment plans?
3. Have key personnel looked into the literature on FASD intervention methods? Are appropriate interventions planned to treat signs of an FASD?
4. Are the FASD prevention and intervention methods already in use (if any) effective with the program's clientele?

5. Are the treatment teams interdisciplinary (e.g., psychiatrist, nurse, licensed master's level clinicians, certified counselors, clinicians, and counselors in training)? If not, your agency can still address FASD through interagency collaboration.
6. Does the supervisory staff have the knowledge, skills, and attitudes necessary to supervise or coach the line staff in addressing FASD?
7. Does the program have referral or consultation relationships with the necessary agencies and professionals (e.g., trained and licensed physicians, physical therapists, occupational therapists, neuropsychologists and speech language pathologists, prenatal care, FASD evaluation/diagnosis teams or agencies)?

Note: For more information on assessing capacity and capabilities, see Sample Policies 1–6 and Checklists 1–4.

or program to deliver FASD prevention and intervention (see How-To 2.2).

How Do You Organize a Team to Address the Problem?

Once you have identified an issue or problem, you need to create a workgroup to address the problem (see How-To 2.3).

How Do You Identify a Specific Outcome to Target for Change?

Once you've organized a workgroup to address the problem, you need to identify a specific outcome to be targeted for change (see How-To 2.4).

How Do You Decide Where to Start?

Once you've identified a specific outcome or outcomes to target for change, you will want the workgroup to assess the agency and the staff (both frontline and supervisory) to be targeted by the implementation. You will have

How-To 2.3: How to Organize a Team to Address the Problem (Figure 2.1, Steps D and E)

1. Identify one person to lead the effort. Many programs that have successfully implemented programming for individuals with an FASD were able to do so because there was one committed, passionate person willing to lead the effort, a 'champion.' This person must have the backing of senior administration and the respect of direct treatment staff.
2. Obtain the commitment of the Chief Executive Officer of the agency to articulate the vision for implementation throughout the agency and with all stakeholders (including clients).
3. Convene an implementation workgroup consisting of key leaders from different stakeholder groups; client leaders, family leaders, team leaders, clinical leaders, and program and administrative leaders. Some stakeholders will serve as ongoing members of the workgroup, while information from others may be solicited through focus groups. If your program has a residential or inpatient component, be sure to include an individual from the night staff (i.e., aide, tech, night nurse). This staff will actually have more conversations with patients than most clinical staff and are in a position to support this program through their observations and understanding.
4. Identify the program oversight committee to which the work group will report. For example, if your agency has a quality improvement committee, the work group may report its findings, recommendations, strategic plans, and modifications to that committee. This is one way to initiate and sustain implementation.

How-To 2.4: How to Identify a Specific Outcome to Target for Change (Figure 2.1, Step F)

1. Begin with the issue or problem identified in Step A of Figure 2.1, and determine a specific variable that can be measured that is directly related to improving the management of FASD. For example, in terms of prevention, the variable may be to "Add FASD awareness as an element of client education with all female clients of childbearing age, whether pregnant or not." In terms of intervention, the variable may be to "Increase staff ability to identify signs of a client who may have an FASD."
    - Identify a way to measure "identify signs of a client who may have an FASD." For example, there is a list of common physical and behavioral manifestations of FASD in Part 1, Chapter 2 of this TIP, and repeated later this chapter, that can be used as a checklist.
    - Identify a way to measure "client education with all female clients of childbearing age, whether pregnant or not." For example, tracking instances of client education on the topic of alcohol-exposed pregnancies, and/or rates of abstention among pregnant clients.
2. Measure a baseline prior to implementing FASD prevention or intervention. For example, determine how many women of childbearing age you see at your agency in a given month. In terms of intervention, review cases of client noncompliance, particularly where no specific cause of the noncompliance is known. Did these clients forget appointments? Not follow directions? Act out? Exhibit family instability and/or have a history of multiple foster care placements? These can become cues for identifying case of possible FASD in the future.
3. Identify which outcome you are most interested in measuring to determine whether implementing FASD prevention or intervention is working. For example:
    - **Intervention**
        - Number of staff trained in FASD intervention methods
        - Rates of identifying potential cases of an FASD
        - Rates of conducting FASD evaluations/assessments
        - Rates of finding/filling FASD assessment slots
        - Diagnoses achieved
        - Follow-up/Aftercare: Family stability over time
        - Multiple foster placements reduced
    - **Prevention**
        - Number of staff trained in FASD prevention
        - Implementation of alcohol screening with all women of childbearing age, whether pregnant or not
        - Treatment planning adaptation based on this screening
        - Achieving abstinence/reduction of at-risk drinking
        - Use of effective contraception by the client

an easier time implementing your plan if you start with a small program where staff members already work well with one another and believe in the new techniques. Staff members on closely knit teams work with one another's strengths and will have an easier time assigning responsibilities when it comes time to implement the practice. Alternatively, you may choose a small, core group of staff members who are ready to try new techniques and are

prepared to be part of an implementation process (i.e., target early adopters across programs). These will be the first staff members trained and coached in using these techniques. Other advantages to starting small include the following:

1. It is easier to track the success of the implementation.
2. It is easier to identify and make any modifications to the techniques that may be necessary to accommodate the agency's clientele.
3. The core group members will talk about the success they are having with the techniques and get other staff interested in learning and using the techniques.

For more information on assessing your agency's readiness for implementation, see How-To 2.5.

How-To 2.5: How to Assess the Agency's Organizational Readiness for Implementation (Figure 2.1, Step G)

1. The committee assesses the agency's organizational readiness by first determining whether implementing practices to improve the management of FASD in the agency's clientele are consistent with the agency's mission statement. (See also the section *Modifying Existing Policies*, this chapter).
2. The committee determines the obstacles to implementation:
   a. Rate of staff turnover in the agency, including average longevity of clinical and support staff.
   b. Inadequate funding for training, technical assistance, and outcome measurement.
   c. Policies and procedures that would have to be changed (see Sample Policies 1–6, this chapter).
   d. Agency facilities and resources.
   e. Federal, state, and local regulations that affect the decision to implement FASD prevention and intervention (see *Addressing Relevant Regulations*, this chapter).
3. The committee determines the opportunities created by implementing FASD prevention or intervention:
   a. Increased funding.
   b. Increased collaboration with other agencies.
   c. Improved community relations and marketing opportunities.
4. The committee determines the organization's stage of change (see also the ATTC's Change Book, p. 29).
5. The committee determines where the resources will come from to provide support for the change initiative (Change Book, p. 29).
6. The committee determines what adoption of this change will mean at all levels of the organization and what the benefits are for administrators, supervisors, and counselors (Change Book, p. 29).
7. The committee determines what is already happening that might lay the foundation for the desired change (Change Book, p. 29). For example, you may already have an FASD 'champion' on your staff.

Addressing Policies and Procedures

Although varying in format and structure as a result of regulatory and organizational diversity, policies and procedures serve as the foundation of organizational practice. Planning and implementing a new program component almost always impacts existing policies and procedures, but those same policies and procedures constitute one of the most common and effective mechanisms for institutionalizing organizational practices. As such, they will need to be reviewed and adapted to be sure they are in conformance with the new program.

Modifying Existing Policies

In addition to adopting policies on addressing FASD, provider agencies might consider modifying other policies and program descriptions to provide continuity of care for (1) women who are or may become pregnant who screen positive for at-risk drinking, and (2) individuals who have or may have an FASD.

For example, each program will develop its own approach to screening and monitoring for FASD based on (a) the characteristics of its clientele; (b) its resources, especially its staff training and background; (c) legal and reimbursement considerations; and (d) other factors unique to your agency (e.g., specific arrangements worked out with referral resources or consultants, participation in clinical trials, or other external influences). Your professional input into developing the necessary policies and procedures is essential, and at a minimum there should be a protocol that stipulates:

- What standard questions a client is asked, when they are asked (by interview and/or self-report mechanisms), and when they should be repeated (especially what observations or events might trigger a fuller evaluation for an FASD)—**These elements of the protocol should use published, reliable tools as discussed in Part 1 and the Literature Review for this TIP** (Appendix C, *Public and Professional Resources on FASD*, contains useful links to sites where tools can be accessed);
- Who can ask these questions and what training is provided or needed regarding the questions and the overall process, procedures, and policies;
- Exactly how scoring or assessment of the clients' responses will be done, including exact guidelines for the follow-up triggered by various responses;
- Where these policies and procedures fit within the agency's policies and procedures and what chain of command and communication exist;
- How long AEP screening and prevention and/or treatment modification for FASD intervention will typically take, which will help you calculate how many interventions one staff member can realistically accomplish per day, anticipate staffing requirements for the project, and project potential income (consult with your administration and billing department—billing for both Medicaid and private insurance may require an intervention of at least 15 minutes' duration);
- How personnel will obtain necessary training, forms, or materials;
- How FASD-informed prevention and/or intervention will be introduced to the client (it might be helpful to have introductory statements worked out and written down in advance, and available to all staff); and
- How FASD prevention and/or intervention will be documented, whether as written or electronic medical record documentation.

This section provides six samples of critical policies and procedures related to addressing FASD prevention and intervention within substance abuse treatment and mental health agencies. In each topic area, a policy statement and set of procedures related to the topic are presented. These sample policies can be used as presented, combined into one or more comprehensive policies, or integrated into the organization's existing policies. Each policy is divided into an example of a policy statement and a set of procedures, as the language will differ depending on whether an agency is revising policies to incorporate FASD intervention or FASD prevention.

Sample Policy 1a

Topic: Clinical staff training and competency [FASD intervention].

Policy Statement: All clinical staff will demonstrate basic competency in identifying signs of an FASD.

Procedures:

1. All clinical and support staff will participate in a 3–5 hour training session covering FASD, the impact of these disorders on treatment, retention, and outcomes, and criteria and procedures for referring individuals to services aimed at formally diagnosing and addressing FASD. (See Appendix C, *Public and Professional Resources on FASD*, for training resources.)
2. The clinical supervisor of new employees will provide site-specific information on the procedures for screening and referring individuals who exhibit signs of a possible FASD.
3. Clinical competency checklists completed at hire and annually thereafter will ensure that all clinical staff members have a basic knowledge of FASD, an understanding of strategies for assessing the significance of FASD, and an awareness of appropriate referral procedures.

Sample Policy 1b

Topic: Clinical staff training and competency [FASD prevention].

Policy Statement: All clinical staff will demonstrate basic competency in screening women of childbearing age (whether pregnant or not) for alcohol consumption.

Procedures:

1. All clinical and support staff will participate in a 3–5 hour training session covering FASD, the impact of alcohol on a fetus, and (if necessary) criteria and procedures for referring women who screen positive for at-risk drinking to appropriate services. (See Appendix C, *Public and Professional Resources on FASD*, for training resources.)
2. The clinical supervisor of new employees will provide site-specific information on the procedures for screening and referring women who screen positive for at-risk drinking.
3. Clinical competency checklists completed at hire and annually thereafter will ensure that all clinical staff members have a basic knowledge of FASD, an understanding of strategies for assessing the dangers of alcohol consumption for women of childbearing age, and an awareness of appropriate referral procedures.

Sample Policy 2a

Topic: Recruitment, training, and supervision of FASD-capable clinical staff [FASD intervention].

Policy Statement: Counselors interested in providing FASD-informed care and who possess the relevant basic counseling skills, knowledge, and attitudes (see Checklist 2, *Characteristics and Competencies of All Clinical Staff*, this chapter) will be recruited, trained, and supervised to deliver these interventions.

Procedures:

1. At least one clinical position in each program or modality of care will be designated to provide FASD-informed care.
2. Individuals exhibiting the attitudes, knowledge, skills, and job performance required to provide FASD-informed care will be identified by their clinical supervisor and designated to provide these services.
3. The counselors identified to provide FASD-informed care will receive an initial training and additional "update" training each year in some or all of the following areas (see Appendix C, *Public and Professional Resources on FASD*, for training resources):
    - Fundamentals of FASD, including the effect of alcohol on the developing fetus and typical cognitive and behavioral impact across the lifespan.
    - Summary of current literature on FASD intervention, and on scientifically validated FASD intervention approaches.
    - Adapting treatment approaches for individuals with an FASD.
    - Talking with individuals with an FASD about their diagnosis.
    - Planning for client safety.
    - Principles of trauma-informed care.
    - Providing a "hands-on hand-off" approach to outside services (i.e., not simply making a referral and assuming that the client takes the appropriate action).
    - Addressing FASD in the context of cultural competency.
    - Building client self-efficacy and self-advocacy
    - Client-centered care.
    - Motivational interviewing.
    - Targeted provider and school consultation.
    - Personal boundaries and professional ethics.
    - Termination, referral, and discharge planning.
    - Appropriate community linkages.
    - Anticipatory guidance and planning for the future.
4. Counselors providing FASD-informed care will receive clinical supervision twice monthly that includes direct observation or review of tapes of individual sessions with clients who have or may have an FASD.
5. Counselors providing FASD-informed care will meet quarterly to provide peer support, supervision, and share resources related to the management of clients who have or may have an FASD.

Sample Policy 2b

Topic: Recruitment, training, and supervision of clinical staff capable of screening women of childbearing age (whether pregnant or not) for alcohol consumption [FASD prevention].

Policy Statement: Counselors interested in providing alcohol screening and referral and who possess the relevant basic counseling skills, knowledge, and attitudes (see Checklist 2, *Characteristics and Competencies of All Clinical Staff*, this chapter) will be recruited, trained, and supervised to deliver these interventions.

Procedures:

1. At least one clinical position in each program or modality of care will be designated to provide alcohol screening to women of childbearing age.
2. Individuals exhibiting the attitudes, knowledge, skills, and job performance required to provide alcohol screening will be identified by their clinical supervisor and designated to provide these services.
3. The counselors identified to provide alcohol screening will receive an initial training and an additional update training each year in some or all of the following areas (see Appendix C, *Public and Professional Resources on FASD*, for training resources):
    - Fundamentals of FASD, including the effect of alcohol on the developing fetus and typical cognitive and behavioral impact across the lifespan.
    - Summary of current literature on FASD intervention, and on scientifically validated FASD intervention approaches.
    - Planning for client safety.
    - Principles of trauma-informed care.
    - Providing a 'hands-on hand-off' approach to outside services (i.e., not simply making a referral and assuming that the client takes the appropriate action).
    - Addressing FASD in the context of cultural competency.
    - Building client self-efficacy and self-advocacy
    - Client-centered care.
    - Motivational interviewing.
    - Targeted provider consultation.
    - Personal boundaries and professional ethics.
    - Termination, referral, and discharge planning.
    - Appropriate community linkages.
    - Anticipatory guidance and planning for the future.
4. Counselors providing alcohol screening will receive clinical supervision twice monthly that includes direct observation or review of tapes of individual sessions with female clients of childbearing age.
5. Counselors providing FASD-informed care will meet quarterly to provide peer support, supervision, and share resources related to providing alcohol screening to female clients of childbearing age.

Sample Policy 3a

Topic: Observation and referral of clients exhibiting signs of an FASD [FASD intervention].

Policy Statement: The possible presence of an FASD will be considered with all noncompliant or resistant or 'problem' clients, and possible indicators will be noted through a process of observation and interviewing. Clients exhibiting signs of a potential FASD will be referred as needed.

Procedures:

1. During intake and throughout the early stages of treatment (i.e., first month), all clients exhibiting persistent (and otherwise unexplained) noncompliance with treatment will be observed, and the individual's case history reviewed, for FASD "indicators" based on a checklist (see the *FASD 4-Digit Code Caregiver Interview Checklist* in Part 1, Chapter 2 of this TIP).
2. Individuals exhibiting signs of an FASD will either be assessed by an identified in-house team with FASD expertise or be referred to an accepted FASD evaluation agency.
3. With or without a formal diagnosis of FASD, a client exhibiting signs of an FASD will be referred to a counselor competent in providing FASD-informed care and capable of modifying treatment to account for the observed behavioral/cognitive deficits (see Sample Policy 2).
4. All screening results, consultation sessions with the clinical supervisor, and referrals (and ongoing communications) to an FASD evaluation agency will be documented in the client's record.
5. The counselor providing FASD-informed care will provide the client with an emergency contact list that includes agency personnel and emergency care providers. The client can refer to this list if he or she has treatment or safety issues outside business hours or when a counselor is not available. (See Appendix F for a *Sample Crisis/Safety Plan* that can be filled out with clients.)

Sample Policy 3b

Topic: Screening and referral of female clients of childbearing age exhibiting signs of an alcohol use/abuse [FASD prevention].

Policy Statement: All women of childbearing age (whether pregnant or not) will be screened for alcohol consumption and referred as needed.

Procedures:

1. During the intake process, all women of childbearing age will be screened for alcohol consumption.
2. Staff will be trained in using specific alcohol screening tools that are validated for use with women, such as the T-ACE or TWEAK (for pregnant women), the AUDIT-C Questionnaire (non-pregnant women), or the CRAFFT Interview or FRAMES (with adolescent and young adult clients).

3. Individuals screening positive for at-risk alcohol consumption will receive an appropriate assessment or be referred for one, to be conducted by a qualified substance abuse treatment professional.
4. Clients who are determined by a qualified substance abuse treatment professional to have an alcohol-related disorder will receive or be referred for substance abuse treatment, also to be delivered by that professional. Collaborative relationships with appropriate providers will be developed.
5. All women of childbearing age will receive FASD-related education (pamphlet, suitable Web site, etc.), whether pregnant or not and whether screening positive for at-risk alcohol consumption or not.
6. All screening results, consultation sessions with the clinical supervisor, and referrals (and ongoing communications) to a qualified substance abuse treatment professional will be documented in the client's record.
7. The counselor providing substance abuse treatment will provide the client with an emergency contact list that includes agency personnel and emergency care providers. The client can refer to this list if she has treatment issues outside business hours or when a counselor is not available. (See Appendix F for a *Sample Crisis/Safety Plan* that can be filled out with clients.)

Sample Policy 4a

Topic: Treatment planning, service recording, discharge planning, and continuity of care [FASD intervention].

Policy Statement: Management of FASD will be integrated with substance abuse/mental health services, be properly documented, and include appropriate discharge and transfer planning.

Procedures:

1. Screening and observation for signs of an FASD and—when indicators are present—strategies for addressing FASD will be included in the client's treatment plan.
2. Treatment plans incorporating FASD management will be jointly developed by the interdisciplinary team and the client within and/or across programs.
3. To minimize client confusion, the client will be provided with information about the roles and responsibilities of those delivering care.
4. Treatment plans will include referral to other community resources and peer support activities that may increase the client's self-efficacy and reduce FASD-related treatment barriers.
5. Interdisciplinary treatment update sessions including all professionals involved with the client's care should occur regularly. (The frequency of treatment plan updates should be consistent with state and organizational standards and will vary by modality of care and regulatory agency.) Ideally these would be held weekly for short-term residential treatment and monthly for long-term residential treatment and outpatient settings.
6. Services delivered by the primary counselor will be recorded in the client's record at each contact and will be available to other members of the treatment team.

7. Major changes in the client's condition or treatment compliance/success will be communicated between the primary counselor and the interdisciplinary team.
8. The checklist of FASD "indicators" (see Sample Policy 3) will be completed at the last session before termination to assist in developing the discharge plan and to be used by the quality assurance department for outcome monitoring.
9. Discharge and transfer planning will include recommendations for the client about self-care, self-advocacy, and other available FASD-informed services that are available to them.

Sample Policy 4b

Topic: Treatment planning, service recording, discharge planning, and continuity of care [FASD prevention].

Policy Statement: Treatment for at-risk alcohol consumption among all women of childbearing age (whether pregnant or not) will be integrated with substance abuse/mental health services, be properly documented, and include appropriate discharge and transfer planning.

Procedures:

1. Screening for alcohol consumption among all women of childbearing age (whether pregnant or not) and strategies for addressing the client's alcohol use will be included in the client's treatment plan.
2. Treatment plans incorporating alcohol use management will be jointly developed by the interdisciplinary team and the client within and/or across programs.
3. To minimize client confusion, the client will be provided with information about the roles and responsibilities of those delivering care.
4. Treatment plans will include referral to other community resources and peer support activities that may increase the client's self-efficacy and reduce alcohol consumption.
5. Interdisciplinary treatment update sessions including all professionals involved with the client's care should occur regularly. (The frequency of treatment plan updates should be consistent with state and organizational standards and will vary by modality of care and regulatory agency.) Ideally these would be held weekly for short-term residential treatment and monthly for long-term residential treatment and outpatient settings.
6. Services delivered by the primary counselor will be recorded in the client's record at each contact and will be available to other members of the treatment team.
7. Major changes in the client's condition or pattern of alcohol use (or simply changes in alcohol use, if this is the primary objective of treatment) will be communicated between the primary counselor and the interdisciplinary team.
8. An appropriate alcohol screening tool agreed upon by the interdisciplinary team will be completed at the last session before termination to assist in developing the discharge plan and to be used by the quality assurance department for outcome monitoring.
9. Discharge and transfer planning will include recommendations for the client about self-care, self-advocacy, and other alcohol use support services that are available to them.

Sample Policy 5a

Topic: Counselor performance appraisal [FASD intervention].

Policy Statement: Counselors capable of providing FASD-informed services will have job descriptions that include a high level of specific performance expectations related to provision of services for these clients.

Procedures:

1. Job descriptions for counselors agreeing/qualified to provide FASD intervention services may include reduced caseload and productivity expectations, particularly during an agreed-upon early stage of implementation.
2. Performance appraisal of counselors providing FASD intervention services will include demonstration of relevant core competencies (e.g., as observed directly and/or through videotaping).
3. Annual training requirements will be outlined in the job descriptions of counselors identified to provide FASD-informed services.
4. Client satisfaction surveys and outcome reports will be discussed in performance evaluations with counselors providing FASD intervention services. Such evaluations may need to occur more regularly than annually when implementing new practice.

Note: The following sample policy is potentially more relevant in mental health treatment settings than in substance abuse treatment settings, as alcohol use management services are a core competency in substance abuse treatment and presumably would not be separated out in a policy statement in this fashion.

Sample Policy 5b

Topic: Counselor performance appraisal [FASD prevention].

Policy Statement: Counselors capable of providing alcohol consumption screening for women of childbearing age (whether pregnant or not) and appropriate services/referral will have job descriptions that include a high level of specific performance expectations related to provision of services for these clients.

Procedures:

1. Job descriptions for counselors agreeing/qualified to provide FASD prevention services may include reduced caseload and productivity expectations, particularly during an agreed-upon early stage of implementation.
2. Performance appraisal of counselors providing FASD prevention services will include demonstration of relevant core competencies (e.g., as observed directly and/or through videotaping).
3. Annual training requirements will be outlined in the job descriptions of counselors identified to provide alcohol use management services.
4. Client satisfaction surveys and outcome reports will be discussed in performance evaluations with counselors providing FASD prevention services. Such evaluations may need to occur more regularly than annually when implementing new practice.

Sample Policy 6a

Topic: Evaluation of service effectiveness and quality assurance [FASD intervention].

Policy Statement: Services for addressing FASD will be reported annually through the agency's quality assurance system along with indicators of effectiveness based on client outcomes.

Procedures:

1. The agency's quality assurance program will include monitoring the implementation of policies related to FASD screening and treatment modifications, FASD evaluation referral procedures, documentation and treatment planning, and supervision of counselors providing FASD-informed services.
2. Data from admission and discharge screening of clients exhibiting FASD "indicators" (see Sample Policy 3) will be aggregated by the quality assurance coordinator for annual reporting to the agency.
3. The following overall agency performance outcomes will be reviewed annually by the management team:
   a. The proportion of clients dropping out of treatment before the third session after implementation of FASD-informed services, or appropriate length of time based on your agency's treatment schedule (it will be important to have information on the dropout rate *after* implementation to assess the impact of these services on treatment engagement and retention).
   b. The number of clients receiving FASD-informed services, as a percentage of overall client population.
   c. The number of clients referred to an FASD evaluation agency, as a percentage of overall client population.
   d. A comparison of (1) the proportion of all clients experiencing a relapse during treatment, and (2) the proportion of all clients receiving FASD-informed care that experience a relapse during treatment.

Note: As with sample policy 5b, the following sample policy is potentially more relevant in mental health treatment settings than in substance abuse treatment settings, as alcohol use management services are already a core competency in substance abuse treatment.

Sample Policy 6b

Topic: Evaluation of service effectiveness and quality assurance [FASD prevention].

Policy Statement: Services for managing alcohol use consumption among women of childbearing age (whether pregnant or not) will be reported annually through the agency's quality assurance system along with indicators of effectiveness based on client outcomes.

Procedures:

1. The agency's quality assurance program will include monitoring the implementation of policies related to alcohol use management among women of childbearing age (whether pregnant or not), substance abuse treatment referral procedures, documentation and treatment planning, and supervision of counselors providing alcohol use management services.

2. Data from admission and discharge screening of clients who are women of childbearing age and have received alcohol use management services (see Sample Policy 3) will be aggregated by the quality assurance coordinator for annual reporting to the agency.
3. The following overall agency performance outcomes will be reviewed annually by the management team:
   a. The proportion of clients who receive screening for at-risk alcohol use who subsequently drop out of treatment, as a comparison with clients who do not receive this screening and subsequently drop out of treatment.
   b. The proportion of these clients evidencing at-risk alcohol consumption at both admission and discharge.
   c. The number of clients who are women of childbearing age who receive screening for at-risk alcohol use, as a percentage of overall client population.
   d. The number of clients who are women of childbearing age who receive services for alcohol use management or a referral to a qualified substance abuse treatment professional, as a percentage of overall client population.
   e. A comparison of (1) the proportion of all clients experiencing a relapse during treatment, and (2) the proportion of all clients who are women of childbearing age and receiving alcohol-use management services that experience a relapse during treatment.

Addressing Relevant Regulations

Another aspect of assessing your agency is to determine whether implementing FASD prevention and/or intervention will conflict with the existing local and governmental regulations and standards that apply to your agency's operation.

For example, both the federal government and individual states have developed their own laws regarding the reporting of cases of known or suspected substance-exposed infants. These laws vary widely in their requirements, but are nonetheless of critical importance to any healthcare setting serving the needs of pregnant women. In addition, providing services to individuals who have or may have an FASD—a recognized disability—carries its own legal and ethical responsibilities.

The following sections discuss relevant regulatory issues related to (1) women who drink during pregnancy, and (2) individuals who have or may have an FASD.

Legal Issues Related to Women Who Drink During Pregnancy

Federal laws related to alcohol use during pregnancy tend focus on prevention and treatment of FASD rather than being punitive. State and local laws vary. Some states, such as Hawaii and Montana, have laws authorizing FASD prevention and treatment programs. Others, such as New Hampshire and Rhode Island, require that information on FASD be available to couples seeking marriage licenses. At least one state, Missouri, requires physicians to counsel pregnant patients about the dangers of alcohol use. It is important for counselors to stay abreast of state laws related to alcohol use during pregnancy and their effect on treatment and recovery.

The Administration for Children & Families, an agency within HHS, provides a searchable guide to state-level statutes regarding the reporting of substance-exposed infants (**http://www.childwelfare.gov/systemwide/laws_policies/state/**).

Custody Issues

Several states (e.g., Florida, South Carolina) do take punitive measures toward alcohol use during pregnancy, such as including prenatal alcohol exposure in their definitions of abuse or neglect. Such measures can be used to remove the child from the parent's custody. Texas allows involuntary termination of parental rights if a woman causes her child to be born addicted to alcohol (other than via a controlled substance legally obtained by the mother by prescription; Section 161.001[1-R]). Generally, a mother who abuses substances may be charged with child neglect or abuse. As a result, her children may be taken from her.

In Virginia, physicians, nurses, teachers, and other professionals are required to report certain injuries to children. For purposes of the law, "reason to suspect that a child is abused or neglected" includes a diagnosis by an attending physician within 7 days of a child's birth that the child has fetal alcohol syndrome attributable to in utero exposure to alcohol (Section 63.2-1509). One state, South Dakota, permits involuntary commitment of a pregnant woman who is drinking.

A number of experts fear that such punitive measures may discourage pregnant women with alcohol problems from seeking treatment. Many states take a more supportive approach:

- Arizona (**http://www.azleg.state.az.us/ars/36/00141.htm**)
- California (**http://law.justia.com/codes/california/2005/hsc/11998-11998.3.html**)
- Washington state (**http://apps.leg.wa.gov/RCW/default.aspx?cite=70.83C.005**)

These three states give pregnant women priority for alcohol treatment slots or otherwise provide access to treatment. Others (e.g., California) provide outreach or case management to pregnant women with substance abuse problems. California also may cover residential treatment for pregnant women under Medi-Cal. In addition, Iowa prohibits discrimination against pregnant women seeking alcohol treatment (**http://www.legis.state.ia.us/IACODE/2001SUPPLEMENT/125/32A.html**).

State and federal governments have established various policies in response to the risks associated with drinking during pregnancy. Among these are various arrangements to increase access to substance abuse treatment by pregnant and postpartum women. Such arrangements include state-run treatment services, funding for private providers, and mandates that such women receive a priority for available treatment. The Alcohol Policy Information System (APIS) addresses statutes and regulations mandating priority access to substance abuse treatment for pregnant and postpartum women who abuse alcohol. In addition, the SAMHSA FASD Center for Excellence Web site provides an FASD legislation report that is updated twice a year.

State statutes that remove custody from birth mothers of children with an FASD are designed to protect the children. However, the threat of losing custody can interfere with the woman's recovery, or cause her to leave prenatal care and/or treatment. The goal is to remain alcohol-free long-term and acquire parenting skills needed to retain child custody and have a healthy, intact family. When screening or referring pregnant women for substance abuse treatment, counselors will need to be familiar with the laws in his or her state and their impact on efforts at family reunification and client recovery.

Child Abuse Prevention and Treatment Act (CAPTA)

One of the most significant pieces of legislation impacting the provision of services to pregnant women is the Child Abuse Prevention and Treatment Act, or CAPTA (P.L. 93-247). Most recently reauthorized on December 20, 2010 (S 3817), CAPTA is designed to protect rather than punish women who give birth to substance-exposed infants. The intent of these reporting laws is that "The newborn and their families will be brought to the attention of the child protective agency in the community, and they will ideally receive needed services within their community" (Burke, 2007).

A new CAPTA state grant eligibility requirement modifies earlier CAPTA language that mandates identifying and making appropriate referrals by healthcare providers to child protective services—and developing service 'plans for safe care' of the child—of newborns affected by prenatal drug exposure. Added as a new category of 'referral' and 'safe care plan' requirement are newborns diagnosed with an FASD. This CAPTA amendment was not meant to cover all situations where a newborn's mother drinks alcohol during her pregnancy, but rather those where a newborn has facial characteristics, growth restriction, or other abnormalities (birth defects) caused by prenatal alcohol use.

This new CAPTA provision (and the earlier requirement regarding drug-exposed newborns) is not intended to have states make prenatal alcohol or drug exposure a category of child abuse or neglect or to make those children subjects of mandatory reporting laws. Congress carefully chose the word "referral" to avoid that. Rather, the goal is to address the safety and well-being of these children. Intervening early through safety plans that promote the health and well-being of these children will be key.

The U.S. Department of Health and Human Services (HHS) provides a comprehensive guide to the CAPTA legislation and its impact on service provision, as well as its implications for community-based family resource and supports grants (**http://www.childwelfare.gov/systemwide/laws_policies/federal/index.cfm?event=federalLegislation.viewLegis&id=142**). CAPTA is also discussed in Part 3 of this TIP, the online literature review.

Territorial and Tribal Laws

At this time, no U.S. Territories have laws related to alcohol use during pregnancy. Tribal laws vary, but the Indian Child Welfare Act (**http://www.nicwa.org/policy/law/icwa/ICWA.pdf**) requires the Indian Health Service (IHS) to make residential treatment available for pregnant women with alcohol problems. In addition, the definition of 'health promotion' in the Act includes FASD prevention. The Act also allows the IHS to make grants to tribes and tribal organizations for various FASD prevention efforts, including alcohol treatment for high-risk women. It also has provisions related to educating Native women about FASD.

Counselors working with Tribal populations will also want to consider the implications of the Tribal Law and Order Act (TLOA) of 2010 and the Indian Health Care Improvement Act (IHCIA), which was made permanent in 2010. Both seek to strengthen access to care and protection of personal rights among Tribal populations, particularly women.

Information about the TLOA can be accessed at **http://www.narf.org/nill/resources/tloa.html**.

Information about the IHCIA can be accessed at **http://www.ihs.gov/ihcia/**.

Confidentiality Issues

Laws such as the Health Insurance Portability and Accountability Act (HIPAA) may affect activities such as reporting of alcohol use during pregnancy. HIPAA has certain requirements regarding privacy and sharing of client information and records. Confidentiality laws vary by state and may affect the addiction professional's ability to share information with various social, health, and legal systems, such as child welfare agencies.

It is essential to be familiar with confidentiality laws in one's state and to consult with an attorney if necessary. Inappropriate reporting of current or previous alcohol use during pregnancy can jeopardize long-term recovery and can harm a counselor's career.

Legal Issues Related to Individuals with an FASD

The most prominent regulatory issue related to individuals who have or may have an FASD is to recognize their rights as individuals with (or potentially having) a recognized disability.

Americans with Disabilities Act Compliance in Treatment Plans

The Americans with Disabilities Act (ADA) of 1990 is a federal law that prohibits discrimination on the basis of disability in employment, state and local government, public accommodations, commercial facilities, transportation, and telecommunications. An individual with a disability is defined by the ADA as a person who has a physical or mental impairment that substantially limits one or more major life activities, a person who has a history or record of such an impairment, or a person who is perceived by others as having such an impairment. Treatment facilities cannot discriminate on the basis of a disability. Many individuals with an FASD will have cognitive disabilities that meet the definitions set forth by the ADA; in any case, such individuals should receive treatment that recognizes their condition as a disability that should not be discriminated against.

Counselors will need to incorporate accommodations for persons with an FASD into any treatment plans. For example, lighting at meetings may need to be dimmed to keep the person with an FASD from becoming overstimulated. Reading materials may need to be adapted to a lower literacy level to accommodate cognitive deficits. More information on accommodating disabilities can be found in Appendix D of TIP 29, *Substance Use Disorder Treatment for People With Physical and Cognitive Disabilities* (CSAT, 1998; **http://www.ncbi.nlm.nih.gov/books/NBK64881/**). Part 1, Chapter 2 of this TIP discusses accommodations specific to individuals who have or may have an FASD.

More information on the ADA can be found at **http://www.ada.gov/**. For technical assistance related to ADA requirements, visit **http://www.ada.gov/taprog.htm** or contact SAMHSA's FASD Center for Excellence toll-free at 1-866-STOPFAS or by visiting **www.fasdcenter.samhsa.gov.**

Addressing Staff Competence

Where Is the Clinical Expertise in Your Agency?

Change in clinical practice is best facilitated by assessing the skills of well-trained and experienced clinicians and targeting them for training and/or enlisting them in helping less skilled counselors facilitate change. Two clinical management structures are described here—interdisciplinary teams and traditional clinical supervisors.

Interdisciplinary teams are one effective way to ensure that the expertise for providing FASD-informed treatment is available in your agency (Clarren & Astley, 1997; Clarren et al., 2000). If you have interdisciplinary teams in your program, the teams assume the responsibility

of tailoring interventions to an individual client's needs in a way that addresses FASD seamlessly. Such teams provide ongoing support, education, and treatment planning assistance for all staff. Teamwork creates an enriched environment for implementing FASD-informed techniques.

If your agency has an interdisciplinary team format for responding to other issues, this may be adapted to FASD. With an interdisciplinary team, you have an advanced level of capability for addressing FASD prevention or intervention in clients with substance use or mental disorders. This assumes that the more experienced and skilled members of the team have the knowledge, skills, and attitudes required to apply FASD-informed interventions and to supervise and coach application of an intervention for other counselors.

Many treatment agencies do not have interdisciplinary teams and instead rely on the expertise of *clinical supervisors* to evaluate and support the work of line staff. Clinical supervisors must have the knowledge, skills, and abilities required to apply an intervention and be able to demonstrate the intervention before they can coach others to perform it. The supervisors must also have the time to supervise and coach the staff. If this describes the supervisors in the setting where you work, you have an intermediate capability to provide FASD-informed care. If the supervisors have not yet reached this level, then you have a beginning capability for implementing FASD-informed care and must develop a plan to build the resources necessary to increase capacity.

The Frontline Staff and Clinical Supervisors

Once you've assessed the agency, you may want to assess the staff who will actually implement the change (see How-To 2.6).

Staff Qualifications and Competencies

As a part of implementing FASD-informed services, a number of process-oriented tasks

How-To 2.6: How to Assess the Frontline Staff and Clinical Supervisors for Change (Figure 2.1, Step H)

The committee determines the specific program and staff members who will be the first to implement change.

1. Are there incentives/organizational supports for change (ATTC Change Book, p. 29)?
2. What are the barriers to change (ATTC Change Book, p. 28)?
3. At what stage of change is the program staff (ATTC Change Book, p. 29)?
4. How will staff practice be affected (ATTC Change Book, p. 29)?
5. What additional support will staff need (ATTC Change Book, p. 29)?
6. Does staff have the prerequisite knowledge, attitudes, and skills?
7. What training and continuing resources are necessary to provide the core intervention com ponents?

See also Sample Policies 1–6 and Checklists 1–4 in this chapter for additional information to be used in assessing staff readiness. See Appendix C, *Public and Professional Resources on FASD*, for links to training resources.

should be completed, including an assessment of initial staff competence, education and training, development of skills and resources, and supervision. These considerations are relevant not only to the counselors' ability to deliver the services but also to clinical supervisors, other clinical staff, and support staff responsible for recording and billing services.

Compared with those providing support services, however, the required level of knowledge and skill is significantly different for those directly involved in clinical care. For this reason, the attitudes, knowledge, and skills required to provide FASD-informed services are separated into four categories:

1. Administrative and support staff
2. All clinical staff
3. Counselors designated to provide FASD-informed services
4. Clinical supervisors overseeing the counselors who provide these services

The four checklists that follow serve two purposes. First, they can be used to assess staff and organizational readiness to implement or sustain FASD-informed services. Second, they can be used to identify gaps in training and supervision to be addressed with individuals or groups.

Addressing Gaps in Staff Capacity to Deliver Services

Not all clinical staff are ready, willing, or able to address co-occurring issues such as FASD. The clinical supervisor is charged with helping staff and administration differentiate the level

Checklist 1: Characteristics and Competencies of Administrative and Support Staff

Attitudes

_____Integrating FASD-informed care is important for promotion of the agency mission.

_____FASD prevention and intervention constitute valid and important experiences for our clients and deserve and require specialized attention.

Knowledge

_____Recognizes the relationship between FASD-informed care and treatment effectiveness.

_____Recognizes how provision of FASD-informed services fits in the mission and goals of the organization.

_____Is familiar with the policies and procedures related to recording and billing services for FASD-informed services.

_____Recognizes the distinction between a person formally diagnosed with FAS/pFAS/ARND and the general signs of an FASD in an individual.

_____Knows the agency's policies and procedures on providing FASD-informed services as they relate to the specific position (e.g., administrative staff in clinical records are familiar with documentation requirements for these services, and the finance staff are knowledgeable about how services are defined for billing purposes).

_____Understands the role of self-help and support groups in recovery and how those groups can support the goals of the program in providing FASD-informed care.

Skills

_____Communicates to the public the role of specialized services related to FASD prevention/intervention.

_____Identifies the 'indicators' of an FASD listed in the screening policy and procedure (see Sample Policy 3).

_____Administers FASD screening and observation properly.

_____Conducts basic client education session on the relationship between substance abuse/mental health issues and FASD.

_____Conducts basic client education sessions with all female clients of childbearing age (whether pregnant or not) on the relationship between alcohol use during pregnancy and the risk of an FASD.

_____Collaborates with other team members on treatment and discharge planning.

_____Conducts a suicide risk screening.

Checklist 2: Characteristics and Competencies of All Clinical Staff

Attitudes

_____Integrating FASD-informed care is important for promotion of the agency mission.

_____FASD prevention and intervention constitute valid and important experiences for our clients and deserve and require specialized attention.

_____Clients have a central role in creating and shaping their treatment goals.

_____Substance abuse/mental health issues and FASD can be both interrelated and independent; resolving one set of concerns may not lead to resolution of the other set of concerns without specialized treatment.

_____There is no one "right" approach to addressing FASD in our clients.

_____Individual sessions can be particularly valuable for clients who have or may have an FASD and can provide an effective adjunct to group treatment.

Knowledge

_____Recognizes the relationship between FASD-informed care and treatment effectiveness.

_____Recognizes how provision of FASD-informed services fits in the mission and goals of the organization.

_____Recognizes the distinction between a person formally diagnosed with FAS/pFAS/ARND and the general signs of an FASD in an individual.

_____Knows the agency's policies and procedures on addressing FASD prevention/intervention.

_____Recognizes the interrelationship between substance abuse/mental health issues and FASD.

Skills

_____Communicates to the public the role of specialized services related to FASD prevention/intervention.

_____Identifies the 'indicators' of an FASD listed in the screening policy and procedure (see Sample Policy 3).

_____Administers FASD screening and observation properly.

_____Conducts basic client education session on the relationship between substance abuse/mental health issues and FASD.

_____Conducts basic client education sessions with all female clients of childbearing age (whether pregnant or not) on the relationship between alcohol use during pregnancy and the risk of an FASD.

_____Collaborates with other team members on treatment and discharge planning.

_____Conducts a suicide risk screening.

Checklist 3: Characteristics and Competencies of All Clinical Staff

Attitudes

_____Integrating FASD-informed care is important for promotion of the agency mission.

_____FASD prevention and intervention constitute valid and important experiences for our clients and deserve and require specialized attention.

_____Clients have a central role in creating and shaping their treatment goals.

_____Substance use/mental health issues and FASD can be both interrelated and independent; resolving one set of concerns may not lead to resolution of the other set of concerns without specialized treatment.

_____There is no one 'right' approach to addressing FASD in our clients.

_____Individual sessions can be particularly valuable for clients who have or may have an FASD and can provide an effective adjunct to group treatment.

_____Resistance to change from clients is surmountable within the influence of the counseling relationship.

_____The client is an integrated whole rather than one or more diagnoses or sets of symptoms.

_____A desire exists to deliver services to clients who have or may have an FASD along with a substance abuse/mental health issue.

_____A desire exists to deliver FASD-informed care to female clients of childbearing age (whether pregnant or not).

Checklist 3: Characteristics and Competencies of All Clinical Staff

Knowledge

_____Recognizes the relationship between FASD-informed care and treatment effectiveness.

_____Recognizes how provision of FASD-informed services fits in the mission and goals of the organization.

_____Recognizes the distinction between a person formally diagnosed with FAS/pFAS/ARND and the general signs of an FASD in an individual.

_____Demonstrates a nuanced understanding of the relationship between substance use/mental health issues and FASD.

_____Recognizes the distinctions among screening, assessment, and diagnosis of an FASD.

_____Knows the common approaches to addressing FASD in substance abuse/mental health treatment settings including motivational interviewing, accommodations, parent/personal navigator, and the importance of coordinated care.

_____Recognizes how FASD presents in ethnic and other cultural groups encountered in the agency.

_____Knows community resources (particularly substance abuse/mental health, primary care, FASD service providers, school contacts when applicable, family/caregiver navigators).

_____Understands how 12-Step and other mutual-help support programs can support someone with an FASD.

_____Is aware of the role of transference and countertransference in the counseling relationship.

_____Recognizes the role of religion and spirituality in promoting recovery for some clients.

_____Knows how to learn more about FASD intervention methods.

Skills

_____Communicates to the public the role of specialized services related to FASD prevention/intervention.

_____Identifies the "indicators" of an FASD listed in the screening policy and procedure (see Sample Policy 3).

_____Administers FASD screening and observation properly.

_____Conducts basic client education session on the relationship between substance abuse/mental health issues and FASD.

_____Conducts basic client education sessions with all female clients of childbearing age (whether pregnant or not) on the relationship between alcohol use during pregnancy and the risk of an FASD.

_____Collaborates with other team members on treatment and discharge planning.

_____Conducts a suicide risk screening.

_____Exhibits evidence-based thinking (tailoring approach to service based on clinical experience, client characteristics, knowledge of field, consultation with supervisor, constraints, and resources available).

_____Uses clinical supervision effectively.

_____Demonstrates empathic listening skills and reflection.

_____Demonstrates competency in common approaches to addressing FASD (e.g., motivational interviewing, accommodations, parent/personal navigator, coordinated care).

_____Displays confidence in ability to provide FASD-informed services.

_____Acts as a role model for a balanced, healthy lifestyle.

_____Exhibits advanced skills in dealing with resistance to change through non-confrontational approaches.

_____Identifies and responds to variations in learning styles among clients.

_____Demonstrates the ability to quickly establish a therapeutic alliance with the client: treating the client with respect, communicating a nonjudgmental attitude, listening reflectively, setting appropriate limits, being sensitive to culture and value contexts, and acting as a role model.

_____Is comfortable with and able to resolve conflict.

_____Is able to prepare clients for discharge.

Checklist 4: Characteristics and Competencies of Clinical Supervisors

Attitudes

_____Substance abuse counselors have the basic characteristics needed to provide FASD prevention/intervention.

_____Clinical supervision extends beyond talking about treatment to observing and coaching counselors directly.

Knowledge

_____Possesses all of the knowledge areas listed on Checklist 3.

_____Is knowledgeable of the role of clinical supervision.

_____Recognizes the limits and opportunities related to the role of counselors with specialized training in FASD-informed services and supports training for counselors as needed.

_____Can determine when a client who has or may have an FASD needs additional skills and services beyond the qualifications of currently-staffed counselors.

_____Is trained to screen and observe for "indicators" of an FASD.

_____Is aware of the role of transference and countertransference in the counseling and supervisory relationship.

_____Recognizes resistance to change among clinical staff and is knowledgeable of strategies to address resistance.

_____Is aware of change processes, process steps and strategies for supporting them.

_____Possesses knowledge of the FASD intervention literature and scientifically-validated intervention techniques.

Counseling Skills

_____Possesses all of the skills listed on Checklist 3.

Supervisory Skills

_____Articulates his or her approach and philosophy to clinical supervision as it relates to clinical supervision approaches described in the literature.

_____Identifies and responds to variations in learning styles among counselors.

_____Is comfortable with and able to resolve conflict among team members.

_____Models advanced counseling skills including development of therapeutic alliance, preparing clients for discharge, and dealing with client resistance.

_____Uses direct observation or taping to conduct supervisory sessions.

_____Is able to teach and model skills for providing FASD-informed services.

_____Is able to determine when referral for a formal FASD assessment is required, and facilitate such a referral.

_____Provides incentives through encouragement and support for counselors to enhance skills in providing FASD-informed services.

_____Conducts competency assessment of counselors' skills in providing FASD-informed services.

_____Shows how to learn more about FASD intervention methods.

of new knowledge, attitudes, and skills needed to help counselors and support staff address co-occurring substance use/mental health disorders and FASD prevention and intervention. The characteristics and competencies checklists presented above outline the qualifications needed at various levels or in agencies wishing to provide FASD-informed services in clients with substance use or mental disorders. However, gaps may exist; staff may be lacking in various areas and require additional training and support. In this instance, the implementation workgroup described in earlier sections may be commissioned to identify these gaps and to develop plans to provide specific training and support to individual staff members on an as-needed basis.

In addition to developing individualized plans to develop attitudes, skills, and knowledge, a number of organizational approaches can be used both to reinforce the change and to overcome resistance to change. *The Change Book* (ATTC, Second Edition 2010) offers valuable

suggestions on addressing resistance to change (particularly pp. 27–28). These include such strategies as openly discussing staff feelings related to the change, celebrating victories, promoting feedback about the change as a vehicle to improve the process, being realistic about goals, identifying and using the change leaders in promoting the change, and providing training related to the change.

Approaches to Staff Training

It is recommended that training aimed at developing the basic attitudes, knowledge, and skills for delivering FASD-informed care be provided to all agency staff as part of implementation. It is important for clinical staff to see the link between the change and organizational leadership. Thus, administrators need to attend these sessions to personally provide the vision of the organization. In addition to training current staff, it is important to consider the ways in which the organization can communicate the vision to new staff. This may be most efficiently accomplished by using existing vehicles, such as new staff orientation and training sessions and worksite orientation procedures.

Training of all clinical staff members on attitudes, knowledge, and skills specific to their positions can be conducted by administrative or clinical supervisors. Again, it is important to communicate the commitment of leadership to integrating FASD-informed services. In addition, it is recommended that training sessions provide practice in the skill areas outlined in Checklist 3. To reinforce the importance of the need to provide FASD-informed services, clinical and administrative supervisors are advised to incorporate didactic education, identification of incompatible attitudes, and coaching on the skills needed to implement the policies within existing supervision sessions and team meetings. In short, the agency's vision and commitment to addressing FASD must inform all clinical interactions between supervisors and counselors.

Figure 2.2 provides a list of recommended credentials for trainers; Appendix C, *Public and Professional Resources on FASD*, lists resources for FASD prevention and intervention training. How-To's 2.7 and 2.8 discuss the process of selecting a trainer, and how to continue the learning after the initial training is completed.

Figure 2.2
Recommended Credentials for Individuals Providing Training in FASD

- Advanced education in counseling, social work, or psychology.
- Minimum of 5 years' experience delivering substance abuse and/or mental health treatment.
- Being a qualified/experienced FASD Trainer.
- Understanding of commitment to preparing counselors to provide FASD-informed services.
- Possessing skills and experience in motivational interviewing, care coordination, and accommodations to address FASD.
- Meeting all certification or licensure qualifications and competencies for clinical supervisors.
- Knowledge of the FASD intervention literature and scientifically-validated intervention techniques.

How-To 2.7: How to Select a Trainer

Qualifications to look for in a trainer include the following:

1. Experience working with the clientele being served.
2. Ability to demonstrate the techniques as needed in role-play with staff or in-vivo (if possible).
3. Ability to address the types of challenging cases frontline staff encounter and how to work with challenging clients.
4. Understanding of the obstacles and challenges with which the frontline staff and the clinical supervisors are dealing.
5. Respectful attitude toward the clinical staff.
6. Models the principles and strategies of the intervention with the participants.
7. Ability to maintain and modify the technique for the treatment setting, willingness to review transcripts or tapes of actual sessions, and willingness to consult on the phone.
8. Willingness to accept specific training objectives to target specific staff skill sets in a case review format.
9. Knowledge of tested methods of FASD intervention and intervention literature.

See Appendix C, *Public and Professional Resources on FASD*, for links to organizations that can provide training and/or trainers. The SAMHSA FASD Center for Excellence, the National Organization on FAS (NOFAS), the Minnesota Organization on FAS (MOFAS), and the CDC's Regional Training Centers (RTCs) are good starting points.

How-To 2.8: How to Continue the Learning After the Initial Training is Completed

1. Assess the staff's knowledge, abilities, and skills with the core components of the techniques.
2. Check to see that staff continue to reframe the issues of individuals with FASD as being due (in part) to underlying neurological impairment.
3. Emphasize mastery of the underlying principles of the interventions. Always give feedback on how well staff members are doing with interventions and provide advice on simple ways to improve practice.
4. Emphasize mastery of the common techniques across approaches (e.g., motivational interviewing, case coordination, accommodations, establishing boundaries, strengths-based approaches).
5. When staff members have the basics, let them choose the approach they want to focus on next (e.g., behavioral, cognitive, beliefs, affective, family-systems, solution-focused).
6. Explore with staff members their interest in learning specific validated FASD intervention methods.

Addressing Community Relationships

How Do You Develop Referral Relationships?

Access to a range of other health and social resources is essential to quality care in substance abuse and mental health treatment settings, particularly for clients who have or may have an FASD. Agencies to which staff might refer can be screened using the following variables:

- Willing to accept referral of clients who have or may have an FASD.
- Sensitive to substance use or mental health issues.
- Able and willing to work with agencies such as ours, including regular review/ discussion of any collaborative issues.
- No or low funding impediments to working collaboratively.
- Good professional reputation in the community.
- Sufficient funding to address the needs of clients we are referring.
- Willing to cross-train with our staff.
- Existing personal relationship with the referral agency.

Also, it is preferable if certain FASD capabilities are present in any agency to which you refer:

- Individualized service planning.
- Acceptance of disability.
- Recognition of strengths.
- Incorporating individual behaviors.
- More active involvement (transportation, personally ensuring client 'hand-off,' follow up, etc.).
- Services available to child and Mom (when the FASD is intergenerational).
- Flexibility in programming (modifications will be necessary; are they willing to make them?).

How Do You Develop Relationships With the 12-Step Community?

It is useful to have the program's policy and procedures manual reflect an understanding of the essential role that 12-Step programs play in the treatment of clients with substance abuse complicated by FASD. Mental health personnel need to be sensitive and competent in integrating the principles and practices of self-help programs into the clinical process. This requires knowledge of the underlying philosophy of the 12-Step model, and an understanding of how the programs function and are structured. In like manner, counselors practicing from a 12-Step facilitation model need to appreciate how principles and practices are linked to sound counseling.

For example, the use of slogans as a form of cognitive restructuring and debate is helpful to most clients. The use of structured practices like daily meetings, sponsor contact, and reading self-help group literature can help create alternate forms of reward, relief, and life-management. The policy should recognize barriers to individuals with an FASD accessing and using 12-Step programs, including:

- Whether the individual being referred requires a navigator to help them find meetings, attend them regularly and on-time, and participate appropriately;
- Insufficient social communication and social awareness skills on the part of the individual being referred; and
- Potential exploitation of the individual by other members of the group.

How Do You Find and Use Behavioral Health Resources in the Community?

Most substance abuse and mental health programs can benefit from consulting relationships with physicians, psychologists, social workers, and other community medical, rehabilitation, social service, and mental health providers who have specialized knowledge and

resources in addressing the needs of clients who have or may have an FASD. As indicated in Part 1, Chapter 2 in the table titled *In-House FASD Assessment: An Ideal Core Team*, important professional areas to focus on in building relationships include neuropsychology and speech language pathology, occupational therapy, physical therapy, and a primary care physician.

These professionals can provide adjunct resources for such issues as difficult assessments and differential diagnosis, placement in appropriate treatment programs and/or support groups, medical management of co-occurring chronic medical conditions, specialized psychopharmacological services for clients with an FASD, discharge planning, and family services.

Finding and using these resources may be different from finding and using referral resources. Understanding the services that can be provided, fees for service, whether the service can be provided in the treatment program or whether the client must travel to a remote site, and the processes for reporting results of evaluations are some of the issues that need to be considered in using community resources. Generally, unlike referral resources, community resources will not have a formalized contract or agreement with the treatment program. Therefore, issues of confidentiality and information reporting will need to be explored.

Addressing Financial Considerations

Billing

Integration of FASD-informed services is intended to enhance treatment outcomes and, because these services are delivered by licensed and/or certified counselors who are *modifying* or offering *tailored* treatment, rather than changing the focus of treatment, such services are likely to be reimbursable under the client's primary treatment diagnosis. In this case, individual sessions that incorporate accommodations for FASD may be billed as individual counseling, psychotherapy (interactive or regular), or family therapy associated with the primary diagnosis. Organizations are advised to clarify this with state, county, federal, and private funding sources and to identify the specific procedures required to facilitate billing. Financial considerations also reinforce the need for support staff responsible for billing to understand how these services are delivered and their relationship to the primary diagnosis.

For organizations reimbursed based on case or capitated rates, reimbursement is not likely to change. Services that incorporate FASD are likely to be viewed by managed care organizations or funding agencies as value-added or optional services and thus included in established rates of reimbursement. Although incorporating FASD-informed services is not likely to increase reimbursement rates, it may improve performance on contractually mandated outcomes such as treatment engagement, retention, and effectiveness.

In their document *Operational Standards for Mental Health, Intellectual/Developmental Disabilities, and Substance Abuse Community Services Providers* (2011), the state of Mississippi has developed operational standards that can help define and inform a state reimbursement system. They are reprinted in full in Appendix H, *Operational Standards for Fetal Alcohol Spectrum Disorders (FASD): A Model*. In addition, Part 3 of this TIP, the online literature review (**http://store.samhsa.gov/home**), contains a discussion of reimbursement codes related to FASD, as well as the implications of the Patient Protection and Affordable Care Act.

Sources of Funding

Most of the costs of implementing FASD-informed services occur early in the process

of implementation, so local foundations are potential sources of funding. A one-time cost of training and knowledge dissemination to staff offers a discrete, relatively low-cost, and an attractive opportunity for local foundations to contribute to improving treatment outcomes. Applying collaboratively with other agencies demonstrates established partnerships, and should be pursued where possible. The Council on Foundations (**www.cof.org**) is an excellent starting point for identifying foundations near you and researching their missions. Other potential sources of funding include traditional state and federal grants and contracts, direct charges for services from third-party payors, and client fees for service.

Additionally, if the services provided are innovative (addressing FASD is an emerging area of care), agencies should consider partnering with social and psychological researchers at a local university to obtain research funds to support clinical efforts. Such research efforts can have many beneficial secondary effects for agency status in the community, such as developing alternative sources of funding, partnering with new groups interested in substance abuse or mental health issues in the community and/or creating learning communities, as well as providing funds for the identified project.

Addressing Continuity and Fidelity

For FASD-informed services to be fully adopted, the importance of these services will need to be consistently communicated. Policies, mission statements, program descriptions, clinical and administrative training, team meetings, and clinical supervision sessions are all useful avenues for communicating the organization's commitment to delivering FASD-informed care (see Figure 2.3). If not formally revised, these policies should at least be reviewed to ensure that they are broad enough to encompass FASD-informed services.

Implementing the Intervention With Fidelity

When implementing any intervention, it is important to identify the active elements that characterize that specific intervention. Ensuring that a new intervention is being implemented with fidelity, as distinguished from standard practice, allows administrators

Figure 2.3 Avenues for Communicating Organizational Commitment to Delivering Services to Address FASD

- Mission and vision statements
- Strategic plans
- Annual goals
- Program descriptions
- Treatment philosophy statements
- Policies and procedures
- Training sessions
- Team meetings
- Clinical supervision
- Management meetings
- Quality assurance plans
- Employee newsletters
- Electronic communication vehicles including e-mail and Intranet

to more easily determine whether the new intervention is responsible for changes in expected outcomes.

For FASD-informed care, fidelity can present challenges. Behavioral health fields are encouraged by federal agencies and funding organizations to use evidence-based approaches that have not been developed for, or accommodated to, FASD. Evidence-based approaches specifically tailored for FASD are, for now, limited, though some that have been developed and tested do have built-in fidelity monitoring mechanisms.

Fortunately, the FASD evidence base is growing rapidly. There are several scientifically validated interventions now available. There is also expert clinical consensus and publications using systematic research review and synthesis that provide support for the interventions recommended in this TIP (e.g., Adubato & Cohen, 2011).

There is also precedent for tailoring interventions. For example, the past decade has brought methods for inclusion of trauma and other co-occurring disorders into treatment provision and planning into mental health and substance abuse treatment. This could be considered 'trauma-informed' care. Established practice (e.g., cognitive behavioral therapy, or CBT) has been altered and improved by informing standard care with methods to respond to these issues (e.g., trauma-focused CBT). The strategies that have been used to modify or transform practice with these issues in mind can be used by agencies to create FASD-informed care while still maintaining fidelity of existing practices.

To create FASD-informed care and demonstrate fidelity, agencies are encouraged to:

- Access reliable FASD prevention and intervention training (training resources provided in Appendix C).
- Use this TIP and/or other manualized approaches for FASD-informed care. Suggested resources for other manualized approaches include:
  - The SAMHSA FASD Center for Excellence (primarily FASD intervention)
  - The CDC (FASD prevention and intervention approaches)
  - (**http://www.cdc.gov/ncbddd/fasd/training.html**)
- Use checklists provided in this Implementation Guide to conduct process and outcome measurement.
  - If available, use fidelity checklists for other manualized approaches for FASD-informed care (be sure that fidelity checklists describe the active elements of an intervention and define them in behavioral terms).
- Where possible, and if not cost-prohibitive, bolster use of checklist(s) with direct observation of new clinical activities.

Some issues to be solved when implementing intervention fidelity monitoring:

- Which staff members measure specific parts of the checklist(s)?
- How are results conveyed to staff?
- How does a program define an acceptable fidelity score?
- How are positive results of the efforts measured by the checklist rewarded?
- What actions need to be taken if there is poor fidelity to program elements and goals?
- How are elements of checklist(s) updated over time, and when program changes occur?

Appendix B—Selected Screening Instruments for Identifying Alcohol Use Among Women

[NOTE: Part 3 of this TIP, the online Literature Review, contains a full discussion of these and other alcohol screening instruments for use with women.]

T-ACE

The T-ACE is a 4-item instrument appropriate for detecting heavy alcohol use in pregnant women (Sokol, Martier, & Ager, 1989). T-ACE uses the **A**, **C**, and **E** questions from the CAGE screening tool and adds one on **T**olerance for alcohol. The first question assesses tolerance by asking if it takes more than it used to, to get "high" (i.e., intoxicated). T-ACE has sensitivity equal to the longer Michigan Alcohol Screening Test (MAST) and greater than the CAGE (Bradley, Bush, McDonell, Malone, & Fihn, 1998). It has been validated only for screening pregnant women with risky drinking (Russell, 1994).

1. How many drinks does it take for you to feel high? (**T**olerance)
2. Have people **A**nnoyed you by criticizing your drinking? A) Yes B) No
3. Have you ever felt you ought to **C**ut down on your drinking? A) Yes B) No
4. Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover? (**E**ye-opener) A) Yes B) No

Scores

Any woman who answers more than two drinks on question 1 is scored 2 points. Each "yes'" to the additional 3 questions scores 1. Scoring 2 or more is considered a positive screen (Chang, Wilkins-Haug, Berman, & Goetz, 1999), and the woman should receive—or be referred to a specialist for—further assessment. At the same time, a woman could drink 2 drinks per day during pregnancy and not get a positive screen using this tool. She may not be at risk for alcoholism, but because of her pregnancy she's drinking at an unsafe level.

- Sokol, R. J., Martier, S. S., & Ager, J. W. (1989). The T-ACE questions: Practical prenatal detection of risk drinking. *American Journal of Obstetrics and Gynecology, 160*(4), 863-870.

TWEAK

TWEAK (Russell, Czarnecki, Cowan, McPherson, & Mudar, 1991) identifies pregnant women who are at risk for alcohol use. It consists of five items and uses a 7-point scoring system. In a study of more than 3,000 women at a prenatal clinic, the TWEAK was found to be more sensitive than the CAGE and Michigan Alcohol Screening Test (MAST), and more specific than the T-ACE (Russell et al., 1996). The tolerance question scores 2 points for an answer of three or more drinks. However, if the criterion for the tolerance question is reduced to two drinks for women, the sensitivity of TWEAK increases, and the specificity and predictive ability decrease somewhat (Chang et al., 1999).

1. (**T** – Tolerance) How many drinks does it take for you to feel high?
2. (**W** – Worried) Does your partner (or do your parents) ever worry or complain about your drinking?
   A) Yes B) No
3. (**E** – Eye-Opener) Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover? (Eye-opener)
   A) Yes B) No
4. (**A** – Amnesia) Have you ever awakened the morning after some drinking the night before and found that you could not remember part of the evening before?
   A) Yes B) No
5. (**K** – K/Cut down) Have you ever felt that you ought to cut down on your drinking?
   A) Yes B) No

Scores
A woman receives 2 points on question 1 if she reports that she can hold more than 5 drinks without falling asleep or passing out. A positive response to question 2 scores 2 points, and a positive response to each of the last 3 questions scores 1 point each. A total score of 2 or more indicates that the woman is a risky drinker and requires further assessment. At the same time, drinking at any level during pregnancy is unsafe, even if the woman scores negative with this tool.

- Russell, M., Martier, S. S., Sokol, R. J., Mudar, P., Jacobson, S., & Jacobson, J. (1996). Detecting risk drinking during pregnancy: A comparison of four screening questionnaires. *American Journal of Public Health, 86*(10), 1435– 1439.

The CRAFFT Screening Interview

The CRAFFT is a behavioral health screening tool for use with children under the age of 21 and is recommended by the American Academy of Pediatrics' Committee on Substance Abuse for use with adolescents. It consists of a series of six questions developed to screen adolescents for high-risk alcohol and other drug use disorders simultaneously. It is a short, effective screening tool meant to assess whether a longer conversation about the context of use, frequency, and other risks and consequences of alcohol and other drug use is warranted. The questions should be asked exactly as written.

Begin: "I'm going to ask you a few questions that I ask all my patients. Please be honest. I will keep your answers confidential."

Part A

Appendix B—Selected Screening Instruments for Identifying Alcohol Use Among Women

During the PAST 12 MONTHS, did you:	No	Yes
1. Drink any alcohol (more than a few sips)? (Do not count sips of alcohol taken during family or religious events.)		
2. Smoke any marijuana or hashish?		
3. Use anything else to get high? ("anything else" includes illegal drugs, over the counter and prescription drugs, and things that you sniff or "huff")		
For clinic use only: Did the patient answer "yes" to any questions in Part A?		
No: Ask CAR question only, then stop.	**Yes: Ask all 6 CRAFFT questions.**	
Part B	No	Yes
1. Have you ever ridden in a CAR driven by someone (including yourself) who was "high" or had been using alcohol or drugs?		
2. Do you ever use alcohol or drugs to RELAX, feel better about yourself, or fit in?		
3. Do you ever use alcohol or drugs while you are by yourself, or ALONE?		
4. Do you ever FORGET things you did while using alcohol or drugs?		
5. Do your FAMILY or FRIENDS ever tell you that you should cut down on your drinking or drug use?		
6. Have you ever gotten into TROUBLE while you were using alcohol or drugs?		

CONFIDENTIALITY NOTICE:
The information recorded on this page may be protected by special federal confidentiality rules (42 CFR Part 2), which prohibit disclosure of this information unless authorized by specific written consent. A general authorization for release of medical information is NOT sufficient for this purpose.

Scores
Each "yes" response in Part B scores 1 point. A total score of 2 or higher is a positive screen, indicating a need for additional assessment.

AUDIT-C

The AUDIT-C comprises the first three questions of the World Health Organization (WHO) AUDIT. The AUDIT-C was first described in VA patients (Bush, Kivlahan, McDonell, Fihn, & Bradley, 1998; Bradley et al., 2003), but has now been validated in other U.S. clinical populations (Bradley et al., 2007; Frank et al., 2008; Seale et al., 2006; Williams & Vinson, 2001).

Q1: How often did you have a drink containing alcohol in the past year?	**Points**
Never - 0 Monthly or less - 1 Two to four times a month - 2 Two to three times a week - 3 Four or more times a week - 4	
Q2: How many drinks did you have on a typical day when you were drinking in the past year?	**Points**
None, I do not drink - 0 1 or 2 - 0 3 or 4 - 1 5 or 6 - 2 7 to 9 - 3 10 or more - 4	
Q3: How often did you have six or more drinks on one occasion in the past year?	**Points**
Never - 0 Less than monthly - 1 Monthly - 2 Weekly - 3 Daily or almost daily - 4	

Scores
The AUDIT-C is scored on a scale of 0–12 (scores of 0 reflect no alcohol use). In women, a score of 3 or more is considered positive.

Appendix C—Public and Professional Resources on FASD

The SAMHSA FASD Center for Excellence

SAMHSA FASD Center for Excellence
www.fasdcenter.samhsa.gov

The official site of the SAMHSA FASD Center for Excellence provides information and resources about FASD, as well as awareness materials, a fully searchable database, and access to training, technical assistance, and conference/event speakers.

National Association of FASD State Coordinators
http://fasdcenter.samhsa.gov/statesystemsofcare/nafsc.aspx

The SAMHSA FASD Center for Excellence helped to establish the National Association of FASD State Coordinators (NAFSC) in 2003 to support state-based efforts to increase the system of care available to individuals with an FASD and their families. NAFSC's mission is to promote prevention, treatment, and care systems for FASD, nationwide, through collaboration with systems within their respective states and among member states. The site provides updates on current activities, a roster of current members, and full contact information.

Assessment and Diagnosis

National Organization on FAS (NOFAS)
www.nofas.org

NOFAS is a leading voice and resource for the FASD community, and was one of the first. Founded in 1990, NOFAS is still the only international non-profit organization committed solely to FASD primary prevention, advocacy, and support. NOFAS has 30 affiliate programs around the country, and provides a Resource Directory to help locate FASD-related services. Also see *Information and Training*, below.

University of Washington: FAS Diagnostic & Prevention Network
http://depts.washington.edu/fasdpn/

The Washington State FAS Diagnostic & Prevention Network (FAS/DPN) is a network of four WA State community-based interdisciplinary FASD diagnostic clinics linked by the core clinical/research/training clinic at the Center on Human Development and Disability at the University of Washington in Seattle. The network was established in 1993. Each clinic in the network uses the same interdisciplinary approach to diagnosis and the same systematic diagnostic method; the *4-Digit Diagnostic Code*. The mission of the FAS DPN is primary and secondary prevention of FAS through screening, diagnosis, intervention, training, education, and research. The FAS DPN began diagnosing patients in 1993, and has diagnosed over 2,000 patients to date. See also *Information and Training*, below.

Grant Opportunities

SAMHSA Grant Opportunities
http://www.samhsa.gov/grants/

SAMHSA's grant management site allows applicants and prospective applicants to review Requests for Application (RFA's) from each of SAMHSA's sub-agencies, submit applications online, track application status, review reporting requirements, and manage the activity of awarded grants.

Grants.gov
www.grants.gov

Grants.gov was established as a governmental resource named the E-Grants Initiative, part of the President's 2002 Fiscal Year Management Agenda to improve government services to the public. Today, Grants.gov is a central storehouse for information on over 1,000 grant programs and provides access to approximately $500 billion in annual awards. The site is searchable by agency, keyword, and a variety of other variables.

Information and Training

Families Moving Forward
http://depts.washington.edu/fmffasd/

The *Families Moving Forward Program* intervention is a scientifically validated behavioral consultation program tailored for families raising preschool and school-aged individuals with FASD or confirmed prenatal alcohol exposure. The intervention includes methods and materials that appropriately trained counselors can use when working with families of a client who has an FASD. Training on FASD intervention, and on the *Families Moving Forward Program*, is regularly available through the East Coast (Florida) or West Coast (Seattle) training centers, or on-site at an agency location in the United States, Canada, or elsewhere. Once training is completed, all materials are freely available on a Web site to be downloaded.

The FASD Information Page of the Centers for Disease Control and Prevention (CDC)
http://www.cdc.gov/ncbddd/fasd/

The CDC's FASD page offers extensive information on the background of FASD, diagnosis and treatment, and training and educational materials, as well as access to articles, print materials, and multimedia tools for raising awareness.

FASD Regional Training Centers
http://www.cdc.gov/ncbddd/fasd/index.html

The CDC's FASD Regional Training Centers (RTCs) develop, implement, and evaluate educational curricula regarding FASD prevention, identification, and care, and incorporate the curricula into training programs at each grantee's university or college, into other schools throughout their regions, and into the credentialing requirements of professional boards. Check the site for links to specific, currently-active regional sites. Currently funded regional sites include the following:

- **Southeastern FASD Regional Training Center**
- **Arctic FASD Regional Training Center**
- **Frontier FASD Regional Training Center**

The National Institute on Alcohol Abuse and Alcoholism
http://www.niaaa.nih.gov

The National Institute on Alcohol Abuse and Alcoholism (NIAAA) is one of the 27 Institutes and Centers that comprise the National Institutes of Health (NIH), a component of HHS. NIAAA is the primary U.S. agency for conducting and supporting research on the causes, consequences, prevention, and treatment of alcohol abuse, alcoholism, and alcohol problems, including health effects such as FASD. NIAAA disseminates research findings to general, professional, and academic audiences. The Web site has links to relevant NIAAA publications. The FASD-specific **Web link** at NIAAA is **http://www.niaaa.nih.gov/research/major-initiatives/fetal-alcohol-spectrum-disorders**. This page also links to overviews of the activities of NIAAA's Interagency Coordinating Committee on FASD (ICCFASD).

National Organization on FAS (NOFAS)
www.nofas.org

NOFAS is a leading voice and resource for the FASD community, and was one of the first. Founded in 1990, NOFAS is still the only international non-profit organization committed solely to FASD primary prevention, advocacy, and support. The official site provides access to materials for educators, healthcare professionals, expectant mothers, and individuals and families living with an FASD. Also see *Assessment and Diagnosis*, above.

University of Washington FAS/DPN Training
http://depts.washington.edu/fasdpn/htmls/training.htm

In addition to assessment and diagnostic services, the University of Washington's FAS/DPN offers 1-day trainings on screening, diagnosis, treatment planning, and primary prevention of FASD, and also 2-day and online trainings for interdisciplinary clinical teams (or individual clinical team members) seeking to establish a FASD Diagnostic Clinic in their community.

Research and Journal Articles

Appendix A of this TIP contains an extensive bibliography for further reading on FASD, and Part 3 of this TIP, the online Literature Review (**http://store.samhsa.gov/home**), contains its own bibliography. In addition, the following Web sites and journals are excellent resources for further literature on FASD and related issues.

Alcohol
http://www.sciencedirect.com/science/journal/07418329/44/7-8

In 2010, the journal *Alcohol* published two issues devoted entirely to FASD diagnosis and intervention (Volume 44, issues 7-8). Together, these issues contain 16 articles, all of which can be accessed via the link above. Note: There is a cost for each article.

The Collaborative Initiative on FASD (CIFASD)
http://cifasd.org/

The Collaborative Initiative on FASD (CIFASD) is a consortium dedicated to informing and developing effective interventions and treatment approaches for FASD through multidisciplinary research involving basic, behavioral, and clinical investigators and projects. The Web site contains an extensive bibliography of recent FASD-related literature (2004 to the present). Many of the bibliographic items link to full abstracts through PubMed, but full articles must be purchased.

The Journal of Psychiatry & Law
http://www.federallegalpublications.com/journal-of-psychiatry-law/

The Winter 2010 (**Volume 38, issue 4**) and Spring 2011 (**Volume 39, issue 1**) issues of *The Journal of Psychiatry & Law* are devoted entirely to FASD-related issues, ranging from intervention approaches, to addressing FASD in the criminal justice system, to FASD as an adoption disclosure issue. A full listing of the articles is contained at the Volume links above. Note: There is a cost for each full issue.

Research Search Engines

Both the SAMHSA FASD Center for Excellence and NOFAS offer free online search engines that can be used to access FASD-related literature by author, title, keywords, or topic area.

Support Networks for Individuals with an FASD and Their Families

Birth Mothers Network
http://www.nofas.org/join-the-circle-of-hope/

The Birth Mothers Network, also known as the Circle of Hope, was founded through NOFAS in 2004. It is a network of women who have consumed alcohol during pregnancy and may have a child or children with an FASD. Members are lovingly referred to as "Warrior Moms" because of their incredible strengths. Many of the women are in recovery from alcoholism, or alcohol and drug addiction. However, the network also includes women without the disease of addiction, but who drank alcohol during pregnancy. The women of the Birth Mothers Network serve as mentors to one another, help each other cope with the challenges of parenting a child with an FASD, and provide caring, non-judgmental support to members who are in recovery.

Living With FASD
http://www.nofas.org/living

The Living With FASD page is provided by NOFAS, and contains links to financial assistance programs such as Supplemental Security Income (SSI) and Social Security Disability Insurance (SSDI) (both can be contacted at 1-800-772-1213), and Medicaid, as well as family and mother support programs such as **Women, Infants and Children** (WIC).

Additional Support Sites

In addition to research and general information, each of the following sites provides access to other members of the FASD community, as well as parenting guidance, personal stories from others who are coping with FASD, and guides to services.

- The FAS Community Resource Center

http://www.come-over.to/FASCRC/

- FASlink

http://www.faslink.org/

- One-Stop Centers

http://www.careeronestop.org/

One-Stop Centers are Internet job sites that can provide links to your state Department of Labor and Workforce Development, the local division for vocational rehabilitation services, and/or specific state initiatives for development of customized employment for people with disabilities.

Appendix D—The FASD 4-Digit Code Caregiver Interview Checklist: Profiles of FASD

The form below was developed by the Washington State FAS Diagnostic and Prevention Network (FAS DPN), and is part of the *4-Digit Diagnostic Code* (Astley, 2004). The caregivers of all patients receiving an FASD diagnostic evaluation in the Washington State FAS DPN clinics participate in a 2-hour interview with the pediatrician and psychologist. The purpose of the interview is to identify areas of significant delay/impairment across a wide array of functional domains.

The article *Profile of the First 1,400 Patients Receiving Diagnostic Evaluations for Fetal Alcohol Spectrum Disorder at the Washington State Fetal Alcohol Syndrome Diagnostic & Prevention Network*, by Dr. Susan Astley (2010), provides a graphical summary of the first 1,400 caregiver interviews conducted by the FAS DPN clinics. Presented is the proportion of patients classified by the pediatrician as "significantly delayed/impaired" in behaviors addressed in a 2-hour, structured caregiver interview administered jointly by the pediatrician and psychologist during the FASD diagnostic evaluation. This graphical presenta-tion illustrates the cumulative increase in impairment as one advances across the FASD diagnostic groups. The illustration is color-dependent and too complex to present in this TIP. However, readers are encouraged to access the article at the following link: **http://depts.washington.edu/fasdpn/pdfs/astley-profile-2010.pdf**

The FASD 4-Digit Code Caregiver Interview Checklist

Severity Score: Severity of Delay/Impairment (Displayed along left margin)

Circle: **0** = Unknown, Not Assessed, Too Young **1** = Within Normal Limits **2** = Mild to Moderate **3** = Significant

Severity	Caregiver Observations
	Planning/Temporal Skills
0 1 2 3	Needs considerable help organizing daily tasks _____
0 1 2 3	Cannot organize time _____
0 1 2 3	Does not understand concept of time _____
0 1 2 3	Difficulty in carrying out multi-step tasks _____
0 1 2 3	Other _____

Appendix D—The FASD 4-Digit Code Caregiver Interview Checklist: Profiles of FASD

	Behavioral Regulation/Sensory Motor Integration
0 1 2 3	Poor management of anger/tantrums _____
0 1 2 3	Mood swings _____
0 1 2 3	Impulsive _____
0 1 2 3	Compulsive _____
0 1 2 3	Perseverative _____
0 1 2 3	Inattentive _____
0 1 2 3	Inappropriately [high or low] activity level _____
0 1 2 3	Lying/stealing _____
0 1 2 3	Unusual [high or low] reactivity to [sound touch light] _____
0 1 2 3	Other _____
	Abstract Thinking/Judgment
0 1 2 3	Poor judgment _____
0 1 2 3	Cannot be left alone _____
0 1 2 3	Concrete, unable to think abstractly _____
0 1 2 3	Other _____
	Memory/Learning/Information Processing
0 1 2 3	Poor memory, inconsistent retrieval of learned information _____
0 1 2 3	Slow to learn new skills _____
0 1 2 3	Does not seem to learn from past experiences _____
0 1 2 3	Problems recognizing consequences of actions _____
0 1 2 3	Problems with information processing speed and accuracy _____
0 1 2 3	Other _____
	Spatial Skills and Spatial Memory
0 1 2 3	Gets lost easily, has difficulty navigating from point A to point B _____
0 1 2 3	Other _____
	Social Skills and Adaptive Behavior
0 1 2 3	Behaves at a level notably younger than chronological age _____
0 1 2 3	Poor social/adaptive skills _____
0 1 2 3	Other _____
	Motor/Oral Motor Control
0 1 2 3	Poor/delayed motor skills _____
0 1 2 3	Poor balance _____
0 1 2 3	Other _____

Source: Astley, S. J. (2004). *Diagnostic guide for Fetal Alcohol Spectrum Disorders: The 4-Digit Diagnostic Code*, Third Edition. Seattle, WA: University of Washington. Appendix E—Comparison of Current FASD Diagnostic Systems

Fetal Alcohol Syndrome (FAS) is a permanent birth defect syndrome caused by maternal consumption of alcohol during pregnancy. Almost four decades have passed since the term FAS was first coined. The condition is now recognized as a spectrum of disorders: Fetal Alcohol Spectrum Disorders (FASD). Substantial progress has been made in developing specific criteria for delineating diagnoses under the umbrella of FASD. In the 14 years since the publication of the seminal report on FAS by the Institute of Medicine in 1996, clear consensus has been reached on two fundamental issues: 1) an FASD diagnostic evaluation is best conducted by a team of professionals from multiple disciplines (medicine, psychology, speech-language, occupational therapy) and 2) the team should use rigorously case-defined and validated FASD diagnostic guidelines.
