Abstract

Drug metabolism and transport processes in the liver, intestine and kidney that affect the pharmacokinetics and pharmacodynamics of therapeutic agents have been studied extensively. In contrast, comparatively little research has been conducted on these topics as they pertain to the eye. Recently, however, catalytic functions of ocular cytochrome P450 enzymes have gained increasing attention, in large part due to the roles of CYP1B1 and CYP4V2 variants in primary congenital glaucoma and Bietti’s corneoretinal crystalline dystrophy, respectively. In this review, we discuss challenges to ophthalmic drug delivery, including Phase I drug metabolism and transport in the eye, and the role of three specific P450s, CYP4B1, CYP1B1 and CYP4V2 in ocular inflammation and genetically determined ocular disease.

Keywords

CYP4B1, CYP1B1, CYP4V2, cytochrome P450, drug metabolism, drug transporters, genetic eye disease

Introduction

Tissue-specific effects on the disposition of drugs, xenobiotics and endogenous compounds are critical to understanding their pharmacological and toxicological activities. While much is now known about drug metabolism and transport in the liver, intestine and kidney, there is a paucity of such information for most extra-hepatic tissues. This is especially true for the eye. From a therapeutic perspective, anatomical and physiological constraints associated with the eye make it challenging to continuously achieve appropriate levels of drug exposure. To overcome the problem, effective but invasive ways to deliver drugs have been developed, such as intra-vitreal injection. However, this treatment route is often associated with complications. Therefore, non-invasive, orally and topically administered drugs are more desirable (Thrimawithana et al., 2011).

While ocular drug-metabolizing enzymes and transporters have been studied in animal models, the catalytic activities, tissue localization and substrate specificities of drug-metabolizing enzymes and transporters may differ from those in humans; thus, caution is necessary when extrapolating such data from animals to man. In short, our present knowledge about ocular transporters and drug-metabolizing enzymes is insufficient for a full understanding of xenobiotic and endobiotic disposition in human ocular tissues. Nevertheless,
at least three cytochrome P450 (P450) enzymes – CYP1B1, CYP4B1 and CYP4V2 – play important physiological roles in
the eye. CYP4B1 is associated with neovascularization in
animal models after hypoxic insult (Mastyugin et al., 1999,
2001, 2004), whereas human CYP1B1 and CYP4V2 are
causally linked to primary congenital glaucoma and Bietti’s
corneoretinal dystrophy, respectively (Li et al., 2004; Suri
et al., 2009; Vasiliiou & Gonzalez, 2008).

This review will discuss (i) barriers to ophthalmic drug
delivery, (ii) drug transport and drug metabolizing activity in
the eye and (iii) the role of the three P450s described above in
ocular inflammation and genetically determined diseases with
an emphasis on the signaling pathways that may connect their
catalytic functions with pathophysiological changes in the eye.

Eye disease and associated challenges of drug delivery

Although eye diseases are not generally accompanied by
severe systemic problems or life-threatening symptoms, they
can still be quite serious and significantly impact quality of
life. An estimated 1 in 28 Americans older than 40 will suffer
from impaired vision in 2020 based on demographics from the
2000 U.S. Census (Congdon et al., 2004) with the leading
causes of blindness and impaired vision being age-related
macular degeneration, glaucoma and cataracts. Although the
etiology of these diseases has been studied for decades,
available treatments are not curative. From the drug-based
treatment perspective, the challenges are not only the
development of effective agents, but also the development of
delivery systems that provide therapeutic drug concentrations
in the target tissues. As for most tissues, important
determinants of ocular drug distribution include lipophilicity
and drug transporter affinity. The optimal logP value for
permeation of the cornea is reported to be 2–3 (Huang et al.,
1983), because a drug must cross both the lipophilic cornea
epithelium and the more hydrophilic stroma (Figure 1).

Typically, the treatment of eye diseases involves topical
administration of eye drops or ointments. However, eye drops
and ointments have low bioavailability for several reasons.
First, tears can wash away topically administered drugs.
Second, the low permeability of the corneal epithelium blocks
absorption and prevents drugs from entering the anterior part
of the eye (Macha et al., 1993). Third, drug-metabolizing
enzymes and efflux transporters, such as those, that will be
described in the next section, can rapidly eliminate the drug.
Fourth, other anatomical and physiological constraints
associated with the eye result in a negligible amount of
topically applied drug reaching the posterior part of eye,
specifically the retina.

Oral delivery is the next most common mode of ocular
drug administration, but drug distribution to the eye from the
systemic circulation is also challenging. Oral drugs targeted
to the eye are often limited by low bioavailability due to the
blood–retinal barrier (BRB), which is composed of the inner
BRB (also referred to as blood–aqueous barrier) and the outer
BRB (Figure 2). Similar to the situation at the blood–brain
barrier, the inner and outer BRBs contain tight junctions
between endothelial cells and retinal pigmented epithelial
cells (RPE) to separate and protect the multilayered retinal
neuronal cells from substances present in the blood (Campbell
& Humphries, 2012). These tight junctions limit the entrance
of xenobiotics to the retinal cells, and, in addition, RPE
expresses drug-metabolizing enzymes and transporters that
facilitate elimination of drugs (Zhang et al., 2008). Hepatic
and intestinal drug metabolism also can significantly reduce
the circulating drug concentration, further compounding
the difficulty in targeting oral drugs to the retina and other
posterior portions of the eye. Therefore, in addition to the
conventional drug delivery methods, eye-specific drug
delivery devices and procedures have become available at
eye clinics.

Intra-vitreal injection with aflibercept has FDA approval
for the treatment of wet age-related macular degeneration
(AMD) and macular edema following central retinal vein
occlusion. Although a valuable pharmacological tool for
many patients, potential complications include cataracts,
inflammation, retinal detachment and hemorrhaging. Also,
due to rapid drug elimination, intra-vitreal injection requires
multiple treatments (Schultz et al., 2011; Thrimawahana
et al., 2011). Nevertheless, biologic drugs such as Lucentis for
wet AMD are considered standard of care despite the invasive
nature of their administration (Ventrice et al., 2013). Other
delivery options include the implantation of biodegradable or
non-biodegradable devices into the intra-vitreal space. In
terms of less-invasive options, hydrogel contact lenses
(Xinming et al., 2008) and iontophoresis (Eljarrat-Binstock
et al., 2005) to deliver the drug deep into the cornea are also
available, but the contact lenses may cause discomfort and
both methods require multiple treatments to maintain a
sufficient drug concentration at the cellular/tissue target.
Newer promising procedures, such as micro-/nano-particle
injections, have been developed, but they are not yet widely
available at clinics because the procedure requires specialized
techniques. In summary, there is ongoing need for methods
that can ensure that ocular drugs are delivered to the target
cells or tissues in therapeutic concentrations that can be
maintained over desired period of time. To this end, a
thorough knowledge of how drugs are metabolized and
transported within eye tissues is important.

Drug transporters

Despite the lack of availability (in most cases) of monospe-
cific antibodies, access to gene sequence information and to
RT-PCR techniques has facilitated measurement of the
transcriptional levels of drug transporters in the eye. A
recent study used high-throughput RT-PCR techniques to
screen ocular tissues for expression of genes from the solute
carrier (SLC) and ATP binding cassette (ABC) families of
transporters, in addition to several metabolic enzymes (Dahlin
et al., 2013). Overall, expression was highest in retinal and
corneal tissues compared to other substructures, and in both
tissues SLC family transporters were the most prevalent with
68% of the total evaluated gene expression in the cornea and
75% in the retina attributed to SLC transporters. Among the
most highly expressed genes, more nutrient transporters were
present in the retina compared to cornea (46 versus 38%,
respectively), and more drug transporters were identified in
the cornea (29%) compared to the retina (13%). In the cornea,
Figure 1. Anatomical structure of the retina and cornea. The retina (upper blowout panel) is a complex tissue comprised of layers of cells built on the structural foundation of the sclera, choroid and Bruch's membrane. The retinal pigmented epithelial (RPE) cells provide a base layer to support the structure and function of photoreceptor cells (rods and cones) located in the outer nuclear layer. When light enters the eye, it penetrates the retinal tissue and is absorbed by photoreceptor cells where it is converted into an electrical signal. A series of nerve-type cells (horizontal, bipolar and amacrine cells) form the outer plexiform, inner nuclear and inner plexiform layers, and are responsible for transmitting the electrical signal to the ganglion cells in the innermost layer of the retina. Ganglion cells connect to the optic nerve and transmit the visual signal to the brain. The cornea (lower blowout panel) consists of an endothelial layer of cells in contact with the aqueous humor of the anterior chamber. The stroma is located between Descemet’s membrane on the endothelial side, and Bowman’s membrane on the epithelial side. The epithelial layer of cells makes up the surface of the cornea.
ABC transporters represented 16% of expressed transporters, nuclear receptors and transcription factors accounted for 9%, and Phase I and II enzymes represented 7% of the evaluated gene expression. In the retina, ABC transporters represented 9% of expressed transporters, nuclear receptors and transcription factors accounted for 6%, and Phase I and II enzymes represented 10% of the evaluated gene expression (Dahlin et al., 2013).

The human cornea expresses both uptake and efflux transporters. RT-PCR studies have detected transcripts for numerous uptake transporters, including several SLC, the amino-acid transporter B⁰⁺⁺ (ATB⁰⁺⁺), nucleoside transporters (CNT, ENT), creatinine transporter (CRT), gamma-aminobutyric acid transporter (GAT), facilitative glucose transporter (GLUT), large, neutral amino-acid transporter (LAT), multidrug and toxin exclusion transporters (MATE), monocarboxylate transporter (MCT) Na⁺-taurocholate cotransporting polypeptide (NTCP), organic anion transporter (OAT), organic anion transporting peptide (OATP), organic cation transporters (OCT), organic cation/carnitine transporter (OCTN), peptide transporter (PEPT), reduced folate transporter (RFT), taurine transporter (TAUT), Na⁺-independent glutamate/cysteine exchange transporter (Xc⁻). Efflux transporters: breast cancer resistance protein (BCRP), excitatory amino-acid transporter (EAAC1), multidrug resistance-associated protein (MRP), monocarboxylate transporter (MCT), multiple drug resistance protein/P-glycoprotein (P-gp).

ABC transporters represented 16% of expressed transporters, nuclear receptors and transcription factors accounted for 9%, and Phase I and II enzymes represented 7% of the evaluated gene expression. In the retina, ABC transporters represented 9% of expressed transporters, nuclear receptors and transcription factors accounted for 6%, and Phase I and II enzymes represented 10% of the evaluated gene expression (Dahlin et al., 2013).

The human cornea expresses both uptake and efflux transporters. RT-PCR studies have detected transcripts for numerous uptake transporters, including several SLC, the amino-acid transporter B⁰⁺⁺ (ATB⁰⁺⁺) and the large, neutral, amino-acid transporter 1 (LAT1), and their functional activities have been confirmed in transporting l-arginine and l-phenylalanine across isolated rabbit cornea (Jain-Vakkalagadda et al., 2003, 2004). Figure 2 illustrates the localization of transporter proteins in ocular tissues as determined by RT-PCR quantitation of gene transcripts. The uptake transporters from the family of solute carriers expressed in the cornea include peptide transporters 1 and 2 (PEPT1 and PEPT2), organic cation transporters 1, 2 and 3 (OCT1, OCT2 and OCT3), organic cation/carnitine
transporter 2 (OCTN2), organic anion transporters 1 and 3 (OAT1 and OAT3), multidrug and toxin exclusion transporters 1 and 2 (MATE1 and MATE2), organic anion transporting peptide 1A2, 1B1, 1B3 and 2B1 (OATP1A2, OATP1B1, OATP1B3 and OATP2B1) and Na+-taurocholate cotransporting polypeptide (NTCP). In terms of efflux, the ATP-binding cassette transporters B1 (ABCB1, multiple drug resistance 1 or P-glycoprotein), C1 (ABCC1 or multidrug resistance-associated protein 1, MRP1), C2 (ABCC2 or MRP2), C3 (ABCC3 or MRP3), C4 (ABCC4 or MRP4), C5 (ABCC5 or MRP5), C6 (ABCC6 or MRP6) and breast cancer resistance protein (BCRP) are expressed in human corneal and in Statens Seruminstitut rabbit corneal cells (Chen et al., 2013; Dahlin et al., 2013; Dey et al., 2003; Karla et al., 2007a,b). However, the quantitative data obtained from these corneal expression studies often varies widely for a given transporter, due possibly to differences in experimental methods, but perhaps more likely to the varying clinical background and post-mortem status of the particular tissue samples that were used. There is very limited information available regarding subcellular localization of transporters within ocular tissues; however, a recent study examined cultured rabbit primary corneal epithelial cells and determined the efflux transporter P-glycoprotein and PEPT1 were present in the mitochondrial membranes (Barot et al., 2013).

Retinal tissue is highly vascularized, and the sensitive tissues are protected from systemic endogenous and exogenous compounds by the BRB. Figure 2 illustrates transporters localized in the inner and outer BRB. In the RPE cells of the outer BRB, the high affinity excitatory amino acid transporter 1 (EAAC1) facilitates removal of extracellular glutamate, an excitatory neurotransmitter used by cells of the neural retina that is neurotoxic in high concentrations. Other amino acid transporters localized in the RPE include neurotransmitter transporters from the SLC6 family (TAUT, system β) that are responsible for transport of taurine, the most abundant retinal amino acid with transport direction dependent upon taurine and ion concentration gradients. Creatinine transporter (CRT) has been identified in rat retinal endothelium, and GABA transporter T3 (GAT3), the most abundant inhibitory neurotransmitter found in retinal tissues. The ATB0;+ has been detected in RPE cells, but the function is unknown at the time of this review. The large, neutral, amino-acid transporter 1 (LAT1) is involved in uptake of L-phenylalanine in ARPE-19 cells, and LAT2 is believed to mediate transport of leucine. The Na+-independent glutamate/cysteine exchange transporters (Xc−) are present in outer BRB as well as inner BRB to support glutamate homeostasis. MCT1, MCT2, MCT3 and MCT4 facilitate uptake of lactate in ARPE-19 cells and isolated bovine RPE, and OCT1, OCT2 and OCT3 have been identified in RPE cells, which may affect drug transport. Folate uptake is mediated by reduced folate transporter 1 (RFT-1). Equilibrate nucleoside transporters 1 and 2 (ENT1 and ENT2) and concentrative nucleoside transporters 1 and 2 (CNT1 and CNT2) have been identified in an immortalized retinal capillary endothelial cells (TR-iBRB), as well as organic anion transporting polypeptides OATP2, OATPE and OATP12. Efflux transporters expressed in the outer BRB include MDR, MRPI, MRP4, MRP5 and BCRP (Mannermaa et al., 2006).

In the inner BRB, transporters are located in the vascular endothelium of vessels in the neural retina. The retinal capillary system includes many of the same transporters that have been identified in the outer BRB. D-Glucose is transported by facilitative glucose transporter 1 (GLUT1) from the blood as the primary energy source for retinal tissue. GLUT1 has been identified in rat retinal vessels, as well as LAT1. MCT1 facilitates movement of lactate in between blood and retina through the inner BRB. The Na+-independent glutamate/cysteine exchange transporters (Xc−) are also present in inner BRB and OATP2, and OATP14 were detected in rat retinal vessels. Efflux transporters expressed in the inner BRB include MDR1, OAT3 and BCRP (Hosoya & Tachikawa, 2009; Hosoya & Tomi, 2005; Mannermaa et al., 2006).

In the retina, MRPI, PEPE2, OCT1 and OCTN1 and OCTN2 exhibited higher expression levels than in the liver, whereas the expression levels of MDR1 and BCRP were approximately 4-fold lower than those in liver (Zhang et al., 2008). Interestingly, there is a good consensus on MDR1 and BCRP expression levels across multiple reports (Chen et al., 2013; Dahlin et al., 2013) although, compared to the data for the cornea, limited numbers of comparator studies are available. In addition, MRPs and LRP retinal expression of MRPs were observed (Chen et al., 2013; Dahlin et al., 2013; Zhang et al., 2008). In ARPE-19 cells, transcripts for the uptake transporters, EAAC1 TAUT, LAT2, creatinine transporter (xCT), peptide histidine transporter 1 (PHT1), MCT1, MCT3 and MCT4, RFT and OCT3 have all been detected (Mannermaa et al., 2006).

It seems plausible that efflux and uptake transporters in the eye could have evolved to perform both an ocular barrier function and to control both endobiotic and xenobiotic disposition because certain transporters show mRNA expression levels comparable to those in the liver, small intestine and kidney (Zhang et al., 2008), organs that play significant roles in drug disposition. Clearly, transporters are likely to have an important role in ocular drug absorption, distribution and clearance, but the degree of involvement by each transporter for a given drug substrate and the subcellular localization of most of these proteins remains to be elucidated. This requires more comprehensive functional studies together with robust transporter protein quantitation data that are becoming increasingly easy to obtain using mass spectrometry techniques (Prasad et al., 2014).

Drug-metabolizing enzymes

Historically, due to limited access to human eye tissue, the majority of ocular drug metabolism studies were carried out in animal models such as the cow, rat and rabbit. In an early study of bovine ocular drug-metabolizing enzymes, benzo-pyrene hydroxylase activity – presumably catalyzed by CYP1 family enzymes – was demonstrated in tissue homogenates prepared from the ciliary body, retina, cornea and iris (Shichij & Nebert, 1982). These researchers also found Phase II drug-metabolizing enzyme activities, including glutathione S-transferase and N-acetyltransferase to be present in the bovine ciliary body, RPE and choroid.

Ocular esterases, a major class of Phase I enzymes, were investigated intensively between the 1960s and 1980s.
Retinal esterase protein was first detected by immunohistochemical staining (Esilae, 1964), and acetylcholine esterase activity was found to be present at high levels in the inner retina compared to the outer retina of the C57BL/6 mouse (Ross et al., 1975). Subsequently, human carboxylesterase activity in sub-retinal fluid was reported (Lam et al., 1977). As acetylcholine is a neurotransmitter at the inner and outer synaptic cell layers in the vertebrate retina, research on ocular acetylcholinesterase was conducted (Hutchins, 1987; Hutchins & Hollyfield, 1987). Recently, phosphodiesterase 10A (PDE10A) has been identified in the retina. PDE10A was found in a subcortical part of the forebrain – the striatum – and is considered an attractive drug target for certain psychiatric disorders (Grauer et al., 2009; Smith et al., 2013).

Numerous studies of corneal esterase in animal models have been performed from the viewpoint of using the enzyme as a possible pro-drug-activating enzyme in the eye (Esilae, 1963, 1964; Lee, 1983; Lee et al., 1982a,b). Lee and colleagues investigated corneal esterase expression based on a functional assay of 1- or 2-naphthyl ester hydrolysis. These authors separated rabbit and bovine eye tissues into corneal epithelium, corneal endothelium, stroma and iris-ciliary and prepared mitochondrial, microsomal and cytoplasmic fractions. The highest to lowest esterase activities were found in the iris-ciliary body, corneal epithelium and stroma (Figure 3). The majority of esterase activity was found in the microsomal fractions (80% of total activity), with some residual activity present in the cytoplasmic fractions. Mitochondrial fractions did not exhibit esterase activity. Because 1- or 2-naphthyl esters were used as functional probes and enzyme activity was largely microsomal, the esterase activities were probably those of carboxylesterase(s), but this remains to be determined.

A good example of a tissue-targeted pro-drug is valacyclovir, the L-valine peptidomimetic prodrug of acyclovir (Anand & Mitra, 2002; Anand et al., 2004). Acyclovir is a first-line drug for the treatment of herpes simplex and herpes simplex keratitis is one of the leading causes of blindness in the U.S. (Turner et al., 2003). However, the low solubility of acyclovir prevents formulation of a topical version of the drug, which requires a relatively high concentration (1–3% w/v) for efficacy. Covalently linking acyclovir to two valine residues provides better solubility and facilitates formulation for topical administration, whereas the presence of peptide transporters in the eye with broad substrate specificity increases overall bioavailability of the drug (Bras et al., 2001; Dias et al., 2002). Presumably the corneal esterase, biphenyl-like hydrolase protein (Kim et al., 2003), hydrolyzes valacyclovir to generate acyclovir intra-ocularly. Treatment of herpes simplex virus infection in the rabbit eye with topical valacyclovir appeared promising (Katragadda et al., 2008). Although a 1-year suppression treatment study showed that valacyclovir (500 mg daily) was as effective as acyclovir (400 mg twice daily; Miserocchi et al., 2007), the disposition of the drug in human eye tissues has not been examined.

Cytochromes P450 (CYPs) constitute a superfamily of enzymes that carry out the majority of Phase I oxidative metabolism in mammals. The CYP1, CYP2 and CYP3 families, collectively known as the “drug-metabolizing P450s”, typically oxidize xenobiotics to generate more polar products, a first step in their elimination and detoxification, although some P450 reactions bio-activate pro-carcinogens.

Figure 3. Localization of ocular cytochrome P450 and esterase enzymes in ocular tissues. CYP1B1 is expressed in the retinal pigment epithelium, Muller cells, ciliary epithelium, corneal epithelium and corneal keratocytes, while CYP4V2 is expressed most highly in the retinal pigment epithelium (**) with lesser expression in the corneal epithelium (*). Weak expression of CYP4V2 was also observed in ganglion cells and internal and external nuclear layers of the retina. CYP4P1B1 is inducible (^) and expression in the corneal epithelium increases under hypoxia. CYP3A4, CYP2A6, CYP2C8, CYP2D5, CYP2E1 and CYP3A4 have been detected at low levels in both corneal and retinal tissue, and CYP2J2 has also been detected in ARPE-19 retinal cells. Esterases have also been detected in the cornea and ciliary body, and phosphodiesterase 10A (PDE10A) is expressed in the retina.

For personal use only.
and generate reactive metabolites that covalently bind DNA and proteins to cause toxicity (Loannides & Lewis, 2004). Zhang et al. (2008) utilized total RNA isolated from various sections of the human eye, liver, small intestine and kidney to measure the transcriptional levels of 10 P450s and 21 efflux or uptake transporters. These workers detected CYP2A6, CYP3A4, CYP2C8, CYP2D6 and CYP2E1 genes in both human cornea and retina/choroid tissues (Figure 3), but the expression levels were low compared to transcript levels measured in human liver. The P450s that were selected for this study were those that are highly expressed in the liver and so are considered to be major drug-metabolizing enzymes. In the following sections, we focus on three P450s: CYP1B1, CYP4V2 and CYP4B1. None of these three are considered to be important drug metabolizing hepatic P450s, but they each have important ocular roles because functionally disrupting mutations in CYP1B1 and CYP4V2 give rise to eye diseases in humans, whereas disruption of CYP4B1 in animal models causes neovascularization problems in the cornea. These effects and their relationship to altered metabolism of endogenous compounds are discussed below.

**Ocular CYP4B1 and its role in the defense system**

In terms of understanding the biochemical mechanism of self-defense, endobiotic-metabolizing P450s in the eye have been largely overlooked. An exception is ocular CYP4B1, which appears to generate bioactive mediators of oxidative stress in the cornea under hypoxic conditions (Bonazzi et al., 2000; Masyugin et al., 1999, 2001, 2004; Vafeas et al., 1998). Typical substrates of CYP4 enzymes are endogenous saturated and unsaturated fatty acids, but CYP4B1 also metabolizes numerous xenobiotics (Baer & Rettie, 2006; Hardwick, 2008). CYP4B1, which is predominately expressed in extra-hepatic tissues, such as lung and kidney, bio-activates a range of pro-toxins that often exert tissue-specific toxicological effects (e.g. 4-ipomeanol; Parkinson et al., 2013). The majority of CYP4B1 research has been performed with the recombinantly expressed rabbit enzyme because the expression of the recombinant human CYP4B1 native form (wild-type CYP4B1) has been challenging. In fact, human CYP4B1 expressed in insect cells was inactive, but an S427P mutation introduced into the gene “restored” activity (Zheng et al., 1998). A conserved proline residue at position 427 may be essential for CYP4B1 enzyme activity because proper incorporation of the heme prosthetic group appears to require the presence of an intact meander region Pro-X-Arg motif (Zheng et al., 2003). In the absence of readily available functional human CYP4B1, the closely related rabbit ortholog has been used extensively to probe the function of this enzyme in *vitro* and *in vivo*.

The preferred saturated fatty-acid substrates of CYP4B1 have short- to medium-carbon-chain lengths that are preferentially hydroxylated at the thermodynamically unfavored ω-terminus (Fisher et al., 1998). A more physiologically interesting substrate is the ω6 polyunsaturated fatty acid (PUFA), arachidonic acid, from which CYP4B1 appears to generate inflammatory mediators following hypoxic injury. Hypoxia is a low-oxygen condition that occurs when the eyes are closed or when the individual wears contact lenses for long periods. Hypoxic injury initiates the inflammatory response with cyclooxygenases and lipoxygenases generating prostaglandins and leukotrienes. In addition, rabbit CYP4B1 has been reported to generate the very powerful inflammatory mediators 12(R)-hydroxyicosatetraenoic acid (12(R)-HETE) and 12-hydroxyeicosatetraenoic acid (12-HETE) from arachidonic acid in an NADPH-dependent manner (Conners et al., 1995a,b; Stoltz et al., 1994).

The majority of ocular studies involving 12(R)-HETE and 12-HETE have been performed in bovine and rabbit cornea epithelium. These studies suggest that CYP4B1 in the corneal epithelium is responsible for generating these bioactive compounds, because an anti-rabbit CYP4B1 antibody inhibited their formation (Masyugin et al., 1999). In addition, CYP4B1 expression increased in the corneal epithelium during hypoxic injury *in vivo*, and CYP4B1 expression correlated well with the progression of inflammation in the anterior part of the eye. In terms of its physiological effects, 12(R)-HETE is a potent inhibitor of Na⁺/K⁺-ATPase. 12(R)-HETE is a vasodilator and a chemoattractant and angiogenic factor that is generated from both 12(R)-HETE and 12(S)-HETE via an oxidation–keto reduction-generated intermediate (Nishimura et al., 1991; Yamamoto et al., 1994). 12-Lipoxygenase (12-LO) also generates 12-HETE, but only the S-enantiomer, and it is unknown whether either CYP4B1 or 12-LO has a greater influence on the production of 12(R)-HETE.

Ocular CYP4B1 generates bioactive eicosanoids that are mediators of oxidative stress, at least in animal models, and one symptomatic response to oxidative stress in the cornea is neovascularization. The precise signaling pathway by which 12(R)-HETE influences corneal neovascularization is uncertain, however, some insights have been derived from the rabbit eye hypoxia model developed by Laniado-Schwartzman and colleagues (Baragatti et al., 2009; Masyugin et al., 2004; Mezentsev et al., 2005; Seta et al., 2007). These researchers have suggested that vascular endothelial growth factor (VEGF) expression depends on 12(R)-HETE levels and that CYP4B1 expression parallels VEGF expression in the cornea. Moreover, CYP4B1-dependent VEGF induction was sensitive to the CYP4 inhibitor 17-octadecynoic acid, and CYP4B1 gene knock-down by siRNA negatively influenced VEGF expression (Seta et al., 2007). Collectively, these data prompted the hypothesis that CYP4B1 generates 12(R)-HETE, which activates pathways that induce expression of VEGF to initiate neovascularization. While the extent to which the animal models translate to humans is uncertain, it seems clear that CYP4B1 has a physiological role in the rabbit eye.

**Role of CYP1B1 in the ocular genetic disease glaucoma**

**CYP1B1 localization and disease-associated mutations**

It is now well established that CYP1B1 mutations are a risk factor for several types of glaucoma (Vasiliou & Gonzalez, 2008). CYP1B1 is expressed widely in the eye, kidney, spleen, thymus, prostate, lung, ovary, small intestine, colon, uterus, mammary gland and liver (Doshi et al., 2006;
Drug Metabolism Reviews Downloaded from informahealthcare.com by University of Washington on 07/30/14

Although CYP1B1 expression in the liver is as low as erocyclic amines and aromatic amines (Guengerich, 2005). Compounds, such as polycyclic aromatic hydrocarbons, het-

CYP1B1 can bioactivate a wide range of procarcinogenic compounds including melatonin (Ma et al., 2005), steroids, fatty acids and retinoids (see below). Since CYP1B1 null mice exhibited abnormalities in their trabecular meshwork and ocular drainage structures similar to those reported for PCG patients (Libby et al., 2003), a reasonable hypothesis was that mutations in human CYP1B1 disrupted the metabolism of key endogenous substrates for the enzyme (Vasiliou & Gonzalez, 2008).

Steroids

When the Rotterdam study highlighted an association between early menopause and open-angle glaucoma (Hulsman et al., 2001), endogenous steroids became a focus of attention as possible pathogenic CYP1B1 substrates. Wild-type CYP1B1 generates predominantly the 6β- and 16z-hydroxylated metabolites from testosterone and progesterone and the major, 4-hydroxy and 2-hydroxy metabolites of estradiol (Jansson et al., 2001). Early functional studies showed that the CYP1B1 G61E and R469W disease-causing mutants reduced catalytic activity towards each of these substrates by 50–75%, with only modest changes in the regioselectivities for hydroxylation (Jansson et al., 2001). These workers further suggested that the loss of functional activity for the G61E mutation, at least, was due to protein instability.

Arachidonic acid

CYP1B1 hydroxylates arachidonic acid (AA) to produce two series of regioisomeric HETEs (70% of products) and EETs (30%; Choudhary et al., 2008). Currently, the physiological role of 5-HETE, one of the major metabolites formed by CYP1B1, is unknown, and a lack of information about other HETE metabolites’ stereochemistry further hampers analysis of their ocular significance. While the stereochemistry of 12-HETE generated by CYP1B1 is unknown, rat hepatic microsomal P450s and human skin preferentially form the 12(R)-HETE stereoisomer (Capdevila et al., 1986; Woollard, 1986). 12(R)-HETE exhibits enantiomer-specific inhibition of Na+/K+-ATPase activity in rabbit cornea (Masferrer et al., 1990). It is known that Na+/K+-ATPase activity regulates corneal transparency via pressure-induced hydration (Stiemke et al., 1991), the inhibition of which might plausibly promote the corneal clouding associated with glaucoma. However, human CYP1B1 has a much higher catalytic efficiency (16.5 μmol·min⁻¹·mg⁻¹) towards arachidonic acid hydroxylation than mouse CYP1B1 (0.3 μmol·min⁻¹·mg⁻¹), 12(R)-HETE is neither a major metabolite of either the mouse or rabbit enzymes, nor are the animal orthologs as catalytically efficient at its production as the human form (Choudhary et al., 2004). Therefore, because the Cyp1b1-null mouse recapitulates features of the human congenital disease (Libby et al., 2003), it seems unlikely that arachidonic acid is the endogenous substrate whose metabolism is deranged by CYP1B1 mutations in glaucoma.
CYP1B1 mutants and gene regulation in the retinoic-acid signaling pathway

Retinoic acid (RA), a ligand of the retinoid signaling pathway, regulates gene expression that induces morphogenesis and differentiation during embryogenesis and during development of stem cells in tissues. RA is the oxidized form of retinol (vitamin A) formed via two oxidation reactions catalyzed by retinol dehydrogenases (RDH) and retinal dehydrogenases (RALDH), respectively. However, CYP1B1 also will carry out these two oxidation steps (Choughary et al., 2004). The catalytic efficiency ($K_{cat}/K_M$) of RDH enzymes isolated from human liver for the conversion of all-trans retinol to all-trans retinal ranged up to 4.5 $\mu$M$^{-1}$ min$^{-1}$ (Han et al., 1998) and the RALDH2-catalyzed conversion of retinal to retinoic acid was also an efficient process, exhibited a $K_{0.5}$ of 0.3 $\mu$M and a $V_{max}$ of 82 nmol/mg protein/min (Paik et al., 2014). By comparison, the catalytic efficiencies for CYP1B1 in the conversion of retinol to retinal and retinal to RA were also high at 8.3 and 90.8 $\mu$M$^{-1}$ min$^{-1}$, respectively. Therefore, CYP1B1 may contribute significantly to RA formation, especially in tissues where RDH and RALDH enzymes are poorly expressed (Chambers et al., 2007).

Schenkman and coworkers analyzed the effect of the relatively common CYP1B1 R368H mutation on metabolism of retinol and retinal (Choughary et al., 2008). In contrast, to its moderate effect on estradiol metabolism, this mutation greatly reduced (>90%) metabolism of retinol and retinoic acid relative to the wild-type enzyme. Substrate-dependent alterations in catalytic efficiency are well recognized for certain P450 polymorphic variants (Boggi et al., 2005). These workers also found that several other mutations found in PCG either abolished or greatly attenuated CYP1B1 function which could result in a disruption of RA signaling, although more studies are required to elucidate the importance of this pathway in PCG.

In summary, many of the CYP1B1 coding region mutations identified in PCG patients cause a functional deficit, due either to reduced protein stability or intrinsic enzymatic activity (Choughary et al., 2008; Chavarria-Soley et al., 2008). A complete mechanistic analysis of the functional consequences of the CYP1B1 mutations found worldwide has yet to be performed, although this might be facilitated, in part, by interrogation of the recently solved crystal structure of human CYP1B1 (Wang et al., 2011). Regardless, additional work is needed to identify the physiological substrate(s), if one exists, whose regulation is impacted by deleterious mutations in the CYP1B1 gene.

The orphan P450, CYP4V2, and Bietti’s corneoretinal dystrophy

CYP4V2, a relatively new member of the family of human cytochrome P450 enzymes, has been termed an ‘‘orphan’’ P450 due to its unknown substrate specificity and physiological role (Stark & Guengerich, 2007). Of the 57 functional cytochrome P450 genes that have been identified in the human genome (Nelson et al., 2004), approximately a dozen P450 enzymes can be described as orphans. A partial CYP4V2 gene was first identified and listed as CYP4AH1 in 1998, but a full-length clone of CYP4V2 was not reported until 2003. CYP4V2, along with 11 other enzymes, belongs to the CYP4 family and seven of the CYP4 enzymes metabolize fatty acids. CYP4V2 is located on human chromosome 4, separate from the CYP4ABX2 and CYP4F gene clusters on chromosomes 1 and 19, respectively (Hsu et al., 2007). CYP4V2 has low sequence identity to other CYP4 proteins. ~35% (Rettie & Kelly, 2008), which initially raised the question of whether CYP4V2 should belong to a new P450 family (see ‘‘Substrate specificity and tissue localization of CYP4V2’’ section).

As CYP4V2 gene mutations are closely associated with the development of the ocular disease, Bietti’s corneoretinal crystalline dystrophy (BCD; Li et al., 2004), this orphan P450 is receiving increasing attention from the ophthalmology research community. The following sections will discuss BCD, the physiology of the retina and CYP4V2 tissue localization and substrate specificity.

CYP4V2 mutations in BCD

BCD is a type of retinitis pigmentosa, a group of inherited diseases that cause retinal degeneration. It is progressive in nature, leading to atrophy of the retina, which causes a constriction of the visual field and night blindness similar to that found in glaucoma patients. BCD is an autosomal recessive disease characterized by small, yellow, sparkling crystals scattered throughout the eye (Lin et al., 2005). The Italian ophthalmologist Dr. Gian Battista Bietti first reported three patients exhibiting these symptoms more than 75 years ago (Bietti, 1937), and numerous clinical case reports have been published worldwide (Meyer et al., 2004; Sarraf et al., 2003; Usui et al., 2001; Welch, 1977). The chemical composition of the crystal deposits has not yet been determined, although their appearance has been reported as resembling cholesterol or cholesterol esters in complex lipid inclusions (Wilson et al., 1989).

Clues to the etiology of BCD were practically non-existent until Hejtmancik and colleagues at the National Eye Institute found that BCD was strongly associated with mutations in the CYP4V2 gene (Li et al., 2004). Since the initial 2004 article, many additional mutations of CYP4V2 have been identified, and currently more than 30 are described (Garcia-Garcia et al., 2013; Gekka et al., 2005; Haddad et al., 2012; Jing et al., 2006; Lee et al., 2005; Li et al., 2004; Lin et al., 2005; Mamatha et al., 2011; Manzouri et al., 2012; Nakamura et al., 2006; Rossi et al., 2011, 2013; Shan et al., 2005; Song et al., 2013; Wada et al., 2005; Wang et al., 2012; Xiao et al., 2011; Yokoi et al., 2010, 2011; Zenteno et al., 2008). As reviewed in Kelly et al. (2011), the most common mutation in BCD results in deletion of exon 7. A non-sense mutation, W340X, and a mis-sense mutation, H331P, have also been identified in multiple patient groups. Hejtmancik and colleagues suggested that these (and other) Bietti’s mutations render CYP4V2 non-functional based on homology modeling of CYP4V2 that used an X-ray crystal structure for CYP102A1 (PDB ID: 2IJ2) as a template (Li et al., 2004). We reported recently that the mis-sense mutation, H331P, confers loss of activity to CYP4V2 due likely to protein instability of the mutant (Nakano et al., 2012). The catalytic activity of the other known CYP4V2 coding-region variants remains to be determined.
Physiology and composition of the photoreceptor outer segments in relation to BCD

The retina has the most important function within the eye: capturing information about light and colors to send to the brain. Consequently, disruption of retinal function causes blindness. Within the retina, photoreceptor cells – rods and cones – receive dim light (rods) and colors and brighter light (cones) and relay these signals to adjacent retinal neurons, which eventually lead to the brain via ganglion cells. Photoreceptor cells are either cylindrical (rods) or conical (cones), and are composed of a synaptic neuron, a cell body, an inner segment and an outer segment, the last of which contains rhodopsin-enriched disk membranes.

While the chemical composition of the crystals found in the retina and lymphocytes with BCD is unknown, several research groups have suggested that the crystalline deposits may be due to abnormal lipid metabolism (Kaiser-Kupfer et al., 1994; Lee et al., 2001). The most abundant classes of lipids in these disk membranes are phosphatidyl cholines and phosphatidyl ethanolamines, and the most abundant fatty acids comprising these phospholipids are palmitic acid (C16:0), stearic acid (C18:0), oleic acid (C18:1) and docosahexaenoic acid (C22:6, DHA) (Anderson, 1970).

There is a physiological requirement for efficient lipid recycling systems in photoreceptor cells and the RPE to regenerate disk membranes given that rod and cone outer segments are constantly shed, occurring at a rate of 10% per day in primates (Young, 1967, 1971, 1976). The precise mechanisms of outer membrane regulation of the synthesis and disposal of disk membranes are not well understood (Guisto et al., 2000). However, it is known that the tip of the outer segment of photoreceptors is shed, the shed membranes are phagocytized, and lipids from processed membranes enter into RPE cells by endocytosis (Gordon & Bazan, 1993). The lipids are then transferred from RPE cells to photoreceptor inner segments for use in the biosynthesis of new disk membranes. Also, polyunsaturated fatty acids (PUFA), including DHA formed in the liver from precursor ω3 fatty acids such as linolenic acid (C18:3), are taken up by RPE cells and further transferred to photoreceptor inner segments (Scott & Bazan, 1989). In addition, whether mice are fed a DHA-supplemented or DHA-deficient diet, DHA levels in ROS remain constant, whereas the concentration of this PUFA in the liver changes markedly (Nishizawa et al., 2003). These data indicate tight regulation of DHA homeostasis in RPE cells. The DHA-derived compounds, protectin D1, neuroprotectin D1 and resolvins D1, have been identified as anti-inflammatory lipid mediators (Bazan et al., 2010; Mukherjee et al., 2004; Serhan et al., 2004). Therefore, the well-recognized role of CYP4 enzymes in fatty acid metabolism and the suspected abnormal lipid metabolism in BCD raises the possibility that a deficiency in the PUFA-hydroxylase catalytic function of CYP4V2 might play a role in BCD (Kelly et al., 2011).

Substrate specificity and tissue localization of CYP4V2

Despite its low-sequence homology to other CYP4 enzymes, recombinant CYP4V2 expressed in insect cells displays catalytic properties similar to other CYP4 enzymes. First, CYP4V2 was found to be a selective medium-chain-length fatty-acid ω-hydroxylase (Nakano et al., 2009). CYP4V2 also exhibited ω-hydroxylase activity towards eicosapentaenoic acid (C20:5) and DHA, and the rates of ω-hydroxylation were similar to CYP4F2, an established hepatic PUFA hydroxylase (Fer et al., 2008; Nakano et al., 2012). These data demonstrate that CYP4V2 is an efficient ω-hydroxylase of both saturated and unsaturated fatty acids. In addition, like several other CYP4 enzymes (Miyata et al., 2001; Sato et al., 2001; Seki et al., 2005), CYP4V2 activities were potently inhibited by HET0016 at low nanomolar concentrations (Nakano et al., 2012). Since CYP4V2 is a ω-hydroxylase of DHA, a major constituent of ocular membranes (Fliesler & Anderson, 1983), the protein-level localization of CYP4V2 in the eye is a critical element in the puzzle for understanding the role of the enzyme in BCD.

Following the development of a selective polyclonal antibody to purified recombinant CYP4V2, the CYP4V2 protein was localized to the endoplasmic reticulum in ARPE-19 cells and found at a level of ~6 pmol/mg protein (Nakano et al., 2012). In the same studies, the expression of the CYP4V2 protein in paraffin-fixed human ocular tissues from healthy individuals was analyzed by immunohistochemical staining. Strong staining was observed only in RPE cells, with weak staining of ganglion cells and internal and external nuclear layers in the retina and moderate reactivity in corneal epithelial cells. Finally, RT-PCR analysis of mRNA isolated from ARPE-19 cells demonstrated that CYP4V2 is the only CYP4 enzyme that is transcribed and its concentration is similar to that of the established ocular P450, CYP1B1 (Nakano et al., 2012). These localization studies demonstrate that CYP4V2 is expressed in ocular tissues that are the target for BCD and that CYP4V2 is a functional fatty acid ω-hydroxylase in RPE cells. Interestingly, the CYP4V2 gene is expressed ubiquitously in human tissues, including the brain, placenta, lung, liver and kidney (Li et al., 2004; Nakano et al., 2012), yet clinical symptoms of BCD occur only in the eyes.

Conclusions and prospects for future work

Whereas hepatic drug-metabolizing enzymes and transporters have been studied in detail, metabolism and transport in the eye is a developing area. The expression of several ocular P450s and drug transporters have been characterized at the mRNA and protein levels, but much remains to be learned about substrate specificity and the application of this information to the prediction of ocular drug disposition and the rational development of ocular pro-drugs.

A strong case can be made that human CYP4B1 is functionally defective (vide infra), yet the gene persists. An intriguing possibility is that the protein has some other, non-monoxygenase, function. Examples of such pseudoenzymes include the recently discovered iRhoms (Adrain & Freeman, 2012). The recent development of a Cyp4b1-null mouse may aid in the evaluation of other potential non-metabolic functions for CYP4B1 (Parkinson et al., 2013).

Whereas CYP1B1 gene mutations alone does not cause PCG, disruptive mutations of CYP4V2 are the sole cause of BCD. In the last 5 years, significant progress has been made...
on the expression, purification, substrate specificity and tissue localization of CYP4V2 – the latter two characteristics supporting a key functional role for the enzyme in BCD. However, the exact molecular mechanism(s) underlying CYP4V2 involvement in crystal accumulation and atrophic damage in the eye remain to be elucidated. Early biochemical tracer studies indicated a potential cellular defect in the anabolism of ω-3 PUFAs by BCD patients (Lee et al., 2001). More recently, analysis of total fatty acids in the plasma of BCD patients relative to control subjects suggested a defect in the synthesis of oleic acid from stearic acid, but the link between altered lipid profiles and development of BCD-associated ocular crystals is unclear (Lai et al., 2010). A Cyp4v3 null mouse has been created in our laboratories (Lockhart, submitted for publication) and BCD-like phenotype and lipidomic analyses are underway with this animal model that may shed some light on the biochemical mechanisms that underlie this debilitating disease.

Declaration of interest

The authors declare no conflicts of interest.
